It is important for the student of tropical medicine to be able to recognize the genera and species of the more important Anophelinæ. For this purpose we give the following tables taken from Theobald's 'Manual of the Culicidæ,' vol. v., 1910. For fuller information the original work must be consulted, but it must be admitted that there is a growing opinion that Theobald's genera imperceptibly merge with one another, and are not founded on essential points; and Edwards has returned to two genera, *Anopheles* and *Bironella*, therefore in Chapter XXXV. (p. 883) we will give another classification when considering the anophelines which carry malaria.

SUBFAMILY ANOPHELINÆ Theobald, 1901.

Table of Genera.

- A. First submarginal cell very small—*Bironella* Theobald.
- B. First submarginal cell large:—
  - I. Antennal segments with dense lateral scale-tufts—*Chagasia* Cruz.
  - II. Antennal segments with outstanding scales on the second segment and more appressed ones on the first At least one abdominal segment with long flat more or less spatulate scales—*Calvertina* Ludlow.
  - III. Antennal segments without dense lateral scale-tufts:—
    - 1. Thorax and abdomen with hair-like curved scales:—
      - (*a*) No flat scales on head, but upright forked ones.
        - (A) Basal lobe of male genitalia of one segment.
          - (1) Wing scales large, lanceolate—*Anopheles* Meigen.
          - (2) Wing scales mostly small, or narrow, or slightly lanceolate costa spotted—*Myzomyia* Blanchard.
          - (3) Wings similar to (2), but with fourth longitudinal vein very near base of third Prothoracic lobes with outstanding scales—*Neomyzomyia* Theobald.
          - (4) Wings with patches of large inflated scales—*Cycloleppteron* Theobald
        - (B) Basal lobe of two segments:—
          Prothoracic lobes with dense outstanding scales—*Feltinella* Theobald.
      - (*b*) Median area of head with some flat scales; prothoracic lobes mammillated. Wing scales lanceolate—*Stethomyia* Theobald.
    - 2. Thorax with narrow curved scales; abdomen hairy:—
      - (*a*) Wing scales small and lanceolate; head with normal forked scales—*Pyretophorus* Blanchard.
      - (*b*) Wing scales broad and lanceolate; head with broad scales not closely appressed, but not forked or fimbriated—*Myzorhynchella* Theobald.

3. Thorax with hair-like, curved scales, and some narrow curved ones in front; abdomen with apical lateral scale-tufts and scaly venter; no ventral tuft. Wing scales lanceolate *Arribalzagia* Theobald

4 Thorax with hair-like, curved scales, no lateral abdominal tufts; distinct apical ventral tuft Palpi densely scaly Wing with dense, large, lanceolate scales *Myzorhynchus* Blanchard

5. Thorax with hair-like, curved scales, and some narrow, curved lateral ones; abdomen hairy, with dense, long, hair-like, lateral, apical, scaly tufts Wing scales short, dense, lanceolate; fork cells short-- *Christya* Theobald

6. Thorax with very long hair like, curved scales; abdomen with hairs, except last two segments, which are scaly Dense scale-tufts to hind femora Wings with broadish, blunt, lanceolate scales *Lophoscelomyia* Theobald.

7. Thorax and abdomen with scales: -

(*a*) Thoracic scales narrow-curved or spindle shaped; abdominal scales as lateral tufts and small dorsal patches of flat scales *Nyssorhynchus* Blanchard

(*b*) Abdomen nearly completely scaled, with long, irregular scales, and with lateral scale tufts *Cellia* Theobald.

(*c*) Similar to above, but no lateral scale tufts -*Neocellia* Theobald

(*d*) Abdomen completely scaled with large flat scales, as in *Culex* *Aldrichimelia* Theobald

(*e*) Thoracic scales hair-like except a few narrow curved ones in front, abdominal scales long, broad and irregular *Kertészia* Theobald

(*f*) Thorax with narrow hair like, curved scales, some broad straight scales, and some spatulate laterally. Abdomen with fine hairs except last three segments, which have scales Tufts of scales on hind femora Wing scales lanceolate - *Manguinhosia* Cruz

NOTE - The genus *Calodiacesis* Dyar and Knab is said by Theobald to be invalid, being based on *Anopheles barberi*, which is a true *Anopheles*.

Anopheles Meigen, 1818.

Essentially *Anopheles* are temperate zone or hill station Anophelinæ, of which the type *Anopheles maculipennis* Meigen, 1818, has been already described

Eighteen species are definitely known, but in addition there are the uncertain species of *A ferruginensis* Wiedemann, *A martini* Laveran, *A. pursati* Laveran, *A vincenti* Laveran, *A vestitipennis* Dyar and Knab, 1906, *A strigimacula* Dyar and Knab, 1906, *A apicimacula* Dyar and Knab, 1906, *A punctimacula* Dyar and Knab, 1906, etc

Theobald gives the following table by means of which the species may be recognized. -

ANOPHELES

A Wings spotted·

I Legs unbanded·

1. Wings with spots formed of collections of scales on the wing field, no costal spots *maculipennis* Meigen

2 Wings with light and dark costal markings.

(1) Costa with two yellow spots:-

(*a*) Large species: --

(A) No fringe-spots --*punctipennis* Say.

(B) Fringe-spots present--*pseudopunctipennis* Theobald.

(*b*) Small species. Wings much spotted—*franciscanus* McCracken.

(2) Costa with one spot—*perplexus* Ludlow.

II. Legs with basal pale bands:—
  1. Costa with two large dark spots—*gigas* Giles.
  2. Two large and two small basal spots—*formosus* Ludlow.
III. Legs with narrow apical bands:—
    Costa dark, with two small pale yellow spots—*wellcomei* Theobald

B. Wings unspotted:—
  I. Legs unbanded:
    1. Thorax adorned as in Corethra—*corethroides* Theobald.
    2. Thorax normal ornamentation
      (*a*) Second fork cell much more than half the length of the first.
        (1) Palpi unbanded
          (A) Petiole of first fork cell more than one third length of cell
            Abdomen with golden hairs—*bifurcatus* Linnaeus
            Abdomen with brown hairs—*algeriensis* Theobald.
          (B) Petiole of first fork cell one third length of cell—*barberi* Coquillett
        (2) Palpi banded. Dark species. Wing scales very dense—*smithii* Theobald
          Wing scales not so dense—*nigripes* Staeger
      (*b*) Second fork cell not more than half the length of the first—*aitkenii* Theobald
  II. Legs banded.
    1. Hind femora only with broad white band—*lindsayi* Giles
    2. Apices of hind tarsi pale—*immaculatus* Theobald

Myzomyia Blanchard, 1902

This *Myzomyia* includes some important mosquitoes found in West Africa, and in India and Ceylon, which are carriers of malaria.

The diagnostic table given by Theobald is as follows:

MYZOMYIA.

A. Proboscis unbanded:
  1. Legs banded:—
    (*a*) Palpi with three white rings.
      (1) Legs with faint apical pale bands
        Wing fringe spotted—*funesta* Giles
      (2) Legs with prominent apical pale bands and a broad, pale, median band to fore and mid-metatarsi—*lutea* Theobald.
      (3) Legs (hind) with apical and basal pale bands
        Wings with five to six pale costal spots, the largest T-shaped—*rossii* Giles.
        Wings with three yellow costal spots—*longipalpis* Theobald.
    (*b*) Palpi with two white rings:
      (1) Apex white—*aconita* Dönitz
      (2) Apex black—*d'thali* Patton
    (*c*) Palpi with four white rings—*p hali* Patton.
  2. Legs spotted and banded:—
    (*a*) Supernumerary cross-vein straight. Palpi with three white bands. Apical and basal pale leg banding.
      (1) Third large costal spot with two spots beneath on first vein—*ludlowi* Theobald.
      (2) Similar, but much smaller—*mangyana* Banks
      (3) Third costal spot T-shaped, as in *rossi*—*indefinata* Ludlow.
      (4) Thorax with two ocelli; wings much spotted—*tessellata* Theobald
    (*b*) Supernumerary cross-vein markedly curved—*pyretophoroides* Theobald.

- 3. **Legs unbanded**:—
  - (*a*) Apex of palpi white and ringed. Three pale palpal bands.
    - (A) Third long vein mostly yellow—*listoni* Liston.
    - (B) Third long vein dark.
      - (1) Several fringe-spots—*leptomeres* Theobald.
      - (2) Two fringe-spots—*culicifacies* Giles.
      - (3) No fringe spots—*rhodesiensis* Theobald.
  - (*b*) Apex of palpi white only—*nili* Theobald.
  - (*c*) Apex of palpi black.
    - (1) Black apex narrow—*turkhudi* Liston.
    - (2) Black apex broad—*hispaniola* Theobald.
- 4. Legs with spots only at joints. Palpi with three bands; apex black—*azriki* Patton.

B. Proboscis banded:

- I. Legs unspotted—*albirostris* Theobald.
- II. Legs spotted—*thorntoni* Ludlow.

Neomyzomyia Theobald, 1912.

This genus includes only one species, *Neomyzomyia elegans* James, 1903. It is found in India.

Pyretophorus Blanchard, 1902.

The important species is *Pyretophorus costalis*, the spreader of malaria in West Africa and Mauritius.

PYRETOPHORUS

A. Legs unbanded:—

- I. **Palpi with three pale bands; apex black**—***nigrifasciatus*** **Theobald.**
- II. Palpi with three pale bands; apex white:—
  - (*a*) Wings with four large and two small black costal spots; mid cross-vein very long—*nursei* Theobald.
  - (*b*) Wings with four large black spots; mid cross-vein normal—*minimus* Theobald.
  - (*c*) Wings with five large black costal spots:—
    - (1) First fork cell much longer than the second posterior—*sergenti* Theobald.
    - (2) First fork cell about as long as the second cell—*palestinensis* Theobald.

B. Legs banded:—

- I. Legs with apical banding. Hind legs only banded. Palpi, black apex, and three pale bands.
  - (*a*) Three dark lines on post scutellum—*myzomyfacies* Theobald.
  - (*b*) Two dark lines on post-scutellum—*chaudoyei* Theobald.
- II. All legs with apical pale bands. Palpi with three white bands.
  - (*a*) Wings with four black costal spots, fringe unspotted—*superpictus* Grassi.
  - (*b*) Wings with four large and two small costal spots; fringe spotted.
    - (A) Apical palpal band broad, other two small—*jeyporensis* Theobald.
    - (B) Apical and median palpal bands broad—*austeni* Theobald.
    - (C) Thoracic scales creamy—*pitchfordi* Power.
- III. **Fore and hind legs with apical pale bands.**
  Four white palpal bands—*cinereus* Theobald.

C. Legs spotted and banded:—

- I. **Last three hind tarsals all white.**
  Thorax golden scaled—*aureosquamiger* Theobald.
- II. **Last hind tarsal not white**:—
  - (*a*) **Femora and tibiæ spotted.** Tarsal bands apical. **Three palpal bands.**

(A) Apical one broad; others narrow:—
(1) Fringe-spots narrow—*costalis* Loew.
(2) Fringe-spots broad—*merus* Dönitz.
(B) Apical and median ones broad—*marshalli* Theobald.
(*b*) No spots on femora—*pseudocostalis* Theobald
(*c*) Femora, tibiæ, and first tarsals spotted. Tarsal bands apical. Four palpal bands—*ardensis* Theobald.

Myzorhynchus Blanchard, 1902.

These mosquitoes are usually said to only occur in the open, but we have repeatedly found *Myzorhynchus barbirostris* in houses. *M. sinensis* is known to carry the parasite of malaria in Japan. No species have so far been reported from America.

The thirteen species can be recognized as follows (it has been asserted that *Anopheles coustani*, which has never been correctly placed, is *M. coustani* Laveran, but see Chapter XXXV. on this point):—

MYZORHYNCHUS.

A. Palpi unbanded:—
I. Last hind tarsals brown Legs with pale apical tarsal bands:—
(*a*) One fringe spot
(1) Legs not spotted—*barbirostris* van der Wulp.
(2) Legs with speckled femora and tibiæ, and more numerous 'round-ended' scales on the wing—*pseudobarbirostris* Ludlow.
(*b*) Several fringe-spots—*bancrofti* Giles.
(*c*) No fringe spot.
(1) One pale costal spot; wings with light and dark scales—*umbrosus* Theobald.
(2) Two pale costal spots; wings mostly dark scaled—*strachani* Theobald
II. Last hind tarsal white—*albotæniatus* Theobald.

B. Palpi banded:—
I. Last hind tarsal brown:—
(*a*) Wing-fringe with one pale spot—*sinensis* Wiedemann.
(*b*) Wing-fringe unspotted.
(A) Palpi with four pale bands; apex white.
1. Wings with two yellow costal spots.
(1) Wings distinctly spotted—*vanus* Walker.
(2) Wings without prominent spots—*pseudopictus* Grassi.
2. Wings with two white costal spots—*minutus* Theobald.
(B) Apex of palpi black—*nigerrimus* Giles.
II. Last two hind tarsals white—*mauritianus* Grandpré.
III. Last three hind tarsals white—*paludis* Theobald.

Nyssorhynchus Blanchard, 1902.

The important member is *Nyssorhynchus fuliginosus* Giles, 1900 which is without doubt a malarial carrier Theobald's diagnostic table is as follows:—

NYSSORHYNCHUS.

A. Last hind tarsals brown:—
Legs spotted:—
(*a*) Apical pale bands to legs.
(1) Proboscis dark—*stephensi* Liston.
(2) Proboscis pale on apical half—*masteri* Skuse.
(*b*) Apical and basal pale banding—*annulipes* Walker.

B. Last hind tarsal white:—
  I. Legs spotted with white:
    (a) Palpi with three white bands *willmori* James.
    (b) Palpi with four white bands *maculatus* Theobald
  II. Legs not spotted, four palpal bands *karwari* James

C. Last two hind tarsals white. Legs with mottled femora, tibiæ, and tarsi; three white palpal bands:
    (a) Two apical palpal bands close together *theobaldi* Giles
    (b) Two apical palpal bands far apart *pretoriensis* Theobald.

D. Last two and a half to two and three quarters tarsals white—*tibani* Patton

E. Last three hind tarsals white
  I. Palpi with three white bands.—
    (a) Palpi spotted, legs spotted—*maculipalpis* Giles
    (b) Palpi spotted, hind legs not banded—*indiensis* Theobald
    (c) Palpi not spotted, legs spotted *jamesii* Theobald
    (d) Palpi and legs not spotted
      (1) Wings with four white costal spots *fuliginosus* Giles.
      (2) Wings with five white costal spots *nivipes* Theobald
  II. Palpi with four white bands *philippinensis* Ludlow

F. Legs uniformly brown *brunnipes* Theobald

Cellia Theobald, 1902

This genus which is widely distributed throughout the tropics, has two malarial carriers, *Cellia argyrotarsis* and *C. albimana* the latter being also known as a filarial carrier

CELLIA

A. Legs with last three hind tarsals white:
  I. Dark species *argyrotarsis* Robineau Desvoidy.
  II. Dark species, but with whitish grey apex to abdomen *braziliensis* Chagas.
  III. Yellowish species *pulcherrima* Theobald.

B. Legs with last hind tarsals white
  I. Femora and tibiæ mottled; apical foot bands *pharoensis* Theobald.
  II. Femora and tibiæ not mottled *bigoti* Theobald

C. Legs with last hind tarsal white except base, second and third white—*albimana* Wiedemann.

D. Legs with last hind tarsal dark
  I. Dark species, three white long lateral thoracic lines *squamosa* Theobald
  II. Pale species:—
    (a) Thorax with two eye like spots, pleuræ pale with large black spots *kochi* Dönitz
    (b) Similar, but with wings more spotted *punctulata* Dönitz

SUBFAMILY CULICINÆ Theobald, 1901.

Definition. Culicidæ with straight proboscis, long palpi in the male, short in the female. Post scutellum nude, wings with a long first submarginal cell and without a third anal vein. Larvæ with respiratory siphons.

Remarks.—There are upwards of sixty-three known genera, but of these only *Stegomyia*, *Culex*, and perhaps *Mansonia*, are of importance to medical men at present.

Stegomyia Theobald, 1901.

Definition.—Culicinæ with the head and scutellum clothed with flat scales.

Remarks.—The important species is *Stegomyia fasciata*, the tiger mosquito, which spreads yellow fever. It is peculiar in that it bites chiefly in the afternoon. It is found all over the world, which is due to the fact that it can live on board ship easily.

Unfortunately its name is about to be changed either to *S. calopus* Meigen, or *S. frater* Desvoidy. Theobald at present is not certain which will prove to be the correct term. The name as it stands at present is *S. fasciata*

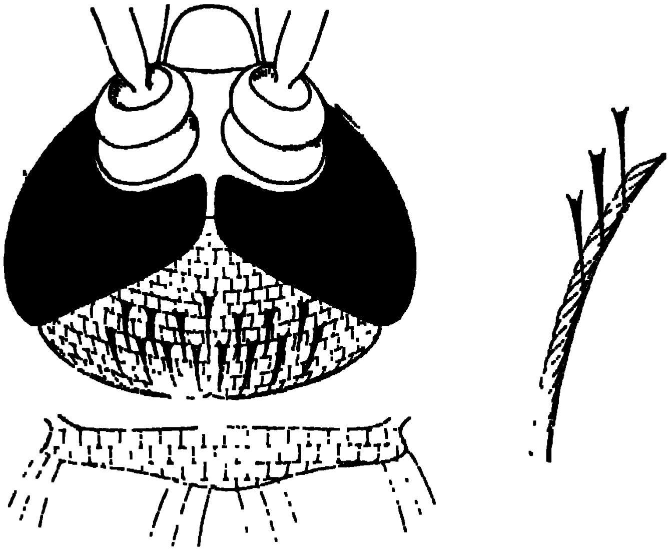

FIG. 308. HEAD AND SCUTELLUM OF STEGOMYIA, TO SHOW SCALES. (After Theobald, 'The Culicidae of the World')

Fabricius 1805, (*non* O. F. Muller, 1764) (synonyms, *Culex calopus* Meigen 1818 (?), *C. frater* Desvoidy, 1827). O. F. Muller, it appears, used the term 'fasciata' for a *Culex* in 1764.

STEGOMYIA

A. Proboscis banded.
  - I. Legs basally banded.
    - (*a*) Thorax brown, with scattered creamy white scales—*annulirostris* Theobald.
    - (*b*) Thorax black, with narrow, curved golden scales—*periskelata* Giles.
  - II. Legs with basal and apical banding. Fore legs with no bands, mid with apical and basal bands on first tarsal and second tarsal, hind with basal bands.
    - Thorax white in front, with a brown eye-like spot on each side—*thomsoni* Theobald.

B. Proboscis unbanded:
  - I. Legs basally banded.
    - (*a*) Abdomen basally banded.
      - (A) Thorax with one median silvery white line—*scutellaris* Walker.
      - (B) Thorax similar, but with two white spots near where the line ends.
      - (C) Thorax with two median yellow lines and lateral curved silvery lines—*fasciata* Fabricius.
      - (D) Thorax with two short median pale lines and a white patch on each side—*nigeria* Theobald.
      - (E) Thorax with large lateral white spots in front, smaller ones by the wings, two narrow median yellow lines, and two posterior submedian white lines—*lilii* Theobald.
      - (F) Thorax with a white W-shaped area in front, a prolongation curved on each side enclosing a brown, eye-like spot—*alba* Theobald.

(G) Thorax with white frontal median spot, two large lateral spots, one small spot on front of wings, one narrow median white line and narrow submedian lines on posterior half. Last two hind tarsi white—***wellmani*** Theobald.

(H) Thorax brown, with broad white line in front, extending laterally towards the wings, where they swell into a large patch, a white line just behind wings. Last two hind tarsi white—*albipes* Theobald.

(I) Thorax with silvery white spot on each side in front, small spot over root of wings, and a white spot over the base of the wings—***pseudonigeria*** Theobald.

(J) Thorax with two lateral white spots, the front one the largest, a small median one near the head; two yellow median lines and a short silvery one on each side before the scutellum—***simpsoni*** Theobald.

(K) Thorax with a silvery white scaled area in front, and another on each side in front of wings—***argenteomaculata*** Theobald.

(L) Thorax with a median, yellowish-white line, a silvery patch on each side in front of the wings, extending as a fine yellow line to scutellum, and another silvery spot before base of each wing—***poweri*** Theobald.

(M) Thorax with small grey-scaled area in front of roots of wings and three short creamy lines behind—***minutissima*** Theobald.

(N) Abdomen black, fifth segment with yellow basal band, sixth unbanded, (seventh) two medio-lateral white spots, (eighth) two baso-lateral white spots; second hind tarsi nearly white—***dubia*** Theobald

(*b*) Abdomen unbanded

(1) Third hind tarsal nearly all white.
Thorax with two lateral white marks directed upwards—***africana*** Theobald.

(2) First hind tarsal all white.
Thorax with one white spot anteriorly, and one in front of each wing—***apicoargentea*** Theobald
Thorax chestnut brown—*terrens* Walker.

II. Legs with white lines as well as basal bands.
Thorax brown, with white lines; abdomen with basal bands—***granti*** Theobald.

III. Fore and mid legs with apical bands; hind basal.
Fourth tarsal of hind-legs nearly all white — ***mediopunctata*** Theobald.
Base of mid-metatarsi, base and apex of hind, and base of first tarsal with pale banding—***assamensis*** Theobald.

IV. Legs unbanded:—

(*a*) Abdomen basally banded

(1) Thorax with front half silvery white, remainder bronzy-brown—***pseudonivea*** Theobald.

(2) Thorax deep brown with scattered golden scales—***albocephala*** Theobald.

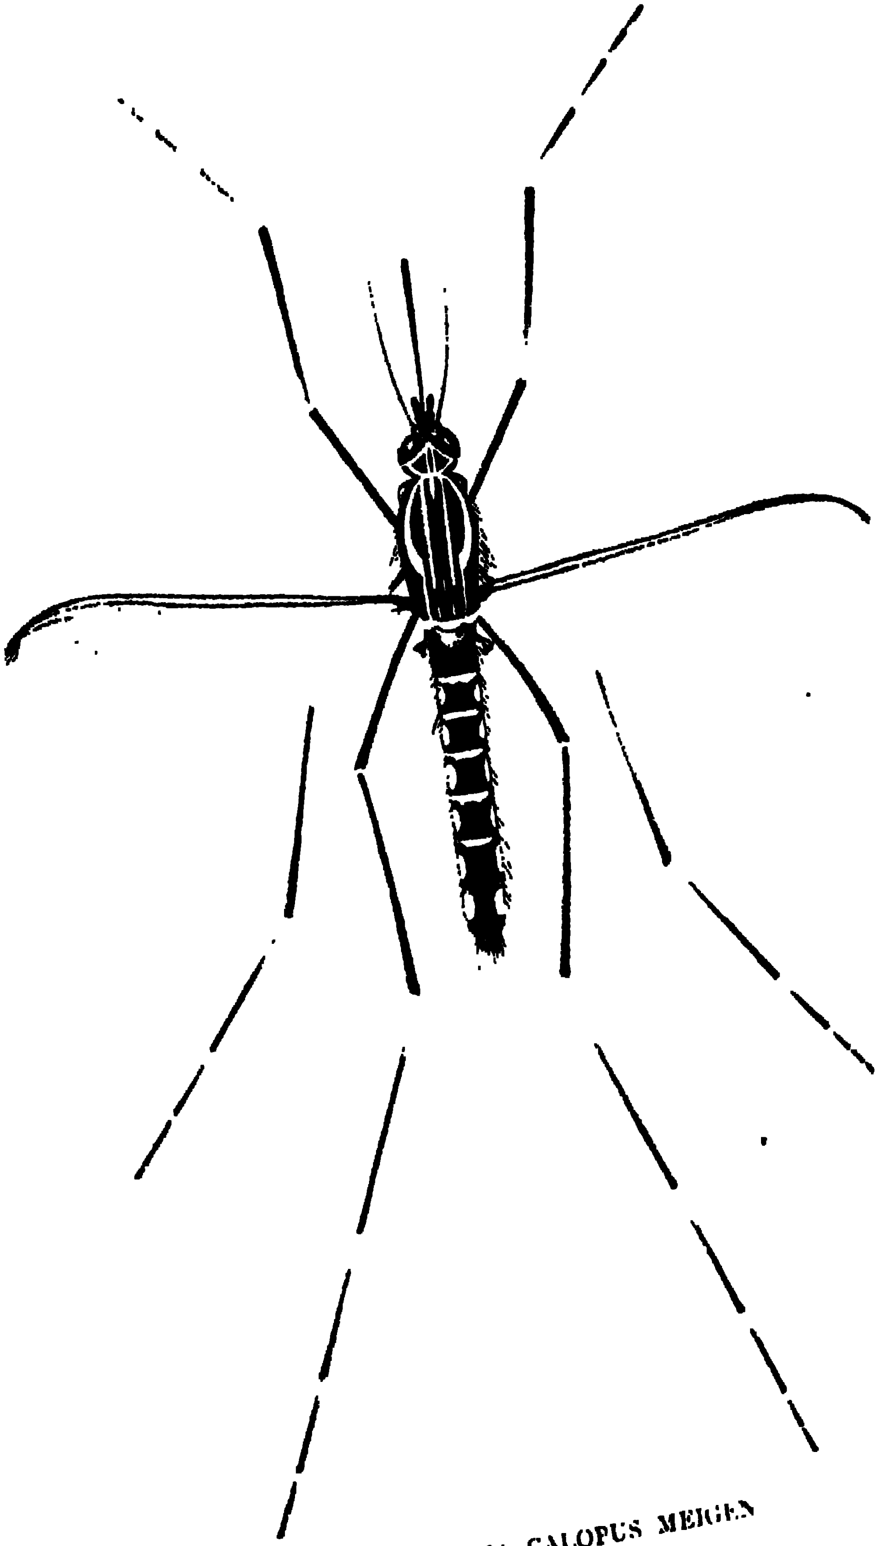
(3) Thorax brown with golden stripes—***auriostriata*** Banks.

(*b*) Abdomen banding indistinct.
Thorax with broad silvery white patch on each side anteriorly—***albolateralis*** Theobald.

(*c*) Abdomen unbanded.
Thorax with six silvery spots—***argenteopunctata*** Theobald.

(*d*) Abdomen with apical white lateral spots.
Thorax unadorned, except for pale scaled lines laterally—***punctolateralis*** Theobald.

PLATE IV.



STEGOMYIA CALOPUS MEIGEN

FEMALE.

To face page 798

Geo. Waterston & Sons Ltd. Edin

(e) Abdomen with basal white lateral spots.
  (1) Thorax with two pale, indistinct, median, parallel lines, and two silvery lateral spots—*minuta* Theobald.
  (2) Thorax unadorned.
    White spot mid-head—*tripunctata* Theobald.
    No white spot—*amesii* Ludlow.

C. Proboscis yellow basally, dark apically.
  Abdomen with apical pale bands—*crassipes* van der Wulp.

D. Proboscis with median interrupted white line on basal half.
  Head black with grey margin—*albomarginata* Newstead.

NOTE.—*S. lamberti* Ventrillon; *S. leucomeres*, *S. desmotes* Giles; *S. striocrura* Giles, of uncertain position.

Culex Linnæus, 1758.

Definition.—Culicidæ with head covered with narrow, curved scales above, flat scales at the sides, and upright forked scales. Male palpi long, acuminate. Female, short. Thorax with hair-like, curved scales or narrow curved scales. Linear lateral vein-scales.

Remarks.—The important species are *Culex pipiens* Linnæus and *C. fatigans* Wiedemann.

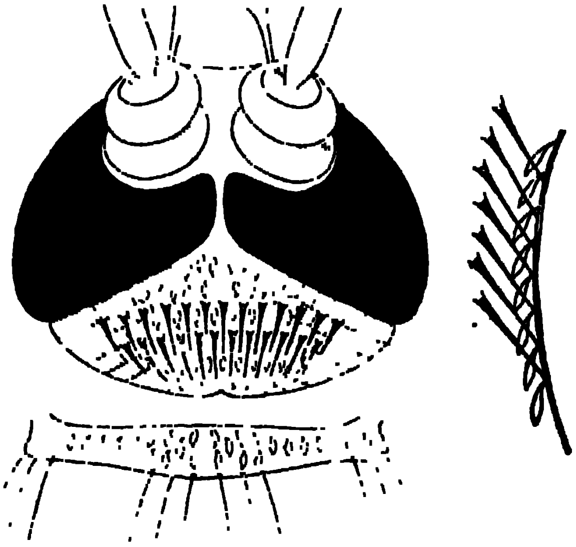


FIG. 309. HEAD AND SCUTELLUM OF A CULEX, TO SHOW SCALES

(After Theobald, 'Culicidæ of the World.')

Culex pipiens Linnæus, 1758.

Synonyms.—*Culex vulgaris* Linnæus, 1767; *C. alpinus* Linnæus, 1767; *C. agilis* Bigot; *C. ciliaris* Linnæus, 1767; *C. communis* de Geer; *C. rufus* Meigen, 1818; *C. phytophagus* Ficalbi, 1889.

C. pipiens is widely distributed in Europe, North Africa, and North America, where it is the common brown mosquito.

Its general appearance is well shown in the illustration in which the head is brownish from the golden-brown scales, as are the proboscis, palpi, and antennæ. The thorax is dark brown, with golden-brown curved scales, and with three black lines due to black bristles. Abdomen brown, with basal yellow bands. Legs are brown and unbanded.

Culex fatigans Wiedemann, 1828.

Synonyms.—*Culex æstuans* Wiedemann, 1828; *C. pungens* Wiedemann, 1828; *C. pallipes* Meigen, 1838; *Heteronychia dolosa* Arribalzaga, 1896.

This is the common brown house-mosquito of the tropics, which is believed to spread dengue fever.

It resembles the above, but has only two dark lines on the thorax as a rule, while the basal abdominal bands are white or pale cream colour, and the first fork cell is longer.

ÆDINÆ Theobald.

Definition.—Culicidæ with straight proboscis, short palpi in both sexes, usually plumose antennæ in the male, pilose in the female. Wings with six scaled longitudinal veins, and with the first submarginal cell as long as or longer than the second posterior. Post-scutellum nude.

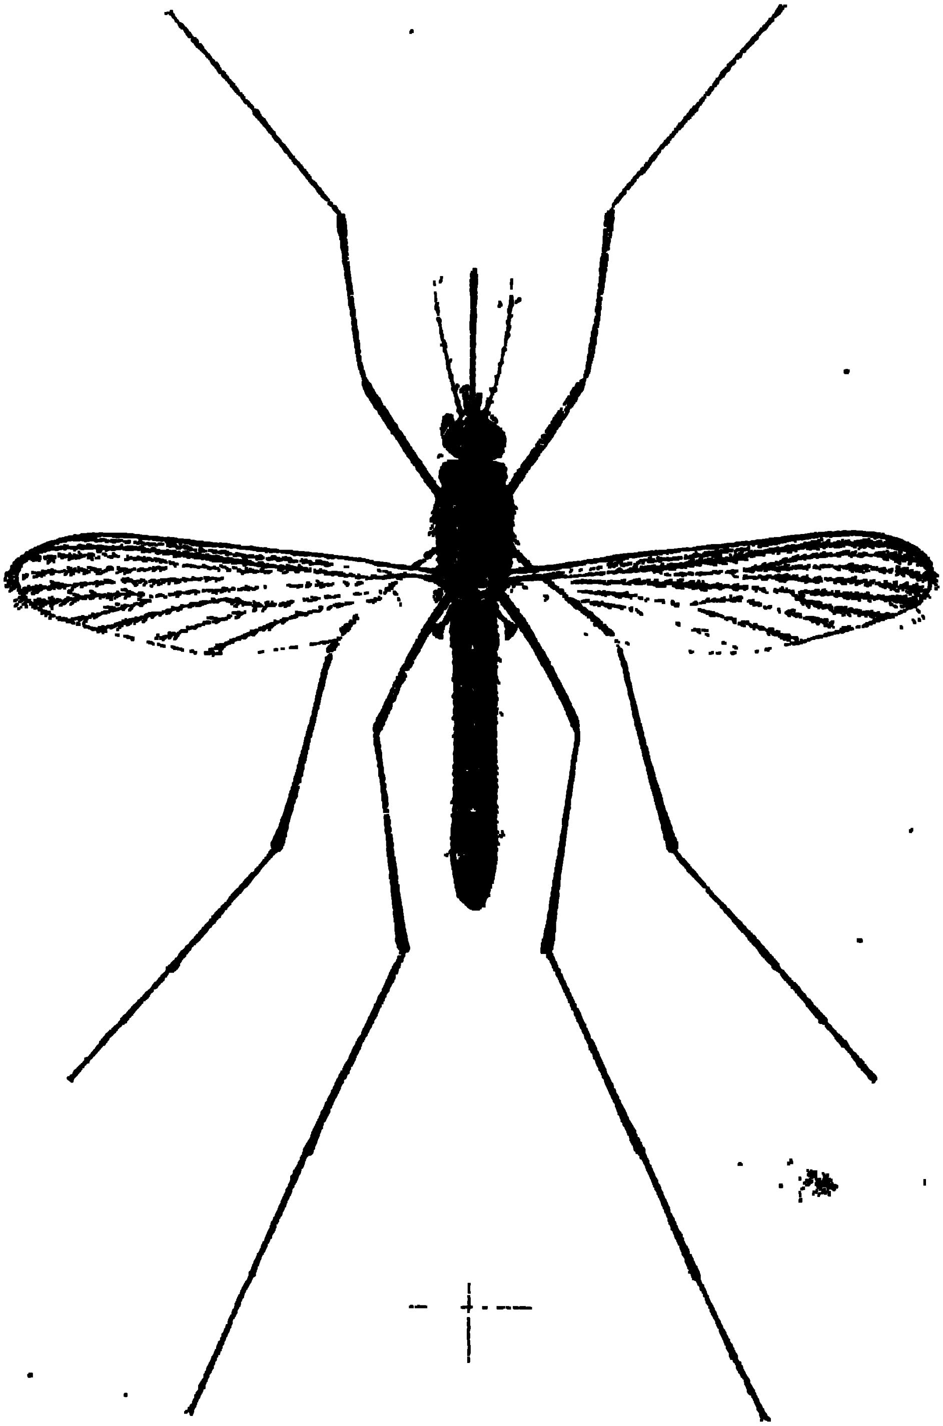

FIG. 400.—*Culex pipiens* LINNAEUS.

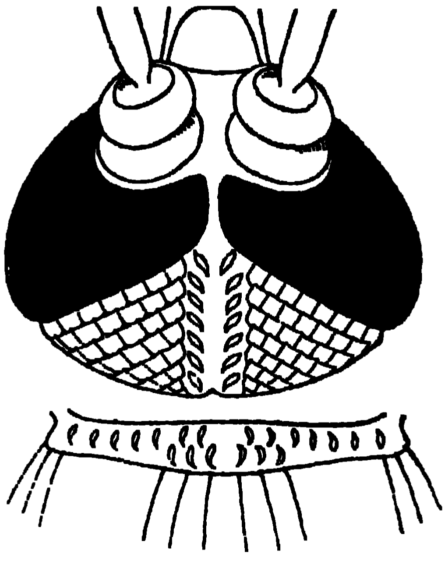
The mosquitoes included in this subfamily are generally found in the jungle, and not in habitations.

Daniels thinks that perhaps they may be proved to be malarial carriers (see

Chapter XXXV.). Loew suspects some of them (*Hæmogogus ?*) as possible carriers of *Filaria* (especially *F. perstans*).

The eggs are laid in rafts, and the larvæ have respiratory siphons. A number of genera are described by Theobald, whose work should be consulted if further information is desired.



[Fig. 401.—Head and Scutellum of Ædes, to show Scales.

(After Theobald, 'Culicidæ of the World.')

Limatinæ Theobald.

Definition.—Culicidæ with elbow-bent proboscis and squamæ on post-scutellum. Palpi short in both sexes. First fork cell longer than second.

Genus.—*Limatus.*

Family Corethridæ

Eysell, 1905.

Definition.—*Orthorrhapha nemocera* with short proboscis not formed for piercing, without scales in the adult condition, with transparent larvæ rather resembling those of *Chironomus.*

Remarks.—The only reason why this family, which includes the genera *Corethra* and *Mochlonyx*, is mentioned here is that it has only cently been separated from the Culicidæ, of which it formed subfamily—Culicinnorphæ.

Family Chironomidæ.

Synonyms. –*Tipulariæ culiformis*, *Culicites* Newman, *Tipiladæ* Leach, *Chironomii* Zelt, *Chironominæ* Rondani

Definition.—*Orthorrhapha nematocera* with head small, often retracted under and covered by the thorax. Ocelli absent. No transverse suture on thorax; eyes reniform. Antennæ from six to fifteen joints: pectinate in male, simple and composed of fewer joints in female. Wings without veins along the posterior margin; costal vein ending near the tip of the wing.

Remarks.—The Chironomidæ include over 800 species of very delicate and often quite minute flies, popularly called 'midges,' which are found all over the world, especially near water.

Kieffer classifies the family into three subfamilies, as follows:—

A. Media and cubitus united by a cross vein—*Tanypinæ.*

B. Media and cubitus united only at the base.

- I. Thorax humped over the head—*Chironominæ.*
- II. Thorax not humped over the head—*Ceratopogoninæ.*

Of these three subfamilies only the last concerns us.

SUBFAMILY CERATOPOGONINÆ Kieffer, 1899.

Definition.—Chironomidæ with the thorax not prolonged over the head, antennæ with fourteen, rarely thirteen, joints in both sexes, and the last joint never longer than the two preceding taken together, while the last five are longer or almost the same as the preceding joint.

Life-History.—The eggs may be laid on land or water. If they are laid on land the larvæ and pupæ resemble those of *Phlebotomus*, presently to be described; while if they are laid in water they occur in small clusters of thirty to sixty eggs. The larva is snake-like and transparent, and lives on the surface of stagnant water, or slowly flowing streams, along which it wriggles and finally develops into a dark coloured inactive pupa, with usually breathing organs on the thorax, which floats on the surface of the water.

Genera.—The subfamily has been especially studied by J. J. Kieffer, who recognizes the following genera: *Leptoconops* Skuse, 1889, *Ceratopogon sensu stricto* Kieffer, 1899; *Culicoides* Latreille, 1809; *Ecacta* Poey, 1851; *Bezzia* Kieffer, 1899; *Brachypogon* Kieffer, 1899; *Ceratolophus* Kieffer, 1899, *Palpomyia* Meigen, 1818. Of the other genera usually mentioned he considers *Tersesthes* Townsend, 1893, and *Mycterotypus* Noé, 1905, to be simply synonyms of *Leptoconops* Skuse, 1889; and *Psychophæna* Philippi, 1865, *Tetraphora* Philippi, 1865, and *Didymophleps* Weyenbergh, 1883, to be identical with either *Ceratopogon* or *Culicoides*, but which it is impossible to say, as the descriptions are too imperfect.

Key of Genera.

- (*a*) Wings absent or rudimentary.
- (*aa*) Wings present.
  - (*b*) Median cubital cross vein present (*i.e.*, cell enclosed by a vein).
  - (*bb*) Median-cubital cross vein absent.
    - (*c*) Wing with four to five very indistinct longitudinal veins, wing club shaped, the anterior margin with a long, curved seta; the antennæ with about twelve joints.
    - (*cc*) Wing margin without long, curved seta.
      - (*d*) Proboscis and palpi rudimentary.
      - (*dd*) Palpi not rudimentary.
        - (*e*) Antennæ with not more than ten joints.
        - (*ee*) Antennæ with thirteen to fifteen joints.
- (*f*) Antennæ fifteen jointed (European and tropical genera).
  - (*g*) Wings hyaline.
  - (*gg*) Wings spotted—(1) *Ecacta*.
- (*ff*) Antennæ fourteen or less joints.
  - (*g*) Thorax rounded and not produced over the head. Antennæ thirteen to fourteen joints, legs of moderate length.
    - (*h*) Antennæ thirteen joints—(2) *Leptoconops*.
    - (*hh*) Antennæ fourteen joints, plumose in the male, sparsely paired in female. Typical wing venation.
- (*i*) Wings hairy; last joint of tarsus with an empodium.
  - (*j*) Empodium well developed, almost as long as the claws, which are without setæ—(3) *Ceratopogon*.
  - (*jj*) Empodium not so distinct, less than half as long as the claws, which have setæ on the underside—(4) *Culicoides*.

(*ii*) Wings bare; pulvilli and empodium wanting.
  (*j*) Wing with R_1 distinctly separated from R_{2+3}, and not connected with it by the cross vein like R_2 (5) *Bezzia.*
  (*jj*) Wing with R_2 present, cells sometimes indistinct.
    (*k*) Media wanting--(6) *Brachypogon.*
    (*kk*) Media present.
      (*l*) Femora unarmed -(7) *Ceratolophus.*
      (*ll*) Some of the femora spinose beneath - (8) *Palpomyia.*

Leptoconops Skuse, 1889.

Synonyms.--*Tersesthes* Townsend, 1893; *Mycterotypus* Noé, 1905.

The flies of the genus are found in Egypt, Australia, New Mexico, and Italy.

The various species are *L. kertészi* Kieffer, 1908; *L. stygius* Skuse, 1889; *L. torrens* Townsend, 1893; *L. bezzii* Noé, 1905; and *L. irritans* Noé, and they can be recognized as follows:

A. Antennæ of the female, twelve joints, with verticillates twice as long as the thickness of the joint. Palpi three jointed. Costal nervure stops at the cubitus. Legs without spines, except four anterior: metatarsi tarsal hooks simple (Egypt- *L. kertészi* Kieffer).

B. Antennæ of the female thirteen articles.

  I. Palpi with four joints, legs without spines, tarsal hooks simple, costal nervure stops at the cubitus, flagellum with dense verticillates (Australia *L. stygius* Skuse).

  II. Palpi with three joints.
    (*a*) Legs without spi[illegible] tarsal hooks simple, costal nervure nearly to the extremity of the wing, verticillates of flagelli a little shorter than thickness of joints (New Mexico- *L. torrens* Townsend).
    (*b*) Legs armed with spinules, especially the tibias.
      (1) Tarsal hooklets of the female with one large basal tooth: those of the male unequal; the anterior with one long, curved, S shaped tooth: the posterior with a short, arched tooth (Italy *L. bezzii* Noé).
      (2) Tarsal hooklets of the female with one strong basal tooth, flagellum with some verticillates, spinose, and stronger than in *L. bezzii* (Italy *L. irritans* Noé).

New species are *L. lauræ* Weiss, 1912, Tunisia; and *L. interruptus* Enderlein, 1907, South Africa.

Ceratopogon *sensu stricto* Meigen, 1803.

Definition.- Ceratopogoninæ, with long haired wings, especially in the female, and with a very apparent and hairy empodium on the last joint of the tarsus.

Type. *Ceratopogon bipunctatus* Linnæus.

Kieffer has subdivided this genus into the subgenera *Ceratopogon*, *Atrichopogon*, and *Forcipomyia*, but none of the species of these genera are definitely known to suck the blood of vertebrates.

although Austen states that in the type specimen of the species *C. castaneus* Walker, 1848, the abdomen is apparently distended with blood as far as can be judged by external examination.

Culicoides Latreille, 1809.

Synonyms.—*Ceratopogon* Meigen, 1803, *pro parte*; *Cheironomus* Fabricius.

Definition.—Ceratopogoninæ with body small, pilose, or bare. Head depressed in front, prolonged into a short rostrum. Proboscis, which is markedly longer than the head, with fleshy labium; labrum horny, seated on base of labium. Maxillæ long and horny. Antennæ filiform, fourteen-jointed, hairy, with the second to eighth joints cylindrical, ovate, and the next four or five more elongate and subcylindrical, and the last joint ovate and cylindrical. Subcostal vein ending much beyond half the length of wing: radial ending near tip; cubital ending by the tip. Abdomen composed of eight segments. Legs almost equal in length; femora armed beneath with spines.

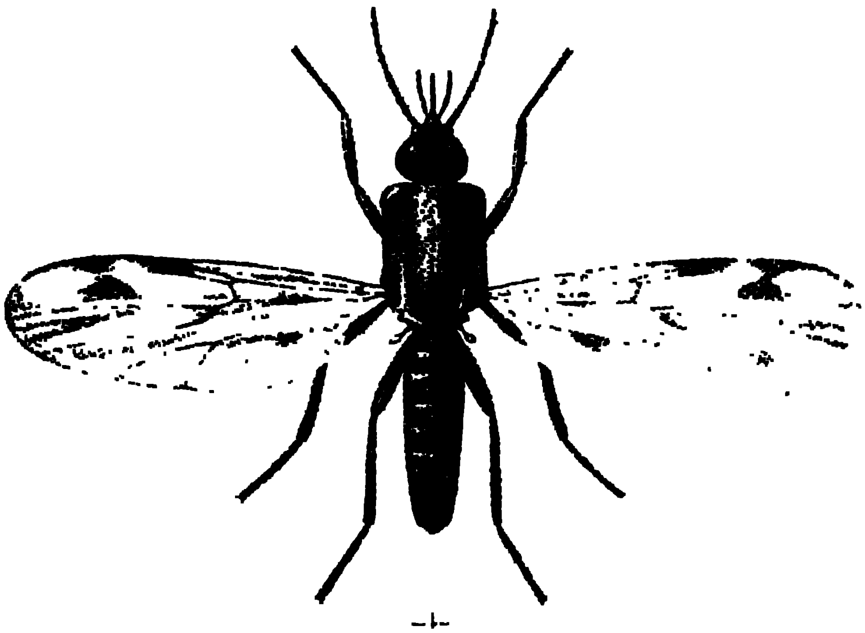


FIG. 402.—*Culicoides pulicaris*: FEMALE.
(After Austen, 'British Blood-Sucking Flies.')

Type.—*Culicoides pulicaris* Linnæus.

There are over one hundred known species of this genus (and many more have been described since this statement was first written), in which only the females suck blood, which they do most viciously, and though they are not known to cause disease, still they give rise to much irritation, especially as, being very small, they can get through any ordinary mosquito-netting. The eggs of the naked species are laid in water, attached to floating algæ, and give rise to white worm-like larvæ and small pupæ, with prominent respiratory horns. The eggs of the hairy species are laid in decaying vegetal matter, and give rise to small larvæ.

Culicoides grahami Austen, 1909.

Synonyms.—*Culicoides habereri* Becker, 1909; *Œcacta hostilissima* Pittaluga, 1910.

This minute fly appears to be extremely common, and to be almost the most troublesome of these blood-thirsty insects in tropical Africa. It is known in the Spanish Guinea, Ashanti, Congo Free State, Uganda, Kamerun, Southern Nigeria, Angola For fuller particulars see Austen's 'African Blood-Sucking Flies,' p. 7, Plate I., Fig. 3, and Pittaluga's works.

Culicoides varius Winnertz, 1867.

This is the blood-thirsty species in Europe.

Œcacta Poey, 1851.

This genus is closely related to *Ceratopogon* and *Culicoides*. The antennæ have fifteen and the palpi five joints. Ocelli are present. The wings have few cells. The tibial spurs and the pulvilli are absent. The sexes are similar, but the antennæ of the male are more hairy than those of the female.

Species.—*Œcacta furens* Poey, 1851, found in America, but according to Austen *Œcacta hostilissima* Pittaluga, 1912, is the same as *Culicoides grahami* Austen, 1912.

Œcacta furens Poey, 1851.

This is the jejen of Cuba, which is said to be very irritating. Its length is 2 millimetres from the head to the end of the abdomen. Frons and antennæ rufous. Thorax bronze-coloured with fuscous spots; abdomen fuscous; legs with whitish articulations and a ring upon each femur; tibia fuscous. Wings broad, whitish, with fuscous spots. They are covered with minute scales and possess conspicuous marginal fringes.

Bezzia Kieffer, 1899.

Synonym.—*Ceratopogon* Meigen, 1803, *pro parte*. *Ceratopogoninæ* with bare wings and tarsi without empodia. Radius with three branches.

Type.—*Bezzia ornata* Meigen, 1803.

Brachypogon Kieffer, 1899.

Ceratopogoninæ with bare wings, media coalescent with R_1; pulvilli absent.

Type.—*Brachypogon vitiosus* Winnertz, 1852 (?) 1846 (?).

Ceratolophus Kieffer, 1899.

Synonym.—*Johannseniella* Williston. *Ceratopogoninæ* with bare wings, simple R_1 and R_3 connected by cross vein, tarsal claws without teeth.

Type.—*Ceratolophus femoratus* Fabricius. *C. fulvithorax* Austen, 1912, is the first *Cerotolophus* to be described in Africa.

Palpomyia Mergele.

Synonym. *Xylocrypta* Kieffer.

Ceratopogoninæ with bare wings and five radial cells R present, media simple; some or all the femora spinose underneath; pulvilli and empodia wanting.

Four subgenera: *Alasion* Rondani, 1857; *Sphæromyas* Stephens, 1829, *Serromyia* Mergele, 1818; *Heteromyia* Say, 1825.

FAMILY PSYCHODIDÆ.

Definition. *Orthorrhapha nematocera* without ocelli, and with body densely covered with coarse hairs. Thorax without transverse suture. Antennæ long, sixteen-jointed. Wings very broad and hairy. No discoidal cell. Legs long, tibiæ without spurs.

Remarks. – The members of this family are small, sometimes very small midges, with the bodies and wings thickly covered with hairs and scales, which give them a most characteristic appearance. They are found all over the world, and have a preference for damp, shady places, while their larvæ have been found in damp places – in cracks in rocks, old walls, etc.; in rotting vegetation, liquid filth, and water. The blood-sucking genera are: *Phlebotomus* and *Sycorax* belonging to the Phlebotominæ, and possibly one in the Psychodinæ.

The Psychodidæ are classified into two subfamilies:—

(1) *Psychodinæ* – Psychodidæ, in which the second longitudinal vein gives off its first branch in the root of the wing. The female has a horny ovipositor, while the male has two claspers.

(2) *Phlebotominæ* Psychodidæ, in which the second longitudinal vein branches after it has passed well into the body of the wing. The female has not got a horny ovipositor, while the male has three claspers.

SUBFAMILY PSYCHODINÆ.

The genera *Pericoma* and *Psychoda* and their allies belong to this subfamily. As a rule it is stated that these flies are not blood-suckers, but Howlett states that an Indian species occasionally sucks blood.

SUBFAMILY PHLEBOTOMINÆ.

This subfamily is of importance not merely because it contains blood-sucking flies, but because the genus *Phlebotomus* is accused of spreading the 'Three Days' Fever.' The two blood-sucking genera may be distinguished as follows:–

(1) Two simple veins between the forks of the second and fourth longitudinal veins– *Phlebotomus*.

(2) One simple vein between the forks of the second and fourth longitudinal veins. Seventh longitudinal vein very short.– *Sycorax*.

Phlebotomus Rondani, 1840.

Morphology.– Phlebotominæ, with mouth parts formed for piercing and sucking, palpi of five joints, antennæ long, filiform, composed normally of sixteen segments. The thorax is mainly mesothorax, the prothorax being very diminutive, but the scutellum and post-scutellum are well developed. Wings hairy, narrow, with second longitudinal vein twice forked, thus forming one of the two simple veins between the forks of the second and fourth longitudinal veins, the other simple vein being the third longitudinal. The cross veins are placed near the basal fourth of the wing. Legs very long and slender, and densely clothed with scales. Ungues simple. The abdomen has ten segments, the last being modified for the genitalia, which in the female are flattened, leaf-like structures, and in the male very complex structures composed of superior claspers, inferior claspers, submedian lamellæ, and intermediate appendages, and a penis.

The buccal cavity is wide in front and narrow behind, where it leads via the pharynx into the œsophagus, which divides posteriorly into two tubes, one leading to the sucking and the other to the mid-gut, at the posterior extremity of which are situate the four Malpighian tubules, after which come the small and large intestines. Attention is invited to the presence of the sucking stomach, and to the number of the Malpighian tubules.

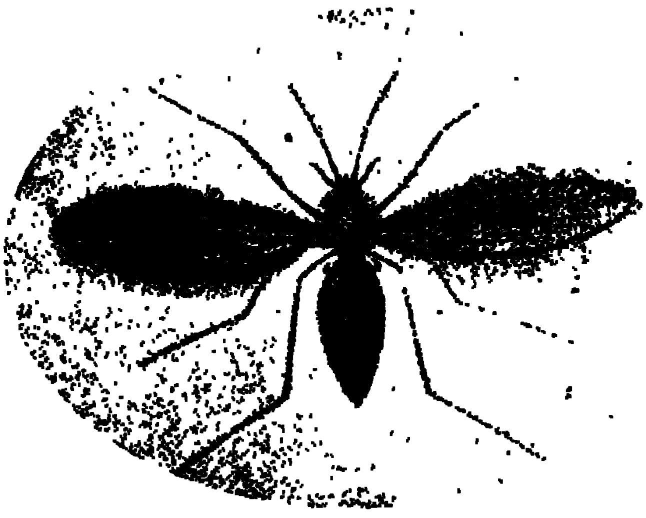

FIG. 403.—*Phlebotomus duboscquii* NEVEU-LEMAIRE, 1906.
(From a photograph by J. J. Bell.)

The female organs consist of ovaries, from which the tubular oviducts pass to unite before reaching the base of the inferior claspers. There are two spermathecæ.

The male organs are testes, seminal vesicles, ejaculatory duct, pompetta or little pump—which regulates the exit of the spermatozoa—and penis.

Life-History.—After fertilization the female takes a meal of blood, even though she may have previously sucked blood. She then lays some thirty to eighty eggs in damp places, usually cracks in rocks, stones, or bricks, and in doing so is apparently much exhausted, and in captivity may soon die. The eggs vary in size in different species from 0·15 to 0·5 millimetre in length. They are elongate oval in shape, marked with longitudinal dark marks, connected at places by means of cross lines. The eggs are laid singly, and require four to six days in warm, and fourteen days in cold, weather before hatching. The larvæ measure some 2 to 5 millimetres in length, and are composed of a head without eyes, but with well-developed mouth-parts and a Y-shaped mark, and cylindrical body of twelve segments, each with a transverse row of spinous hairs, and with spiracles on the first and penultimate segments. The characteristic point about the larvæ is the presence of two very long bristles situate on two tubercles on the ultimate segment. These bristles may be as long as the head and body taken together. The length of the larval stages depends upon the air temperature, and may last from two to fourteen days.

The pupa, 2 to 5 millimetres in length, is motionless, lying in the wrinkled, brownish larval skin which envelops its last three segments, and by which it is attached to the stone on which it lives. The duration of the pupal stage varies from eight or nine to twenty-eight days. The whole development, therefore, requires about one month in warm and two months in cold weather.

Habits.—These little flies are essentially nocturnal in their habits, but are attracted by light. During the day they lie up in cool, shady places in houses, etc., under bricks, in hollow trees, behind shutters, books, pictures, etc., often in bathrooms, and more often in latrines. They are very small, and can easily pass through the meshes of an ordinary mosquito curtain and fill themselves with human blood; or, failing this, they will content themselves with animal blood—*e.g.*, that of cattle, dogs, frogs, geckos, serpents, lizards, etc. They fly quite silently, and only the female bites, and that only at night. She appears to be stimulated in her biting propensities by an increase of humidity and temperature, and will even crawl under the bed-clothes to get at her victim. During the act of biting the posterior end of the abdomen is raised, while the whole abdomen becomes much distended with blood and reddish in colour, except at the posterior tip.

The originally replete female becomes half empty in sixteen, and quite empty of blood in thirty-six to forty hours. When first gorged, she cannot fly easily; and may be unable to escape from the mosquito curtain, where she may be caught while quietly digesting her enormous meal. During the day, as already stated, the flies remain resting in cool, shady places in houses and other buildings, under bricks, in hollow trees, behind shutters, pictures, books, etc., and are often found in bathrooms, and more often in latrines.

The larvæ are very difficult to find, because they are so small, while the pupæ are even more difficult to see, because not merely are they small, but they are also of a colour similar to the stones to which they are attached. Hence the habits of larvæ and pupæ are not well known, and require to be restudied. Their presence may be determined, even when they cannot be found, by placing the stones in a glass case or under fine netting, when the adult flies will appear in due course if any pupæ are present.

Pathogenicity.—*Phlebotomus papatasii* Scopoli, 1786, is the carrier of the virus of 'Pappataci fever,' and the whole genus is composed of virulent blood-suckers, whose bite is generally severe, and may be quite painful to non-immune, new arrivals, when the sensations produced by the bite is stated to resemble that which people imagine ought to be experienced by the application of a red-hot needle. The area of the bite becomes a small rose-red papule, surrounded by a reddish macula, the total result being a maculo-papule, which may persist for several days, and is associated for a day or so with a sensation of itching. Children are especially liable to be attacked.

Prophylaxis.—Newstead classifies the possible means of prophylaxis into—(1) Repellents, (2) fumigation, (3) light, (4) artificial air movements, (5) traps, (6) nets, (7) destruction of breeding-grounds, and of all these he thinks that very fine spraying with a 1 per cent. solution of formalin is the most effective, especially if performed during the day into the dark portions and angles of the sleeping-chamber, while the mosquito curtain might be sprayed towards night. He thinks that an electric fan and a modified biscuit-box trap lined with dark cloth and placed high up in dark places of the sleeping-chamber would be useful. Major Crawford recommends the following ointment for personal use: Oleum anisi, 1 drachm; oleum eucalypti, 1 drachm; oleum terebinthinæ, ½ drachm; and unguentum acidi borici, 1 ounce.

Species.—The species are fairly numerous, and may be grouped geographically as follows:—

Europe.—*Phlebotomus papatasii* Scopoli, 1786 (type species); *P. minutus* Rondani, 1840; *P. mascittii* Grassi, 1908; *P. nigerrimus* Newstead, 1911; *P. perniciosus* Newstead, 1911.

Africa.—*P. duboscquii* Neveu-Lemaire, 1906, found in Timbuktu.

Asia.—*P. papatasii* Scopoli, 1786(?); *P. argentipes* Annandale, 1910; *P. major* Annandale, 1910; *P. malabaricus* Annandale, 1910; *P. babu* Annandale, 1910; *P. himalayensis* Annandale, 1910; *P. perturbans* Meijere; *P. angustipennis* Meijere.

America.—*P. vexator* Coquillett, 1906; *P. cruciatus* Coquillett, 1906; *P. rostrans* Summers, 1912.

Newstead gives the following table for the purpose of recognizing the *Phlebotomi* of Malta:—

A. *Abdominal Hairs Recumbent:*—
  (*a*) Integument black. Large species. Palpi with second segment slightly longer than the third—*P. nigerrimus.*
  (*b*) Integument ochreous. Small species. Palpi with second segment one-half the length of the third—*P. minutus* and *P. minutus* var. *africanus* Newstead.

B. *Abdominal Hairs more or less Erect:*—
  (*a*) Legs in both sexes relatively short; average length of hind-leg 3 millimetres—*P. perniciosus.*
  (*b*) Legs in both sexes relatively long; average length of hind-leg 4 millimetres—*P. papatasii.*

Other species are:—*P. squamiplairis* in Khartoum; *P. antennatus*, Gold Coast; *P. vexator*, *P. legeri* Mansion, 1914, Corsica; *P. duboscquii*, Mauritania.

Phlebotomus verrucarum Townsend, 1913, is believed by Townsend to be the carrier of *Verruga peruviana*, but Strong, Tyzzer, Brues, Sellards, and Gastiaburu consider that the observations need confirmation before they can be accepted.

Phlebotomus papatasii Scopoli, 1786.

Synonyms.—*Cyniphes molestus* Costa, 1840; *Hemasson minutus* Loew, 1844.

Newstead reports that there are two distinct colour varieties of this insect—viz.: (1) A uniformly pale variety which is to be considered typical: and (2) a variety with a dark fringe to the costa and hind margin of wing. These two varieties he distinguishes as the pale variety and the dark variety.

Pale Variety.—Almost uniformly pale, translucent, ochreous; thorax with a long, dull, red-brown median stripe and a single spot of the same colour on either side near the front: wing fringe not markedly darker than the hairs on the disc of the wing.

Dark Variety.—Female with general colour of pale form, but with wing fringes smoky grey, and some of the hairs on the veins also dark grey or smoky grey. The male was not observed.

Life-History.—Ovum when first expelled shows the oolemma (interior) and a micropyle at anterior end. The first instar of the larva is caterpillar-like. Two pairs of caudal bristles, one much longer than the other, the other pair very short. Length, 2 to 3·28 millimetres. Pupa with abdomen curved upwards in varying degree. The eggs hatch in six to nine days, and the larvæ, which live in the earth, become pupæ in about eight weeks. The total item of development is about ten to eleven weeks, and the life of the fly is about eight days.

Pathogenicity.—It is the carrier of Pappataci fever.

FAMILY SIMULIIDÆ.

Synonyms.—*Melusinidæ*, *Tipulariæ* Meigen, *Simulides* Zelt, *Simulites* Newman, *Simulinæ* Rondani.

Orthorrhapha nematocera without ocelli: without transverse suture on the thorax; with short legs, in which the posterior tibiæ and the first joint of the hind tarsi are dilated: with short, straight, cylindrical, eleven jointed antennæ without setæ. Eyes of the male are large, and meet in the middle line, while those of the female are smaller and separate. Size, 1·5 to 4 millimetres in length.

The *Simuliidæ* or *Melusinidæ* are the sand-flies, also called 'brûlots' or 'potu' flies, and have a wide distribution, being particularly found in the tropics, but are also well known in Europe. Though small in size, they are great blood-suckers, attacking man and beast, and also other insects, but only the females suck blood.

Though there is only one genus, *Melusina* Meigen, 1800, more correctly known as *Simulium* Latreille, 1802, there are very many species—*i.e.*, about seventy—of which *Simulium reptans* Latreille and *S. hirtipes* Fries are known in Scotland. *S. columbaczense* Schonberg, locally known as the 'banat,' is the cause of much destruction of cattle in South Hungary. *S. indicum* Becher is the 'dam din' of Assam, which is a cause of irritation to tea-coolies. *S. damnosum* Theobald in Uganda, where it is called 'mbwa,' and in the Sudan, where it is called 'kunteb'; and *S. griseicollis* Becker, of Dongola, locally called 'nimetta,' are very virulent. Austen says that the 'potu' flies were accused of having caused the death of coolies while constructing an Indian road. The effects of the bite of these small insects is most irritating, and the appearance of a person after a severe attack is most peculiar, the face and hands—*i.e.*, the exposed parts—being covered with papules.

Life-History.—The eggs are deposited on stones or plants in running water. The larva is broad posteriorly, where it possesses a sucker, capable of attaching it to any convenient object Anteriorly it has two fan like organs. It moves about in the water after the manner of a leech, and also by the aid of a silken thread which it spins. It feeds on water plants. The larval stage lasts about a month, when a cocoon is spun, inside which the pupa is formed. The pupa breathes by means of branched filaments, and at the end of a week becomes the imago, which is carried to the surface of the water in an air-bubble.

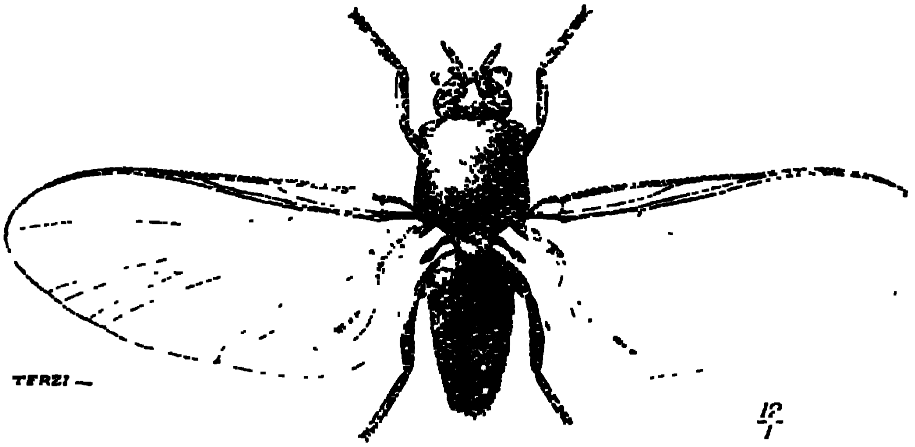

FIG. 304.—*Simulium reptans* LATREILLE: FEMALE.

Habits.—The *Simuliidæ* live in the open country, and very rarely enter houses. They can be found in the early morning, or, better, in the late afternoon, flying in clouds. During the daytime they can be found on trees, grasses, etc. It is common to find the males quite close to the streams in which the eggs, larvæ, and pupæ abound; but the female can apparently travel for considerable distances in search of food, and can quite easily be caught on the wing. They may also be found in the ears of cattle, donkeys, etc., where they feed. They are not all vicious, blood-thirsty insects. Thus, for example, *S. venustum* Say is said to be quite peaceably disposed. It is quite possible that in some instances mistakes have been made with regard to the blood-thirsty propensities of some species, and it is possible that the real culprit was one of the Ceratopogoninæ, and therefore it is necessary to be quite certain that the insect in question is really a *Simulium*, and this can only be done by careful examination. For purpose of quick field examination, it is as well to inspect the antennæ carefully, as they are fairly characteristic.

Enemies.—The *Simuliidæ* have many enemies, among which may be mentioned the larvæ of the May- and that of the Caddis-fly, and many kinds of fish which prey upon the larvæ, pupæ, or flies.

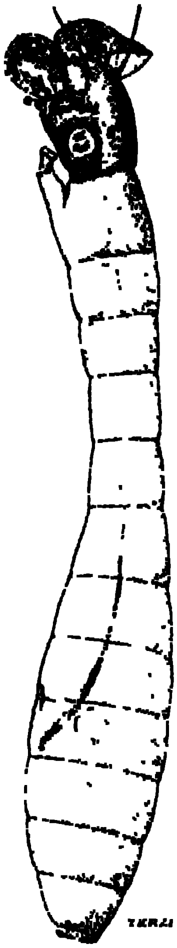

FIG. 405.—SIMULIUM LARVA. (× 8.)

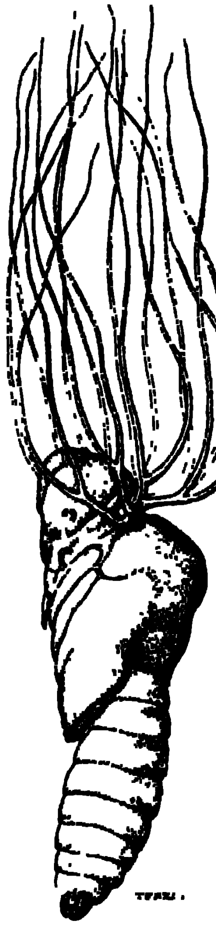

FIG. 406.—SIMULIUM PUPA. (× 8.)

Classification.—The genus has been divided into two subgenera by Roubaud—*i.e.*, *Prosimulium* and *Eusimulium*, but the differentiation of the species is very difficult. In fact, the family urgently requires revision.

Pathogenicity.—Although sand-flies are very irritating, and cause the death of cattle, it is not known whether they are the carriers of any definite disease of cattle or man, though it seems possible that they may be associated with the spread of pellagra, as Sambon has suggested; but more will be said on this subject when discussing pellagra in Chapter LXXIII.

Marchoux and Borret have suggested that sand-flies may play a rôle in the transmission of leprosy.

FAMILY BLEPHAROCERIDÆ Loew, 1860.

Orthorrhapha nematocera, without discal cell and with a secondary set of crease-like lines on the wings.

In this family the genus *Curupira* Osten-Sacken is said to contain species which suck blood. The larvæ live in rapid streams. *C. torrentium* (Muller) is found in Brazil.

CHAPTER XXXIII

DIPTERA (*concluded*)

MUSCIDÆ AND ALLIED FAMILIES

Flies—Orthorrhapha—Brachycera—Tabanidæ—Leptidæ—Asilidæ—Phoridæ—Scenopinidæ—Empidæ—Cyclorrhapha—Œstridæ—Sarcophagidæ—Muscidæ—Anthomyidæ—Pupipara—References.

BITING AND PARASITIC FLIES.

This chapter deals with all those insects which come under the term 'biting and parasitic flies.' In medicine they are of importance because of their blood-sucking habits, through which they are able to disseminate animal parasites. Further, the larvæ of certain species may enter the skin or the alimentary canal, and cause irritation and disease in this way (*Myiasis* Hope, 1837).

Continuing the classification of the Diptera already given, the first section included in this chapter is that known as the Brachycera.

SUBORDER I. ORTHORRHAPHA.

SECTION BRACHYCERA.

The principal Orthorrhapha Brachycera may be divided into two groups:—

GROUP 1: *Brachycera Homœodactyla.*—Imago with pulvilliform empodia. Larvæ with a terminal posterior stigma. Families: Tabanidæ, Leptidæ, Stratiomyidæ.

GROUP 2: *Brachycera Heterodactyla.*—Imago with empodia undeveloped or bristle like. Posterior stigma of the larva not terminal. Families: Asilidæ, Empididæ.

BRACHYCERA HOMŒODACTYLA.

The families with which we are concerned may be recognized as follows:—

A. Antennæ composed of more than five joints, or third joint complex.
    I. Squamæ large—*Tabanidæ*.
    II. Squamæ small.
        Tibia with spurs—*Leptidæ* in part.
B. Antennæ composed of three joints or third joint simple—
    Leptidæ in part.

FAMILY TABANIDÆ.

Orthorrhapha Brachycera with bulky bodies and often large heads. The eyes usually meet in the males, but are separate in the females. Antennæ with third joint marked by four to eight annuli, but without a terminal bristle. Proboscis strong and prominent. Thorax narrower than the head. Wings with large basal cells and five posterior cells. Third longitudinal vein bifurcate. Legs moderately stout. Empodia large.

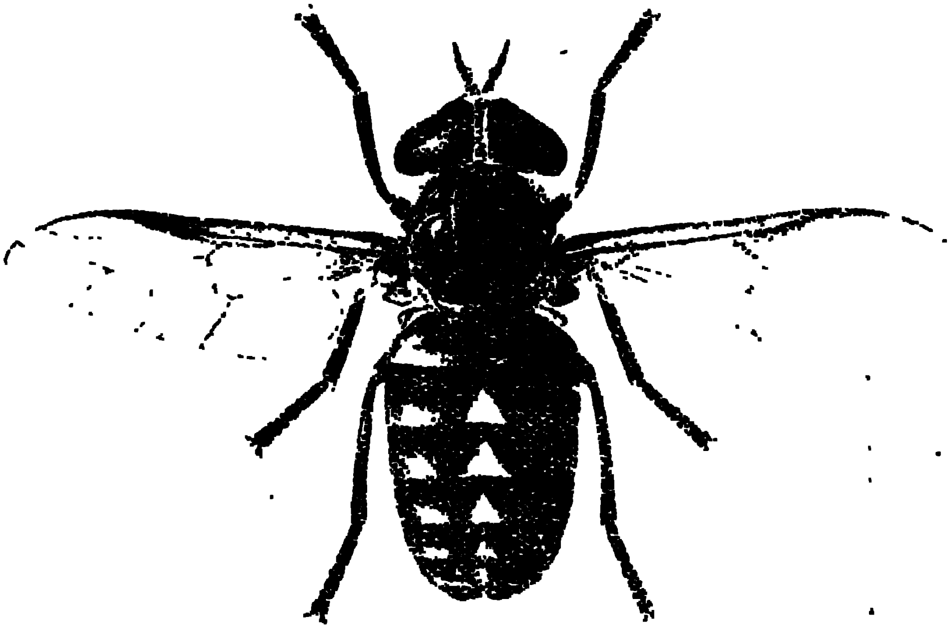

FIG. 407. *Tabanus bovinus* LINNÉ FEMALE.

Remarks. -The Tabanidæ are blood-sucking flies, of which some 2,000 species are known. The blood-sucking habit is confined to the females, while the males live on the juices of plants. They are variously known as horse-flies, breeze-flies, gad-flies, serut-flies (Nile), and mangrove-flies (West Africa), and are distributed widely over the world. They are in the habit of coming to water for drinking purposes, and this has enabled them to be killed in large numbers by sprinkling the water with kerosene, which probably prevents them escaping from the surface of the water, and partially kills them by its poisonous effects.

Morphology.—As a rule the head is as wide or wider than the thorax, convex anteriorly, and concave posteriorly, with very large, brilliantly coloured eyes, with golden-green or purple markings.

The antennæ are very distinct, but the proboscis varies, being very short in some genera and enormously long in others. In the genera in which it is short it hangs vertically downwards from the head. It consists of a labrum, two maxillæ with palps, two mandibles, a hypopharynx, and a thick labium with well-marked labial palps (labella). The wings have a large discoidal cell and very elongate basal cells. When at rest the wings diverge at the tips. They may be mottled. The legs are large and strong. The body is brown, whitish, or yellowish in colour, but there may be markings on the abdomen.

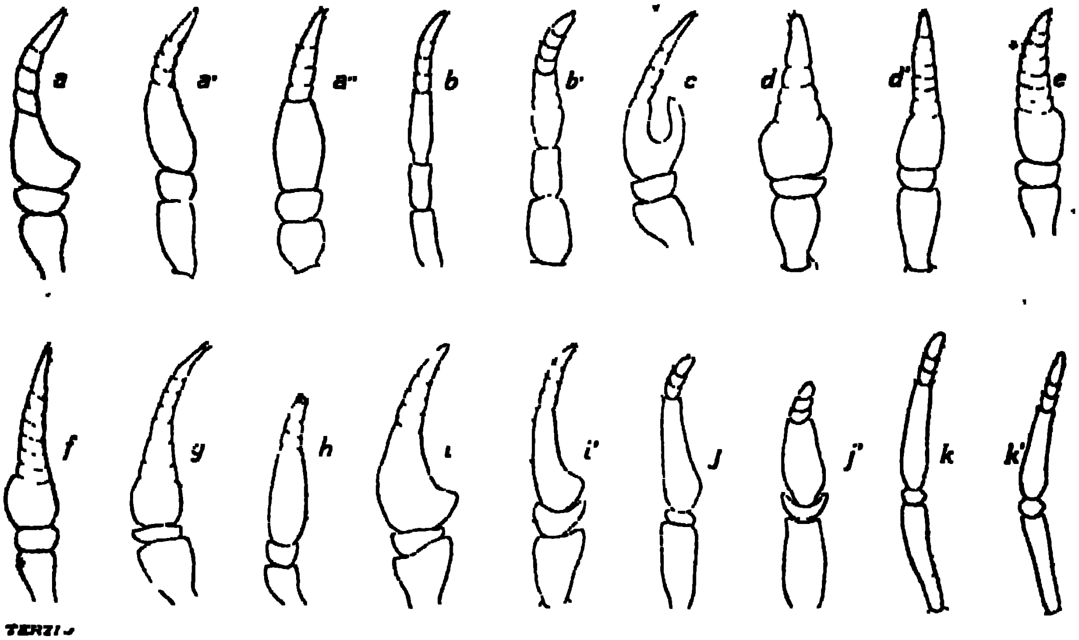

FIG. 408.—ANTENNÆ OF THE TABANIDÆ.

a, a', a", Silvius; *b, b'*, Chrysops; *c*, Rhinomyza; *d, d'*, Cadicera; *e*, Dorcalæmus; *f*, Pangonia; *g*, Erephopsis; *h*, Lepidoselaga; *i, i'*, Tabanus; *j, j'*, Hæmatopota; *k, k'*, Hippocentrum.

Life-History.—The eggs, which are spindle-shaped, and whitish in colour, are laid in raft- or flask-shaped masses attached to water-plants. The larvæ live either in water or damp earth, and feed upon small animal organisms. They are spindle-shaped and segmented, with knobs or protuberances on the rings, either all round or only ventrally. The pupa, which is free, is found in water or damp rubbish.

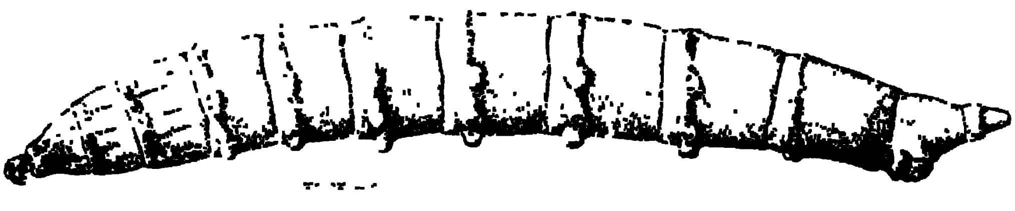

FIG. 409.—LARVA OF A TABANUS. (×2½.)

Pathogenicity.—It is possible that they may disseminate trypanosomes. The diseases m'bori in dromedaries in Timbuktu and souma in Segon are believed to be spread by *Tabanus ditæniatus*, while the dromedary disease of Algeria is spread by *T. nemoralis* Meigen and *T. nigritus* Fabricius. *T. glaucopis* Meigen is infected with *Herpetomonas subulata*. According to Leiper, Chrysops is the carrier of *Loa loa* Cobbold, 1864.

Prophylaxis.--Kerosene spread on water appears to be the best method of dealing with these pests.

Classification.--The family is divided into two subfamilies: Tabaninæ and Pangoninæ.

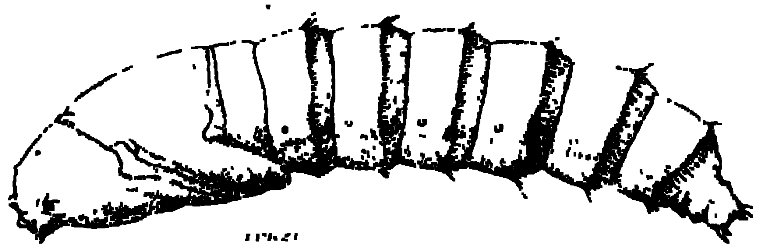

FIG. 410. PUPA OF *Tabanus kingi* AUSTEN. (AFTER KING.)
(From the Fourth Report of the Wellcome Tropical Research Laboratories, Khartoum.)

TABANINÆ.

Tabanidæ without spurs on the hind tibiæ.

The important genera of the Tabaninæ may be recognized by the following table:--

I. Thorax and abdomen with iridescent tomentum--*Lepidoselaga*.
II. Thorax and abdomen without iridescent tomentum.
  1. Eyes bare.
    (*a*) Third joint of the antenna without basal tooth.--
      (1) Antennæ extremity slender, and first joint elongate--*Hippocentrum* (Fig. 408, *k*, *k'*).
      (2) Antennæ not remarkably slender and first joint not remarkably elongate--*Hæmatopota* (Fig. 408, *j*, *j'*).
    (*b*) Third joint of the antenna with well developed basal tooth--*Tabanus* (Fig. 408, *i*, *i'*).

Lepidoselaga Macquart, 1838.

Synonym.--*Hadrus* Perty.

Lepidoselaga lepidota Wiedemann, 1828, the motúca fly of Brazil, is a well-known biter. (Antennæ: *vide* Fig. 408, *h*.)

Hæmatopota Meigen, 1803.

Synonym.—*Chrysozona* Meigen, 1800.

The number of species comprised in this genus is rapidly increasing. About 130 have already been described, and Austen informs us that many more still await description from Africa alone. The characteristics of a species belonging to this genus are--The elongate antennæ, the peculiar wing markings (Fig. 412), and the peculiar arrangement of the wings when at rest, when the bases meet together, while the rest of the wings diverge slightly and slope backwards and outwards. The species of *Hæmatopota* are very blood-thirsty, and are a terrible pest in the wet season to man and beast alike. They are said never to bite in the early morning or after sunset, but, on the contrary, Mayer states that *H. decora* is most troublesome in the early morning and late evening. Neave

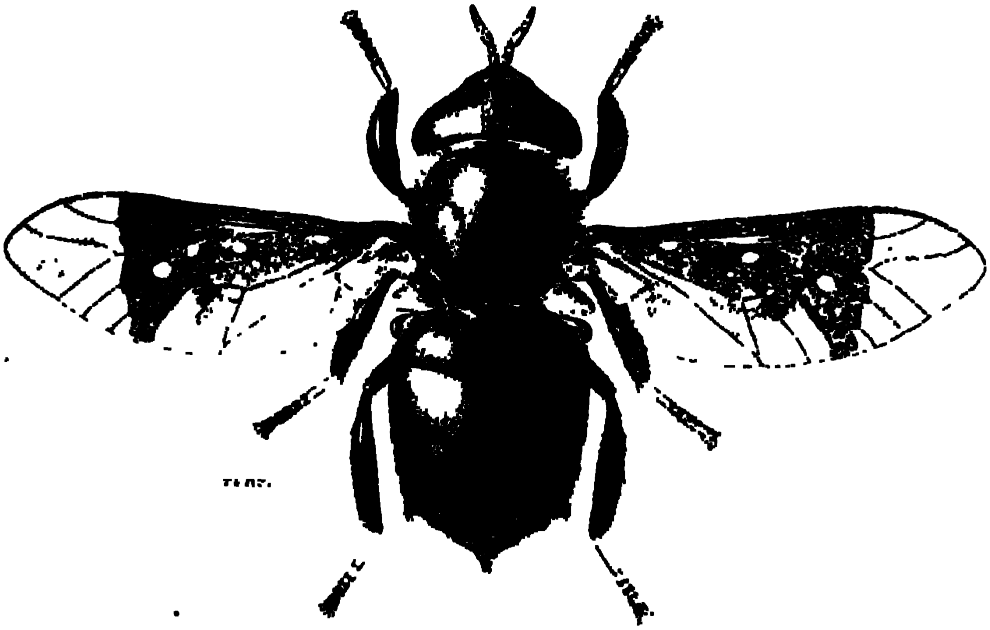

FIG. 411.—*Lepidoselaga lepidota* WIEDEMANN: FEMALE. (×6.)

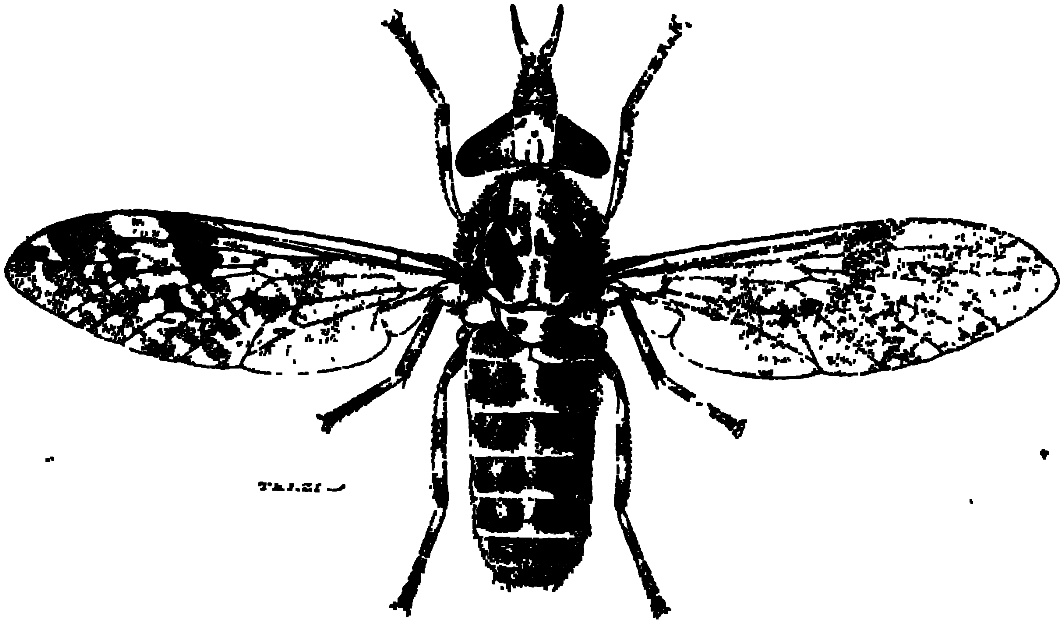

FIG. 412.—*Hæmatopota vittata* LOEW. (×4.)

states that the females bite in rather dull, damp weather, and rarely in the heat of the sun, being mostly in evidence from about 8 to 10 a.m. and from 4 p.m. to sunset in sunny weather, but in the shady, damp forest they may be troublesome all day. The life-history of the tropical species is but little known, but Neave thinks that the majority of the species may have two broods. The life-history of *H. pluvialis* Linnæus is partially known. The egg stage has not, so far as we know, been observed. The larva and pupa are of the Tabanid type, as described above. With regard to pathogenicity, Balfour reports El Takasha (' the attacking fly'), probably *H. taciturna* Austen, is believed to cause swelling of the lungs in sheep and goats.

With regard to individual species, *H. pluvialis* Linnæus is common in Europe, while *H. grahami* Austen, 1912; *H. daveyi* Austen, 1912; *H. rubens* Austen, 1912; *H. beringeri* Austen, 1912; *H. crudelis* Austen, 1912; are some new species recently described by Austen from tropical Africa. Other species are *H. obscura* Loew, 1875, in South Africa; *H. vittata* Loew in tropical Africa; and *H. bullatifrons* Austen in Northern Nigeria.

Hippocentrum Austen, 1908.

This genus is nearly allied to *Hæmatopota* Meigen, 1803, but is, according to Austen, distinguished by the fact that the head is for the most part shining, the antennæ extremely slender, and the first joint elongate (Fig. 408, *k*, *k'*), and the terminal joint of the palpi in the female very large and shining on the outer side, which is strongly convex, while the inner side is flattened; the wings are more or less suffused with dark colour, interrupted with pale streaks or blotches without the peculiar light markings of *Hæmatopota*.

Species.—*H. versicolor* Austen, 1908, in Uganda and the Lado, *H. trimaculatum* Newstead in West Africa, *H. strigipennis* Karsch, which may be identical with *H. trimaculatum*, has only been found in Gaboon, and *H. murphyi* Austen, 1912, in West Africa. The females bite man and animals. The life-history is unknown.

Tabanus Linnæus, 1761.

There are over 900 known species of *Tabanus*, of which *Tabanus bovinus* Linnæus, 1761, is found in Europe, Asia, and South Africa. In the Sudan these flies are called serut-flies: *T. ditæniatus* Macquart, *T. gratus* Loew, *T. tæniola* Palisot de Beauvois, *T. fasciatus* Fabricius, *T. africanus* Gray, may be noted. In West Africa they are known as mangrove flies. Recently Patton has described the life-cycle of a Crithidia (*C. tabani* Patton, 1909), which is a true parasite of *T. hilarius* and another species.

Subgenus Therioplectes Zeller, 1842.

A number of species of this genus are known in Europe. *Therioplectes micans* Meigen, *T. borealis* Meigen, *T. montanus* Meigen, and *T. tropicus* may be mentioned.

Subgenus Atylotus Osten Sacken, 1876.

Atylotus fulvus Meigen and *A. rusticus* Fabricius are met with in Europe.

Other Genera.

In 1906 Grünberg described three genera, with one species in each, as belonging to the Tabaninæ—viz., *Thaumastocera*—*T. akwa* in West Africa; *Holocera*—*H. nobilis*—in Tropical East Africa; *Parhæmatopota*—*P. cognata*—in Tropical East Africa and Zanzibar; while other genera are *Hexatoma* Meigen in Europe, *Dasybasis* Macquart in South America and Australia, *Bolbodimyia* Bigot in South America, *Udenocera* Ricardo in Ceylon, *Diachlorus* Osten Sacken in America, *Stibasoma* Schiner in South America, *Acanthocera* Macquart in South America, *Dichelacera* Macquart in South America, and *Selasoma* Macquart in South America.

PANGONIINÆ.

Tabanidæ with hind tibiæ armed at the tips with spurs.

I. Proboscis short.
    1. Antennæ longer than the head—*Chrysops*.
    2. Antennæ shorter than the head—*Silvius*.
II. Proboscis long.
    1. Proboscis little longer than the head—*Cadicera*.
    2. Proboscis usually much longer than the head, often longer than the body—*Pangonia*.

Chrysops Meigen, 180

This genus has become of greater importance since Leiper has shown that it includes the carrier of *Loa loa* Cobbold, 1864, which in its turn is suspected to be the cause of Calabar swellings.

The genus is world wide in its distribution, and is said to contain more than 100 species, of which some seventeen or more have been found in the Ethiopian region. The African flies belonging to the genus are of medium size, not exceeding 10·5 millimetres in length according to Austen. The wings of the majority show a conspicuous black band (Fig. 413) running across the surface. There are three ocelli on the crown of the head. The characters of the antennæ are shown in Fig. 408, *b*, *b′*; in the latter the first joint is shown to be conspicuously swollen. During life the eyes are of a golden-green

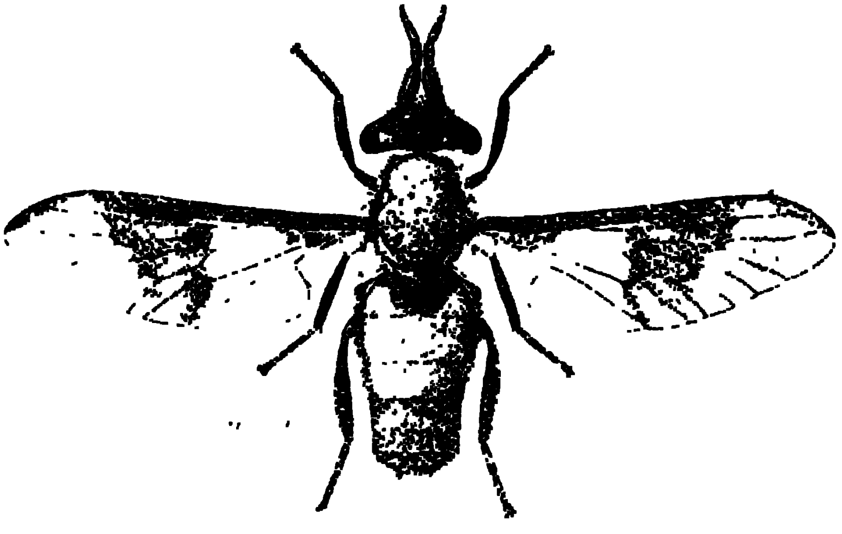

FIG. 413.—*Chrysops wellmani* AUSTEN: FEMALE. (× 4½.)

colour, and are marked with purplish spots and streaks, which Austen considers present useful specific characters. When resting, the wings are kept half open.

The females inflict a very severe bite, which causes pain, inflammation, and even at times œdema and fever.

The eggs, which at first are white and later turn brown or black, are deposited upright in a single layer upon leaves and stems of plants near water, in which, or in the mud in the vicinity, the larvæ live. The larvæ and pupæ resemble those of *Tabanus*, but in the larva the last antennal joint is longer than the penultimate, and in the pupæ the antennæ project beyond the head. With regard to pathogenicity, the genus is now known to contain the carrier of *Loa loa*.

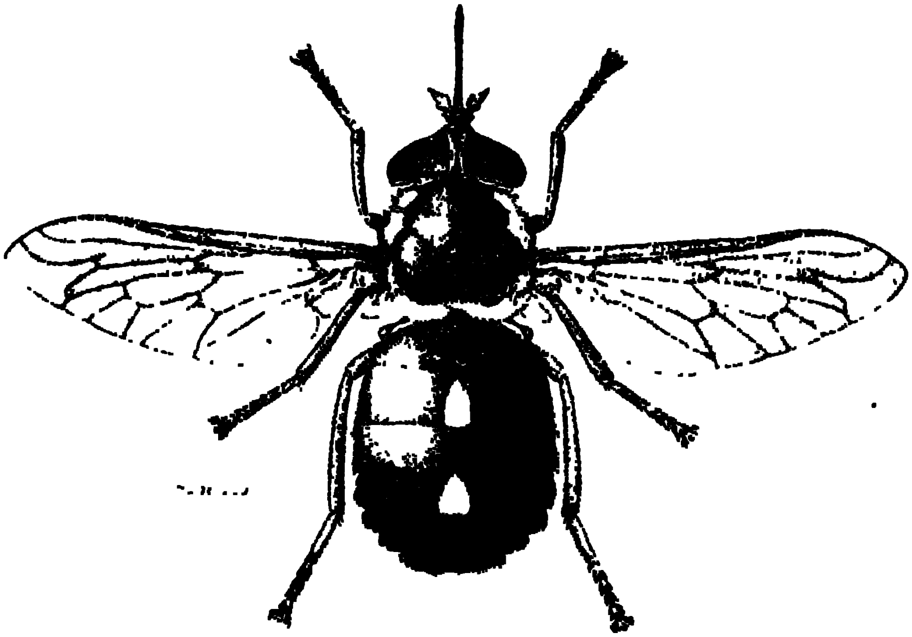

FIG. 414.—*Cadicera chrysostigma* WIEDEMANN: FEMALE. (× 2½.)

As examples the following species may be mentioned. *C. dimidiata* van der Wulp, 1885, in West Africa; *C. distinctipennis* Austen, 1906, in tropical Africa generally; *C. bicolor* Cordier, 1907, in Tropical East Africa; *C. silacea* Austen, 1907, in West Africa; *C. magnifica* Austen, 1911, in Tropical East Africa; *C. centurionis* Austen, 1911, in Uganda; *C. cana* Austen, 1911, in East Africa; and *C. dispar* Fabricius in the Oriental region.

Silvius Meigen, 1820.

This widely distributed genus may be exemplified by *Silvius fallax* Austen, 1912, found in North-Eastern Rhodesia, and *S. decipiens* Loew. The characters of the antennæ are illustrated in Fig. 408, *a*, *a′*, and *a″*.

Cadicera Macquart, 1854.

Over a dozen species of this genus are now known in the Ethiopian region, of which the following may be mentioned: *C. melanopyga*

Wiedemann, 1819; *C. chrysostigma* Wiedemann, 1828; *C. rubramarginata* Macquart, 1885; *C. quinquemaculata* Austen, 1908; *C. biclausa* Loew, 1860; *C. chrysophila* Macquart, 1834; *C. distanti* Austen, 1912; *C. speciosa* Austen, 1912; *C. flavicoma* Austen, 1912; and *C. obscura* Ricardo, 1908. The females have been observed to bite man, but very little is known as to the habits or life-history of the species of this genus.

Pangonia Latreille, 1802.

This widely distributed genus used to contain a very large number of species, but has of late been split up into several subgenera, as may be shown in the following table taken from Miss Ricardo's paper in *The Annals and Magazine of Natural History*, Series 7, vol. v., January, 1900:—

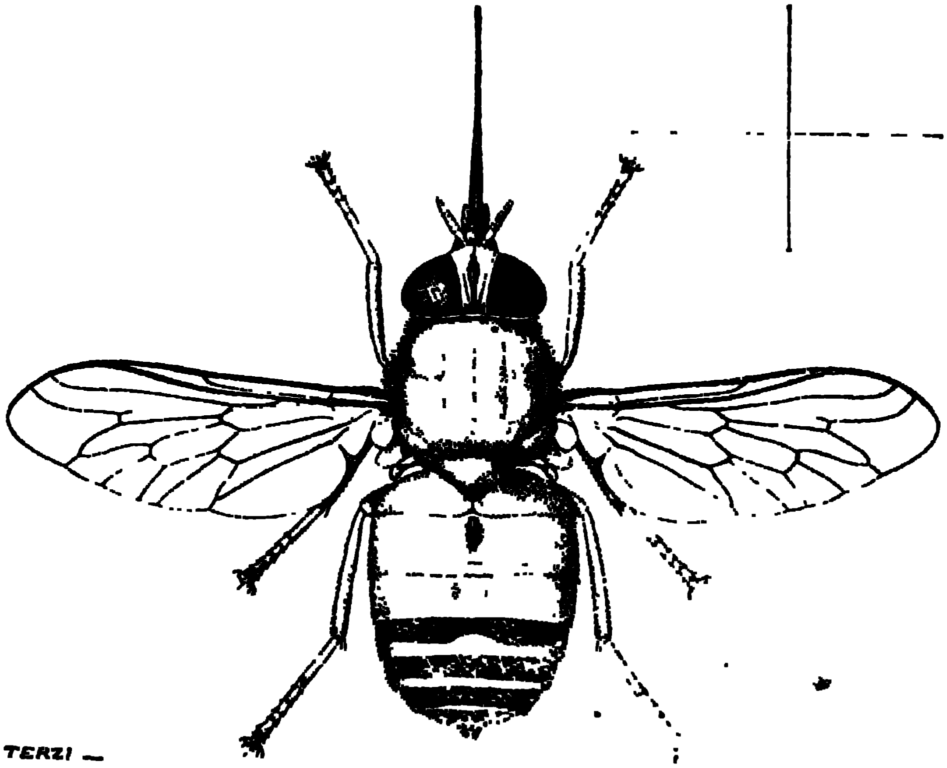

FIG. 415.—*Pangonia ruppellii* JAENNICKE, 1867: FEMALE. (×3.)

I. Wings with first posterior cell closed.
  (*a*) Eyes bare -*Pangonia* Latreille (subgenus *Pangonia*).
  (*b*) Eyes hairy -*Pangonia* Latreille (subgenus *Erephopsis* Rondani).

II. Wings with first posterior cell open.
  (*a*) Eyes hairy—*Dialomineura* Rondani (subgenus *Dialomineura*).
  (*b*) Eyes bare—*Dialomineura* Rondani (subgenus *Corizoneura* Rondani).

The characteristic of the genus is the extremely long proboscis. The antennal characters of ***Pangonia*** are shown in Fig. 408, *f*, and of ***Erephopsis*** at *g* in the same figure. The females are known to be very blood-thirsty and to bite while on the wing, a feat which they can readily perform owing to the length of the proboscis. At the present time the life-history is unknown, and the pathogenicity is also unknown.

As examples the following may be mentioned: ***P. rostrata*** Linnæus, 1764; ***P. varicolor*** Wiedemann, 1828; ***P. gulosa*** Wiedemann, 1828, in Africa; ***P. beckeri*** Bezzi, 1900, in Somaliland; ***P. rüppellii*** Jaennicke, 1867, in the Anglo-Egyptian Sudan and British East Africa: ***P. comata*** Austen, 1912, in East Africa: ***Diatomineura suavis*** Loew, 1858, in South Africa; ***D.*** (***Corizoneura***) ***lineatithorax*** Austen, 1912, in Northern Rhodesia; ***D.*** (***Corizoneura***) ***penetrabilis*** Austen, 1912, in Northern Rhodesia; and ***D.*** (***Corizoneura***) ***hasta*** Austen, 1912, in Portuguese East Africa.

Rhinomyza Wiedemann, 1820.

In this genus the first and second segments of the antennæ are short, while the third segment is composed of five rings (Fig. 408, *c*). Moreover, the third segment has a well-marked tooth. The proboscis is short. *R. fusca* Wiedemann, 1820, is known in Java, and ***R. denticornis*** Wiedemann, 1828, in South Africa. ***R. costata*** Loew, ***R. edentula*** Wiedemann, and ***R. pusilla*** Schiner may also be noted, as may *R. umbraticola* Austen, 1911, in North-Eastern Rhodesia and Kalanga, while ***R. maculata*** Surcouf is found in Madagascar.

Other Genera.

Other genera of the Pangoniinæ are *Dicrania* Macquart in Brazil, *Apocampta* Schiner in Australia, *Pityocera* Tos in Central America, *Goniops* Aldrich in North America, *Pelecorhynchus* Macquart in Australia and South America, *Apatolestes* Williston in California, *Dorcalæmus* Austen in South Africa, *Scione* Walker in South America, *Pronopes* Loew in South Africa, *Gastroxides* Saunders in India, and *Subpangonia* Surcouf in West Africa.

FAMILY LEPTIDÆ.

Orthorrhapha brachycera with brownish, medium-sized, or long narrow bodies and small heads. The third antennal joint is short, and carries either a terminal brush or bristle. The proboscis resembles that of the Tabanidæ, as does the wing venation.

Three genera are accused of blood-sucking: *Leptis*, *Symphoromyia*, and *Trichopalpus*.

With regard to *Leptis*, the species *L. scolopacea* Linnæus and *L. strigosa* Meigen are said to bite persons in France, but this is rare. *Symphoromyia* (species uncertain), characterized by a single spur on the hind tibia and a kidney-shaped third antennal joint, is found in California. *Trichopalpus obscurus* Phil. is known in Chili.

The life-history of the blood-sucking species is not known, but the other larvæ of the Leptidæ live upon decaying vegetable matter.

BRACHYCERA HETERODACTYLA.

A. Antenna apparently two-jointed with a three-jointed arista. Small hunch-backed, quick-running flies - *Phoridæ.*

B. Antenna always three-jointed.
Empodia wanting, vestigial or linear.

- I. Radial 4 and 5 separate.
  - (*a*) Arista dorsal - *Empidæ* (in part).
  - (*b*) Arista terminal.
    - (1) Front hollowed out between the eyes. Males never holoptic. Proboscis without fleshy labellæ at tip - *Asilidæ.*
    - (2) Front plane or convex. Males often holoptic. Not more than four posterior cells. Third antennal joint without bristle or style - *Scenopinidæ.*
- II. Radial 4 and 5 not separate.
  Wings not lanceolate, anal cell short; second basal cell confluent with distal cell. Not brilliantly coloured *Empidæ* (in part).

The orders Therevidæ, Midasidæ, and Dolichopodidæ, while containing species predatory on other insects, do not appear to attack man.

FAMILY ASILIDÆ.

Orthorrhapha brachycera with long narrow body, short broad head, prominent eyes, third joint of the antennæ simple. Thorax narrow in front. Wings with elongate basal cells, third longitudinal vein bifurcate, two intercalary veins present. Empodium with a horny bristle.

It is not known whether the Asilidæ are really blood-sucking flies or not. It is suspected that they bite in the tropics, but there is no definite information.

FAMILY PHORIDÆ.

Phora femorata occurs occasionally in houses. *Aphiochæta ferruginea* Brunner causes intestinal myiasis.

FAMILY SCENOPINIDÆ.

Scenopinus fenestralis Linnæus is the so-called window fly, which is probably the only household fly which is not injurious to health.

FAMILY EMPIDÆ.

Orthorrhapha brachycera with medium or small bodies and small heads. Antennæ with the first two joints very small and hardly distinct, the third joint annulated, often with terminal bristle. Wings with three large complete basal cells, of which the third is shorter than the second. The posterior basal transverse vein is parallel to the border of the wing. Empodium membranaceous.

It is doubtful whether these insects attack man. As a rule they live on the juices of other insects and plants.

SUBORDER II. CYCLORRHAPHA.

Section 1: Aschiza.—This group includes the family Syrphidæ, of which no species is known to bite man.

Section 2: Schizophora.—This group includes the true flies characterized by a distinct frontal lunula and a frontal suture: antennæ with three simple segments, and an arista which is generally dorsal. They may be classified into

Muscoidea.

Synonym.—*Eumyidea.*

This superfamily is divided into:

TRIBE 1: *Muscoidea acalyptratæ,* without squamæ covering the halteres (see Chapter XXXV.).

TRIBE 2: *Muscoidea calyptratæ,* with squamæ covering the halteres.

MUSCOIDEA CALYPTRATÆ.

1. Œstridæ.
2. Sarcophagidæ.
3. Muscidæ.
4. Anthomyidæ.

DIAGNOSTIC TABLE.

A. First posterior cell of the wings not widely open.
  - I. Antennæ small, more or less hidden in round pits; arista single or plumose; body very hairy—*Œstridæ.*
  - II. Antennæ well marked, not hidden; arista more or less plumose; body not very hairy.
    - (*a*) Arista plumose for only half its length, bare in the terminal half, which is hair-like—*Sarcophagidæ.*
    - (*b*) Arista plumose or pectinate along its whole length—*Muscidæ.*

B. First posterior cell widely open—*Anthomyidæ.*

FAMILY ŒSTRIDÆ.

Muscoidea calyptratæ with very hairy bodies, which cause them to resemble bees. Antennæ inserted into round pits, with a terminal bristle on the third joint. Mouth-parts rudimentary.

Remarks.—The Œstridæ are commonly known as the bottle or warble flies, and are of interest because the larvæ become parasitic, either under the skin, in the nasal or pharyngeal cavities, or in the alimentary canal.

Classification.—The genera may be grouped into two subfamilies—(*a*) ***Œstrinæ*** with rudimentary proboscis, including the genera *Gastro-*

philus, *Œstrus*, *Hypoderma*, etc.; and (*b*) *Cuterebrinæ*, with a well-developed retractile proboscis, including *Dermatobia*, etc. The four genera of interest to us may be recognized as follows:—

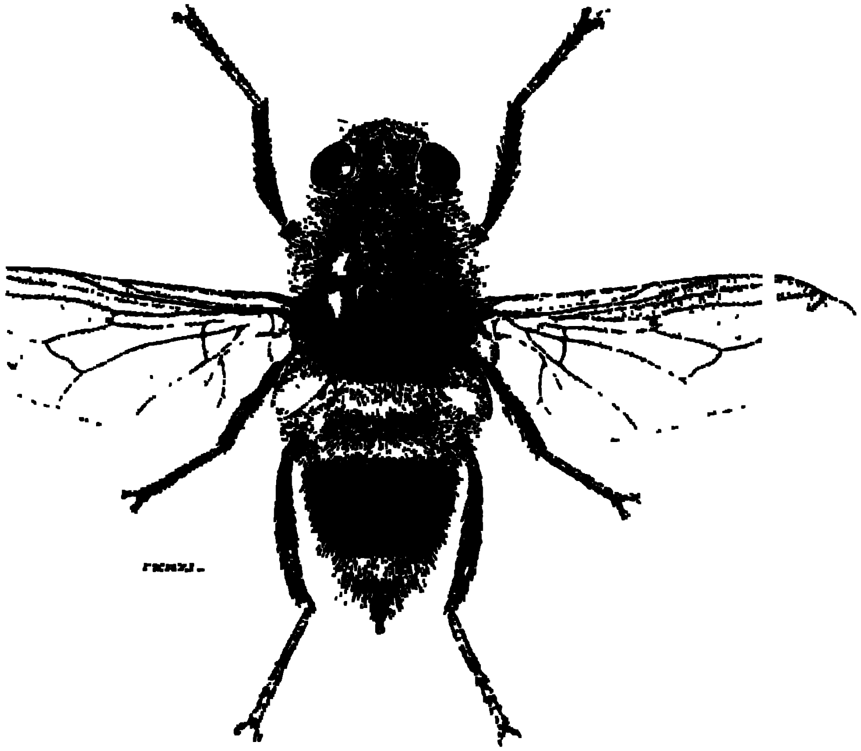

FIG. 416.—*Hypoderma bovis* DE GEER. (×2½.)

Wing without posterior transverse vein; the media runs towards the posterior border. First posterior cell is partly open. Arista naked—*Gastrophilus* Leach, 1817.

II. Wing with posterior transverse vein. The media at its end is bent towards the radius, and the first posterior cell is either open, partially open, or closed.

A. Facial grooves approximated below. First posterior cell closed and petiolate body nearly bare—*Œstrus* Linnæus, 1758.

B. Facial grooves remote.

(*a*) Proboscis straight, capable of being extended, or entirely rudimentary. Antennal groove with small angular dividing wall. Palpi absent—*Hypoderma* Latreille, 1825.

(*b*) Proboscis bent and capable of being drawn into a deep cavity on the under surface of the head, and generally hidden therein. Arista with hairs on the upper side. Third antennal joint much longer than the first two—*Dermatobia* Brauer, 1860.

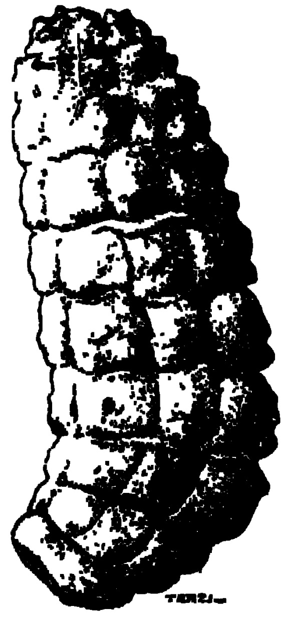

FIG. 417.—LARVA OF *Hypoderma bovis* DE GEER. (×2½.)

Hypoderma.—A good example of dermal infection is *Hypoderma bovis* de Geer, which infests cattle. The eggs are laid on the skin of the animal, and are probably transferred to the mouth by licking, whence they pass via the œsophagus to the skin, in which they form tumours. It is found in Europe and America, and Peiper has gathered together histories of several cases in which *Hypoderma bovis* and *H. diana* Brauer have occurred in man, but this is very rare. The larva which is commonly found in man belongs to *Dermatobia cyaniventris*, which is described below.

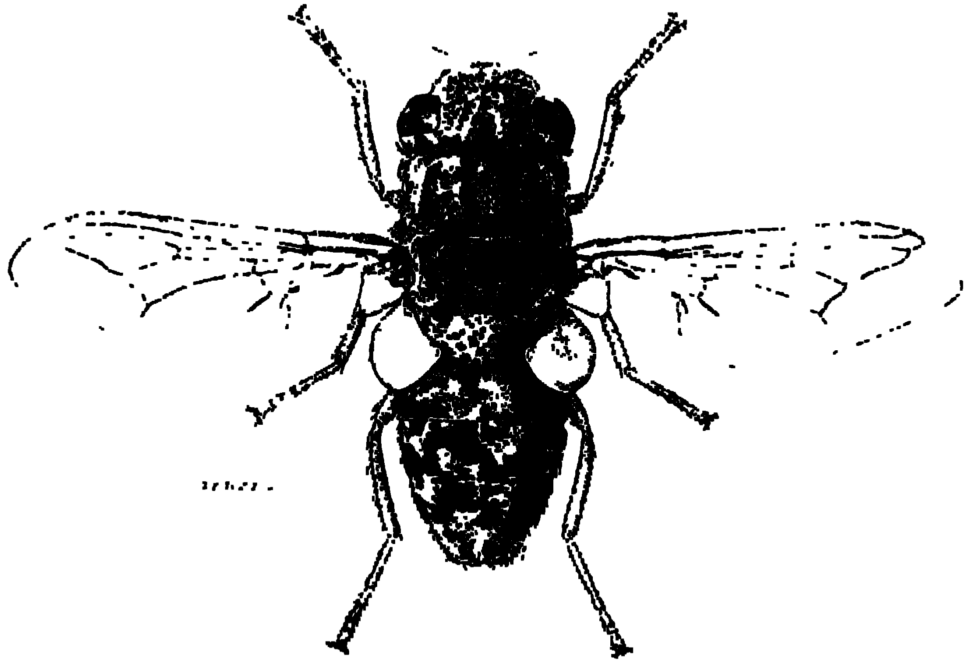

FIG. 418.—*Œstrus ovis* LINNÆUS: FEMALE. (× 4.)

Œstrus.—Rhinal myiasis is exemplified by *Œstrus ovis* Linnæus, 1761, which has been found several times in the nasal cavities of man, though usually found in sheep. The egg is laid in the nasal cavity, in which the larvæ live until they become pupæ.

Gastrophilus.—Intestinal myiasis is exemplified by *Gastrophilus equi* Fabricius. The eggs are laid on the skin, often about the knees, and transferred to the mouth, and so to the stomach, by licking. In this organ they live on the secretions and contents; but though they do not bite the mucosa, they cause irritation. In due course they pass out of the alimentary canal with the fæces, and then

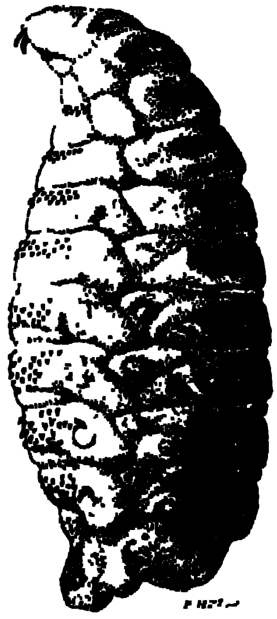

FIG. 419.—LARVA OF *Œstrus ovis* LINNÆUS. (× 4.)

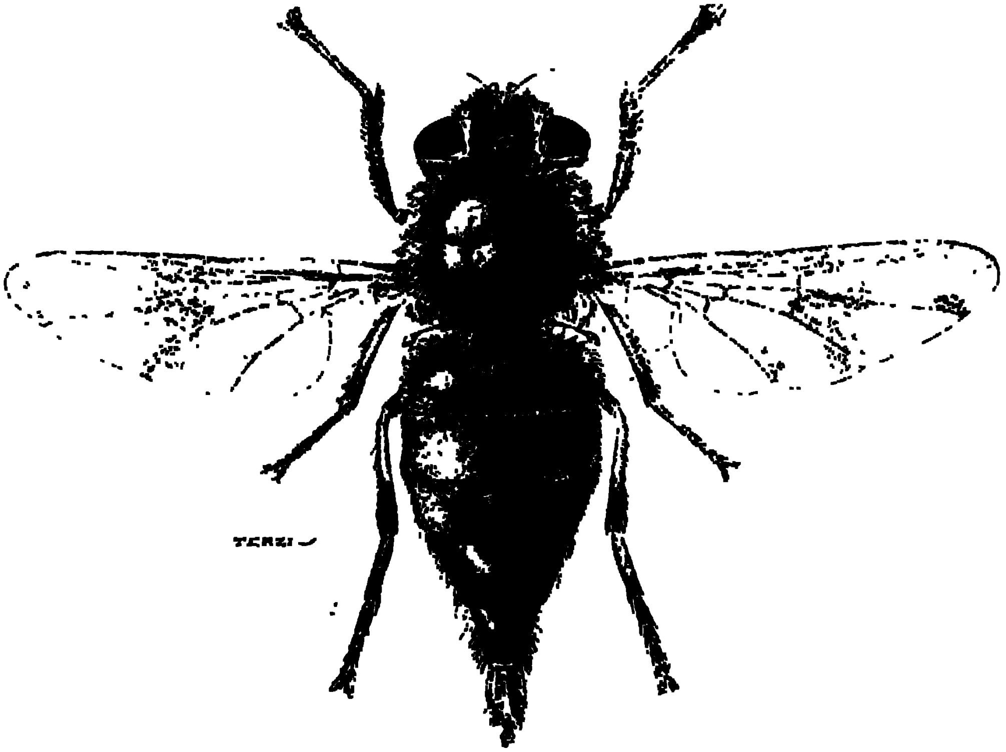
proceed to pupation. *G. pecorum* Fabricius, 1794, is stated to frequently attack man in Siberia.



Fi[illegible] .— *Gastrophilu*[illegible] Fa[illegible] 3½.)

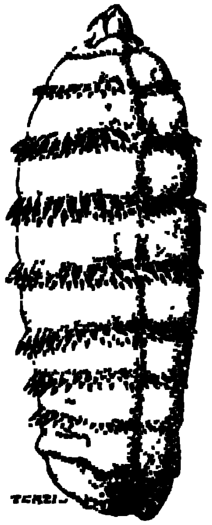


FIG. 421.—LARVA OF *Gastrophilus equi* FABRICIUS. (× 3.)

Dermatobia Brauer, 1860.

Dermatobia cyaniventris Macquart, 1843.

Synonyms.—*Cuterebra noxialis* Goudot, 1845; *Dermatobia noxialis* Brauer, 1860; *Dermatobia hominis* Say, 1822; *Œstrus hominis* Gmelin, 1788.

There appears to have been great doubt as to whether *D. noxialis* is the same as or different from *D. cyaniventris*. At present, on the strength of R. Blanchard's observations, it is usual to look upon them as the same. The larva of this species is found in the skin of man in tropical America at times, and is known by various local names: 'Ver moyoquil' in Mexico; 'ver macaque' in Cayenne; 'torcel' in Venezuela; 'nuche' in Colombia; 'ura' and 'berne' in Brazil; 'cormollote' and 'anal coshol' in British Guiana; 'nuche' or 'gusano' in New Granada.

The fly, which has a yellowish head and dark blue abdomen, is supposed to lay its eggs on the skin of domestic and wild animals and man. The larvæ from these eggs are supposed to enter the skin. The usual areas affected are the head or trunk.

The larva presents two quite different appearances. In the first they are club-shaped, white in colour, with a thick anterior and a

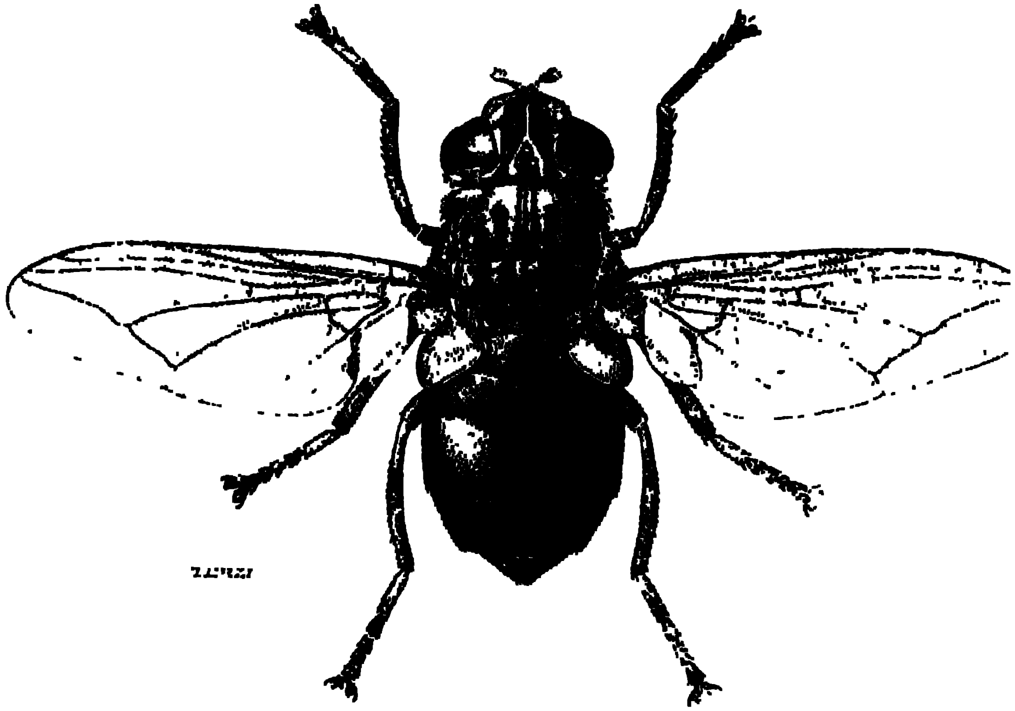

FIG. 422. *Dermatobia cyaniventris* MACQUART. (× 3)

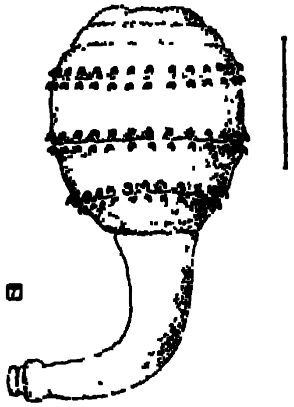

FIG. 423.—YOUNG LARVA OF *Dermatobia cyaniventris*. (× 3.) (After Blanchard.)

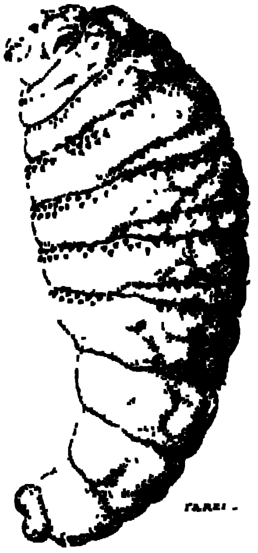

FIG. 424.—OLDER LARVA OF *Dermatobia cyaniventris* MACQUART. (× 2½.)

thin posterior end. The anterior portion is beset with booklets, and has two strong oral hooks. The posterior end carries the stigmata.

If left to themselves, the larvæ will remain in the skin for some time, after which an abscess forms, and they are thrown out, drop on to the ground, and become pupæ, and finally imagos.

We have seen larvæ resembling these in the skins of Europeans in Africa, and similar observations have been made by Plehn, Strahan, Kolb, Nagal, Arnold, and Smith and others, but whether these are *D. cyaniventris* or some other species has not been determined.

Pathogenicity.—They cause pain and itching at the infected spot, with swelling and œdema of the surrounding region, giving rise to a boil-like swelling, rather hard, of a deep red colour, with a central opening. Berne or ura of Brazil is the disease.

Treatment.—On inspecting the region, a small opening will be seen, and the larva may be noted, showing its stigmata at times, and at other times disappearing and reappearing like a jack-in-the-box. There is no difficulty in seizing this parasite with a pair of forceps and forcibly removing it, and then treating the wound antiseptically. The Brazilians try to asphyxiate the larva by tobacco-smoke, or apply some animal fat to the opening in the little tumour. The fat is said to act by preventing the larva from breathing and compelling it to leave the tumour. Some authors advise the application of calomel to the opening.

Dermatobia (?) **keniæ** Kolb.

Kolb described a reddish-brown fly in East Africa under this term.

The fly behaved like *D. cyaniventris* in laying its eggs on the skin of people when bathing. The larvæ entered the skin, forming nodules. The natives called the fly 'ngumba.' It is, however, possible that this is not a true *Dermatobia*, which is a New World genus, but a *Cordylobia*.

FAMILY SARCOPHAGIDÆ.

Muscoidea calyptratæ with large bodies, and antennal bristles feathery at the base, but hair-like and very fine at the tip. Legs stout. First posterior cell closed or only slightly open.

The Sarcophagidæ are the blow-flies, of which *S. carnaria* is common.

Genera.—*Sarcophaga, Wohlfahrtia, Sarcophila, Cynomyia.*

Sarcophaga Meigen, 1826.

It is by no means uncommon in the tropics to find ulcers, and especially syphilitic erosions of the nose, infected with larvæ of flies, which may belong to *S. carnaria* Linnæus, 1758. The larvæ have also been found in several cavities of the human body, and those of the former in the alimentary canal. The following are causes of intestinal myiasis: *S. affinis*, *S. carnaria* Linnæus, 1761; *S. hæmor-*

rhoidalis Fallen, 1810; *S. hæmatodes* and *S. chrysostoma* Wiedemann, 1830. *S. lambens* and *S. ruficornis* cause cutaneous myiasis in South America. *S. plinthopya* and *S. lambens* have been found in ulcers.

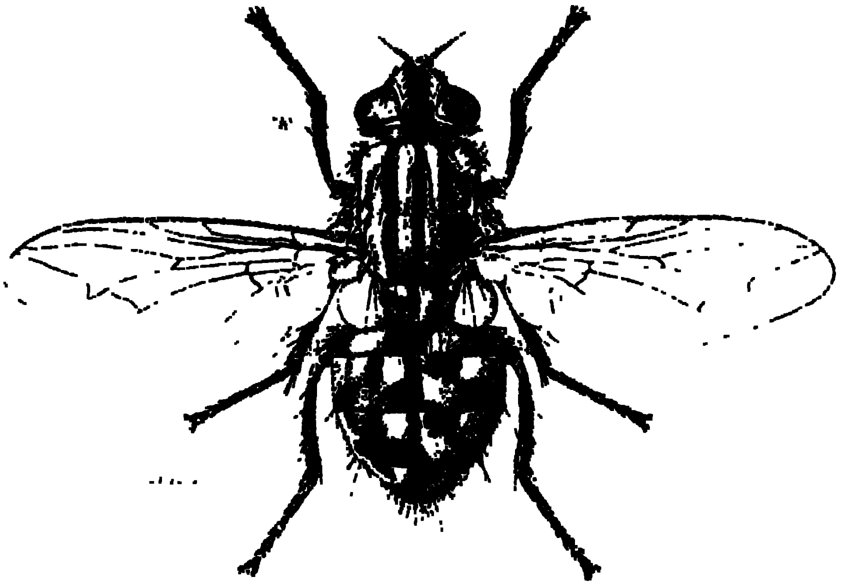

Fig. 425.—*Sarcophaga carnaria* Linnæus: Female. (×3)

Wohlfahrtia Brauer and Bergenstamm, 1889.

The larvæ of *Wohlfahrtia magnifica* Schiner, 1862, have been found in cavities in man's body, and also in cattle, sheep, dogs, and domestic fowls.

Sarcophila Rondani, 1856.

The larvæ of species of this genus *e.g.*, *S. meigeni* Schiner, *S. latifrons* Fall., and *S. ruralis* Fall.--may also be found in ulcers, etc., in Germany, Austria-Hungary, and France.

Cynomyia Robineau-Desvoidy, 1830.

Cynomyia mortuorum Linnæus, 1761, is believed to infect ulcers with its larvæ.

FAMILY MUSCIDÆ.

Muscoidea calyptratæ with stout bodies and short thoraces. Arista either entirely plumose or pectinated. The first posterior cell is either only slightly opened, or else closed at the border of the wing.

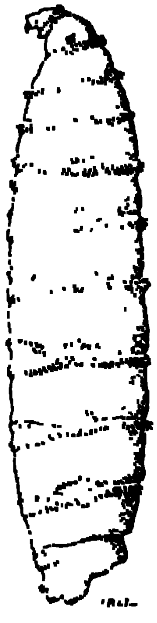

Fig. 426.—Larva of Sarcophaga sp.

The Muscidæ include a number of important genera, which may be recognized by the following table:—

- A. Proboscis long, adapted for biting—***Philæmatomyinæ.***
  - I. Proboscis partly chitinous, partly fleshy, with large fleshy labellæ—*Philæmatomyia.*
  - II. Proboscis entirely chitinous, with attenuated labellæ—*Stomoxydinæ.*
    - (A) Arista feathered dorsally only.
      - (*a*) Palpi thin, much shorter than the proboscis. Third longitudinal vein with bristles proximally; first posterior cell open—*Stomoxys.*
      - (*b*) Palpi thickened, as long as or nearly as long as the proboscis.
        - (1) Proboscis long and tapering; first posterior cell widely open; third longitudinal vein without bristles—*Lyperosia.*
        - (2) Proboscis short and stumpy; first posterior cell narrowly open; third longitudinal vein with bristles proximally—*Stygeromyia.*
      - (*c*) Palpi strongly built everywhere, not thickened. Proboscis thin, more than twice the head length, swollen at the base. Arista with many branched hairs. Media (fourth longitudinal) with two sharp bends—*Glossina.*
    - (B) Arista feathered dorsally and ventrally.
      - (*a*) First posterior cell narrowly open; third longitudinal vein without bristles—*Hæmatobosca.*
      - (*b*) First posterior cell widely open.
        - (1) Third longitudinal vein with bristles proximally—*Hæmatobia.*
        - (2) Third longitudinal vein without bristles proximally—*Bdellolarynx.*
- B. Proboscis short, not adapted for biting—*Muscinæ.*
  - (*a*) Mid tibia without bristle on inner side—*Musca.*
  - (*b*) Mid tibia with bristles on inner side.
    - (1) Thorax and abdomen bluish-black, not lustrous—*Calliphora.*
    - (2) Thorax and abdomen green or greenish, lustrous.
      - (*a*) Scutum longitudinally marked—*Chrysomyia.*
      - (*b*) Scutum not so marked.
        - (A) Thorax metallic green or bluish-green—*Lucilia.*
        - (B) Thorax brassy green or purplish-blue—*Pycnosoma.*
    - (3) Thorax and abdomen dirty brownish-yellow.
      - (*a*) Eyes wide apart in both sexes, second abdominal segment of the female more than half the length of the abdomen—*Auchmeromyia.*
      - (*b*) Eyes of male not wide apart, and second abdominal segment without the above character—*Cordylobia.*

PHYLÆMATOMYINÆ.

Philæmatomyia Austen, 1909.

Stomoxydinæ resembling *Musca domestica* Linnæus, being grey flies with remarkable proboscis. Front in male narrow, its width in centre being from one-eleventh to one-fifteenth of total width of head; width of the front in the female, one-third of total width of head. Proximal portion of proboscis shows a swollen chitinous bulb, distal portion soft and fleshy, and folded back under distal end of bulb when not in use, but when extended there is a tubular extension furnished with a circle of chitinous teeth. Distribution: India, Ceylon (very common), Cyprus, Senegal, and the Congo.

Type Species.- -*Philæmatomyia insignis* Austen, 1909.

Philæmatomyia insignis Austen, 1909.

Smoke grey or yellowish grey in colour, with dorsum of thorax with four dark longitudinal stripes. The eggs are laid in batches of fifty to sixty in cracks in dry cow's-dung. Egg is 2 to 2·2 millimetres in length by 0·4 millimetre in breadth. Larvæ hatch in eight to nine hours, and when mature measure about 1·25 centimetres. They are bright lemon yellow in colour. They burrow under the ground on the evening of the second day, and pupate. The puparium resembles that of *Musca*, 0·5 centimetre long by 0·18 centimetre broad. It is of a light mahogany colour, and has eleven segments. The life-history may be summarized: Egg-laying, five to ten minutes; egg, eight to ten hours; larvæ, two days; pupa, three and a half to four and a half days; total, six to seven days. The fly is ready to feed eight hours after hatching. Feeds usually on cattle only occasionally bites man They pass out a clear watery fluid from the anus while feeding (common in a blood-sucking fly).

Enemies.—Hymenoptera spiders, tachinids.

Other Species. *Ph. lineata* Brunetti, 1910 (synonym, *Pristirrhynchomyia lineata* Brunetti, 1910), and *Ph. gurnei* Patton and Cragg, 1912, both in India.

STOMOXYDINÆ.

Stomoxys Geoffry, 1764.

Arista of three segments, feathered dorsally only; proboscis long, tapering, chitinized in all its extent, non-retractile; palpi slender, very short, less than half the length of the proboscis. Fourth longitudinal vein curved so as to merely narrow the first posterior cell distally; third longitudinal vein bristly at its proximal end. Front narrower in the male than in the female.

Type Species.- -*Stomoxys calcitrans* Linnæus, 1758.

The genus *Stomoxys* is cosmopolitan in its distribution. The principal species are- -

European Species.- -*S. calcitrans* L., 1758.

Asiatic Species.—Twelve species known and two synonyms: *S. brunnipes* Grünberg, *S. calcitrans* L., *S. plurinotata* Bigot, *S. dacnusa* Speiser, *S. indica*

Picard, *S.* ***limbata*** Austen, *S.* ***nigra*** Macquart, *S.* ***bengalensis*** Picard, *S.* ***oblongopunctata*** Brunetti, *S.* ***prattii*** Summers, *S.* ***pulla*** Austen, *S.* ***siliens*** Rondani, *S.* ***triangularis*** Brunetti.

African Species.--Fourteen species and four probable synonyms are known: *S. calcitrans* L. (*S. korogwensis* Grunberg), *S. siliens* Rondani, *S. griseiceps* Becker, *S. nigra* Macquart (*S. glauca* Grunberg and *S. lafonti* Picard), *S. boueti* var. *clara* Roubaud, *S. inornata* Grunberg, *S. omega* Newstead, *S. varipes* Bezzi, *S. intermedia* Roubaud, *S. bouffardi* Picard, *S. bilineata* Grunberg, *S. brunnipes* Grunberg (*S. stellata* Grunberg), *S. tæniatus* Bigot, *S. ochrosoma* Speiser.

American Species.- *S. calcitrans* L.

Australian Species. *S. calcitrans* L.

For the methods of diagnosis of these species, *vide* Summers, L. M. (1912), *Journal of London School of Tropical Medicine*, July, p. 184; London.

The following table, modified from Grunberg, gives the diagnosis of a few of the species:--

A. Legs entirely yellow. Wings yellowish. *S. tæniatus* Bigot, 1887.

B. Legs either entirely black or largely black or blackish-brown. Wings clear or darkish coloured.

I. Venter brilliantly white--*S. siliens* Rondani, 1873.

II. Venter pale dusky brown, with characteristic omega mark on the thorax-- *S. omega* Newstead, 1907.

III. Venter grey or yellow.

1. Thorax without clear black stripes. Hinder part black without any markings. *S. inornata* Grunberg, 1906.

2. Thorax with clear black stripes. Abdomen with regular dark marks or spots.

(*a*) Knee, tibia, and tarsus--at all events, on the two anterior pairs of legs--entirely brown.

(1) Tibia and tarsus on the anterior and middle legs light brown, on the hind legs dark brown. Thorax with two small brown longitudinal median lines--*S. bilineata* Grunberg, 1906.

(2) Tibia and tarsus brown on all three legs. Thorax with broad black longitudinal stripes.

Wings blackish, head and thorax brown yellow--*S. brunnipes* Grunberg, 1906.

Wings glassy, head and thorax grey. *S. stellata* Grunberg, 1906.

(*b*) Legs black, with light brown knees or decidedly dark brown spots.

(1) Wing brushes yellowish-brown, with black tips. Abdomen with dark middle longitudinal line. Second and third segments with dark anterior and posterior borders. *S. glauca* Grunberg, 1906.

(2) Wing brushes black. Abdomen grey. Both middle segments with regularly arranged dark spots without dark median longitudinal line.

Second and third abdominal segments with one middle basal, one side apical dark spot, and dark anterior border, with which the basal spot unites. *S. korogwensis* Grunberg, 1906.

Second and third abdominal segments with the same dark spots, but without anterior border-lines--*S. calcitrans* Linnæus, 1761.

Stomoxys calcitrans Linnæus, 1758.

S. calcitrans is the common stable-fly, found in houses, stables, and in the open near cattle. It bites all classes of mammals, and in so doing is suspected of spreading trypanosomes, especially *T. evansi*. Manders considered *S. nigra* Macquart, 1850, to be the cause of the spread of surra in Mauritius.

It is rather like the common house-fly, but is easily recognized by the head being raised in the resting position, by the projecting proboscis, and by the closed wings, touching one another at their bases, and diverging behind.

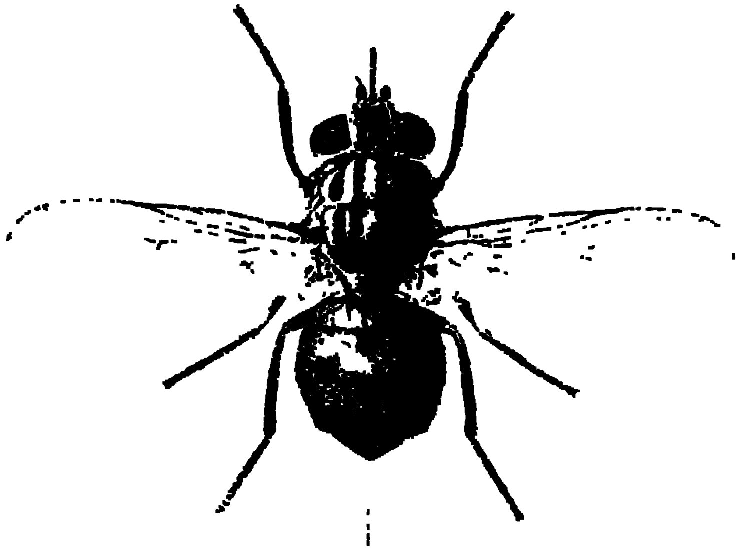

FIG. 327. *Stomoxys calcitrans*. Female.

Morphology. The mouth-parts consist of a proboscis, composed of rostrum, haustellum and labellæ, which are bent posteriorly forming an elbow-shaped joint. The posterior portion can be retracted or projected forwards, and carries the chitinous fulcrum of the pharyngeal wall, the maxillæ and their palps. It is cone-shaped and is called the rostrum.

The structure of the haustellum, or proboscis proper, is very complex. It consists essentially of a labrum, hypopharynx, and labium. The labrum is a sharp-pointed stylet, which near its apex bears a ventral ridge with four sensory hairs. Posteriorly it is attached to the head, where it forms a chitinous projection. It is horseshoe-shaped on transverse section, the ventral opening being closed by the hypopharynx, while laterally its walls, which expand and enclose a cavity containing muscles, articulate with the labium, thus keeping the hypopharynx in its place. The hypopharynx, which contains the salivary tube, starts from the labium and runs forwards, expanding laterally and closing in the labial, pharyngeal, or blood-tube mentioned above. Its lateral expansions contain a cavity. At its tip it appears to be membranous, which Stephens and Newstead think by its flaccid condition prevents ingress of fluid during blood sucking, while freely permitting the egress of saliva. The labium is stout and thick, with a swollen basal portion gradually tapering towards the proximal and distal extremities, but less so basally. Posteriorly it encloses the labrum and hypopharynx, which it carries on a sclerite, which farther forwards forms the boundary of the labial gutter and is joined dorsally by another dorsal hooked sclerite. These sclerites stop at the base of the labellæ. Ventral to the dorsal sclerites are two ventral sclerites, which

anteriorly articulate with a transverse forked sclerite whose arms run forwards. To these arms the tendons of longitudinal muscles are attached, which are capable of rotating them, causing the eversion of the labellæ. Farther forward the two labellæ are strengthened internally by dorsal and ventral sclerites, while a pear-shaped axial apophysis projects forwards freely from the labium.

The ventral plate is obliquely placed, and carries—(1) five teeth; (2) nine sets of petiolated blades; (3) six sets of rod-like hairs; (4) five sets of operculate hairs; (5) six sets of bifurcated hairs; (6) an anterior dorsal fringe of hairs; (7) a posterior ventral set of hairs; (8) ventral phalanges or lips with ventral hairs; (9) dorsal external set of hairs; and (10) latero-external set of hairs.

Internal Anatomy.—The pharyngeal tube leads into the pharynx, whose wall is formed by the chitinous fulcrum. The œsophagus, at first flattened, afterwards cylindrical, passes into the thorax and opens into the ventral surface of the proventriculus. At this point it is joined by the duct from the crop or sucking stomach, which is a large hollow blood-reservoir lying in the abdomen. The chylific ventricle has three coils. The usual Malpighian tubules, small and large intestine and rectum are present. The salivary gland resemble those of *Musca* and *Glossina*.

Method of Biting.—*Stomoxys* carefully inspects the skin, and having selected a spot, everts the labellæ, and by a rotatory motion cuts a hole through the epidermis by means of its teeth, and then, inserting the proboscis into the wound, sucks the blood.

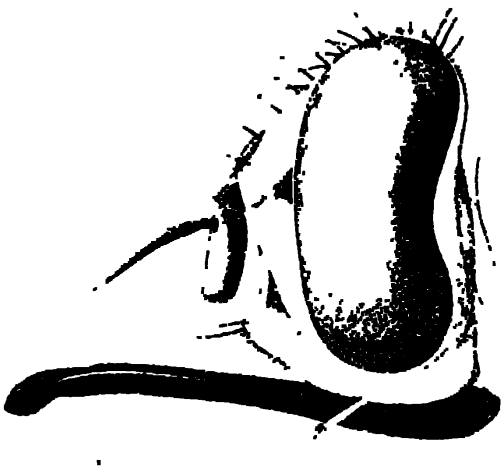

FIG. 428.—HEAD OF *Stomoxys calcitrans*: FEMALE.

Life-History.—The life-history has been studied by Newstead, who finds that the incubation period of the egg is two to three days, the life of the larva fourteen to twenty-one days, the pupal stage nine to thirteen days, making the total life-cycle twenty-five to thirty-seven days, but this may be considerably prolonged by the incubation and larval stages being lengthened in the absence of moisture, or the presence of a low temperature.

The eggs are 1 millimetre in length, white, turning later to a cream colour; coriaceous and reticulated; curved on one side and straight on the other, where there is a broad deep groove, wider anteriorly, where the larva escapes. The number of eggs varies from forty-eight to seventy-one, and they are laid in warm dung and fermenting grass.

The larva is 11 millimetres long, and tapering, yellowish in colour, with blackish mouth parts. The segmentation is not well marked. The head has two large diverging processes, which carry the four-jointed antennæ. The mouth is armed with a hook-like mandible, which carries a ventral tooth, and is attached by means of a hypostomal sclerite to two large cephalo-pharyngeal sclerites, in front of the upper arms of which is a small perforated sclerite. The posterior stigmata are two in number. The mouth-hook is used for locomotion.

Pupation is brought about in two hours by the larva shortening itself and becoming barrel-shaped, the colour turning to red. The pupa measures 5 to 5·5 millimetres in length, and possesses eleven visible segments. In a few days the pupal skin is split along lateral and median lines anteriorly, and at the fourth segment transversely, and the imago escapes.

Lyperosia Rondani, 1862.

Synonym.—*Glossinella* Grunberg, 1906.

Stomoxydinæ resembling *Stomoxys*, but with palpi as long as the long slender proboscis, around which, as they are broad, they form almost a sheath, with no bristles on the third longitudinal vein. Distribution: Europe, Asia, Africa, North America, and Australia.

Type. —*Lyperosia irritans* Linnaeus, 1761

They are dirty brown or dirty yellowish-grey, very small blood-sucking flies, with inconspicuous markings, and usually only attack animals, and do not come into houses.

European Species. *L. irritans* L., 1758, *L. titillans* Bezzi, 1911.

Asiatic Species.—*L. minuta* Bezzi, 1892, *L. schillingsi* Grunberg, 1906, *L. exigua* de Meijere, 1903; *L. flavohirta* Brunetti, 1910; *L. rufipalpis* Becker 1910 (probably *Stygeromyia maculosa* Austen, 1907).

African Species.—*L. minuta* Bezzi, 1892; *L. longipalpis* Roubaud, 1906 (= *L. pallidipes* Roubaud, 1907), *L. schillingsi* Grunberg, 1906 (= *St. maculosa* ?); *L. potans* Bezzi, 1908; *L. punctigera* Austen, 1909; *L. exigua* (Meijere, 1903); *L. thirouxi* Roubaud, 1903.

American Species.—*L. irritans* L., 1758, *L. alcis* Snow, 1891 (synonym: *Hæmatobia alcis* Snow, 1891).

Australian Species. *L. exigua* Meijere, 1903.

(For details see Summer's paper, *vide infra*.)

Stygeromyia Austen, 1907.

Stomoxydinæ with general appearance and body like *Stomoxys*, proboscis and palpi like *Hæmatobia*, arista feathered dorsally only. Head flattened from front to rear; proboscis short, stout, shiny, chitinous, not tapering, palpi as long as the proboscis; clavate at tips, curving upwards. Cell opening as in *Stomoxys*. Apical portion of fourth vein straight beyond bend—*i.e.*, not bent inwards as in *Stomoxys* and *Hæmatobia*. Distribution: Africa and Southern Arabia.

Type.—*Stygeromyia maculosa* Austen, 1907.

Stygeromyia sanguinaria Austen, 1909, is stated by Yale Massey to be a blood-sucker in the Congo Free State, while *S. maculosa* Austen, 1907, found in Little Aden, is inferred to be also a blood-sucker, and *S. woosnami* Austen, 1912, in East Africa.

Glossina Wiedemann, 1830.

Synonym.—*Nemorhina*, Robineau-Desvoidy, 1830.

Narrow bodied, elongate, greyish-brown or yellowish-brown, dull-coloured flies, with the wings closed flat over one another, and projecting considerably beyond the abdomen when at rest, with an anterior projecting proboscis, beyond which the palpi slightly extend, and in which they are ensheathed. Base of proboscis bulbous.

This is the genus of the tsetse-flies, a name probably derived from the noise which they make when flying, and now used in a generic sense. They were first named by Wiedemann from *G. longipalpis*, brought from Sierra Leone by Adam Afzelius, and in the same year Robineau-Desvoidy named another species from the Congo *Nemorhina palpalis*. Their bites have been long known to be dangerous to animals, but it was not till Bruce showed that they were the spreaders of *Trypanosoma brucei* and the cause of the disease nagana in horses, etc., that they received much attention. The interest in them became vastly greater when in 1903 Bruce and Nabarro showed that they were the spreaders of *T. castellanii* and especially when Kleine showed that the transmission was not mechanical.

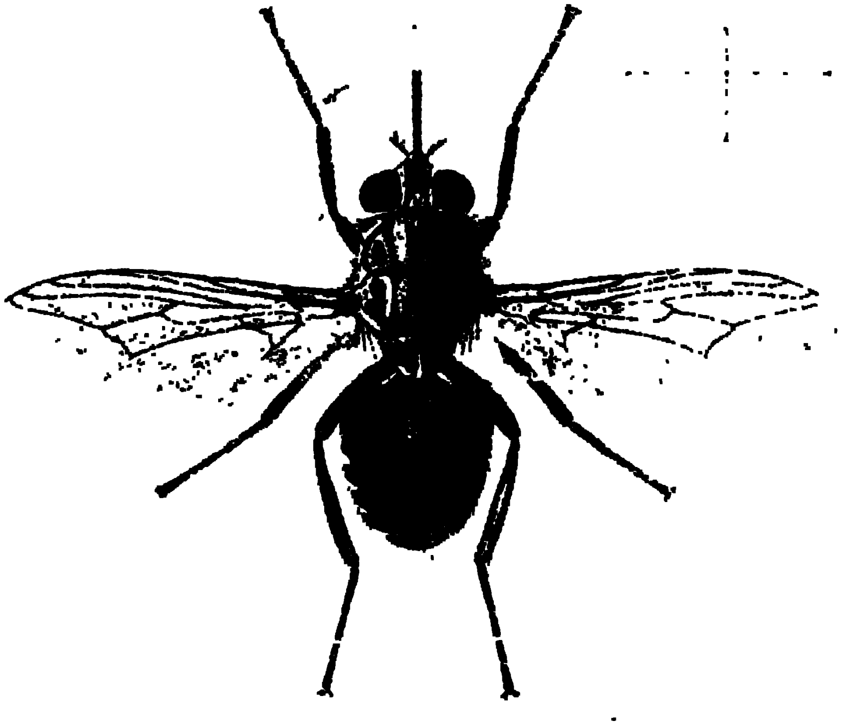

FIG. *Glossina palpalis*: FEMALE

The genus is confined to tropical Africa and Arabia.

Morphology.—The points in the morphology to which attention should be paid are as follows:—

The eyes are large and bare, and between them the vertex is depressed, and at its back carries ocelli. In front a deep facial pit is separated by a transverse impression from the gena. The proboscis projects horizontally forwards, while its bulbous posterior portion is enclosed in a fold of skin. Palpi are rod-like, and clothed with short black hairs, and enclose the proboscis. The antennæ are three-jointed, the first two being small and the third large, with its anterior external angle prominent and directed forwards and outwards. At its base is attached a two-jointed arista, of which the first segment is small, and the second long and tapering, bearing some twenty-two fine, curving, branched hairs on its upper surface only. Bristles are frontal, vertical, ocellar, and post-medial.

With regard to the thorax, the most important feature is the wing, which is brownish, with a peculiar venation. The costal vein is

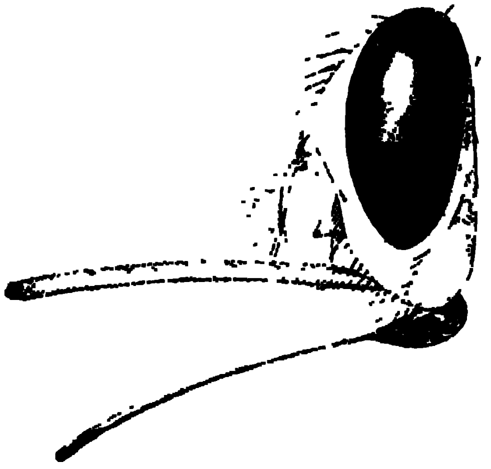

FIG. 430.—HEAD OF A GLOSSINA.

This figure shows the proboscis being lowered previously to piercing the skin to suck blood.

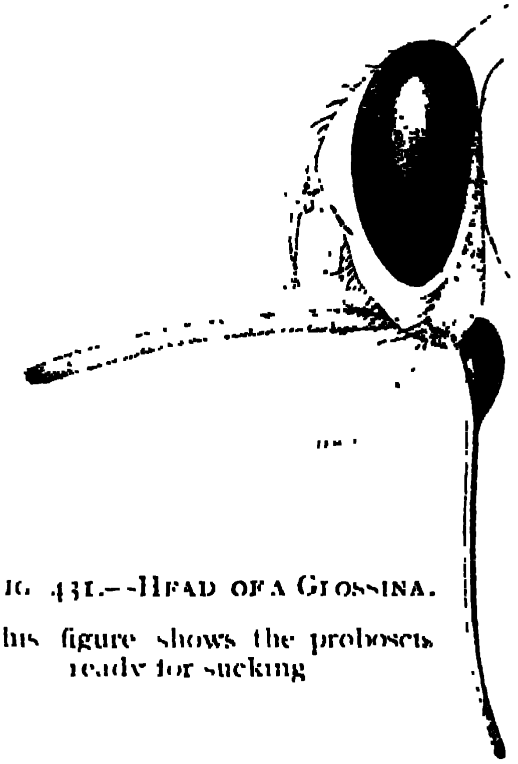

FIG. 431.—HEAD OF A GLOSSINA.

This figure shows the proboscis ready for sucking.

well marked, and the subcostal vein (auxiliary) joins it about the junction of the inner with the outer third in the extended position of the wing, thus enclosing the costal cell, which is divided into two portions by the humeral transverse vein. The radius 1 (first longitudinal) curves forwards, joining the costa about the junction of the inner two thirds with the outer one-third, thus forming a very narrow subcostal cell. The radius 2 and 3 (second longitudinal) also curves forwards, meeting the costal margin before the tip of the wing is reached, as does the radius 4 and 5 (third longitudinal); hence the marginal and submarginal cells are long and narrow. The media (fourth longitudinal) is highly characteristic. It starts separately from the preceding, and running outwards, after meeting with the anterior basal vein, curves forwards to join with the anterior transverse vein, when it bends at right angles, turning backwards

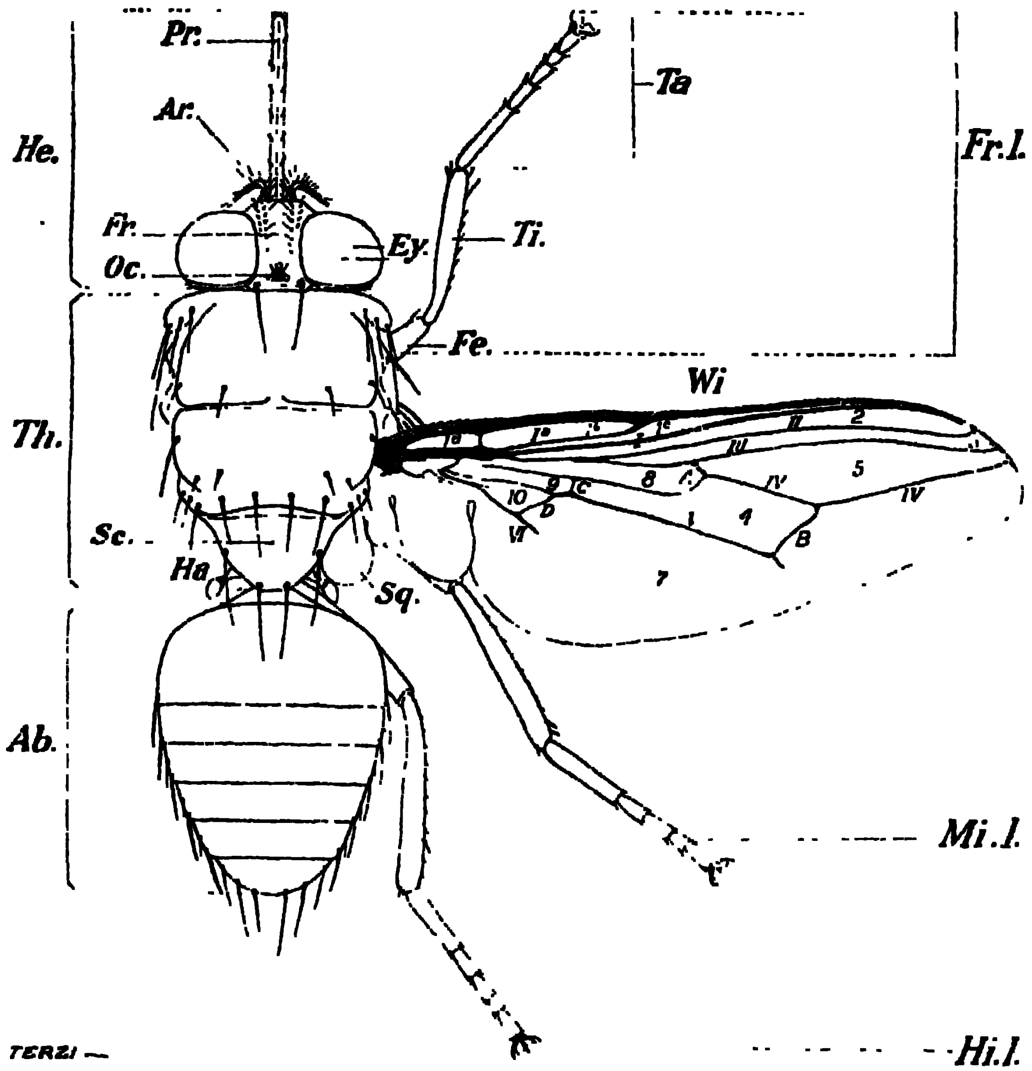

FIG. 432.—DIAGRAM OF A TSETSE-FLY.

(Modified after Austen, from 'Monograph of Tsetse-Flies')

Venation of Wing.—*Ia*, Subcostal or auxiliary vein; 1*a*, 1*b*, two portions of the costal cell divided by the humeral transverse vein; 1*c*, subcostal cell; *I*, radius 1, or first longitudinal; 2, marginal cell; *II*, radius 2 and 3, or second longitudinal; 3, submarginal cell, *III*, radius 4 and 5, or third longitudinal; 8, first basal cell; 5 first posterior cell; *A*, anterior transverse vein; *IV*, media or fourth longitudinal; 9, posterior basal cell; 4, discoidal cell, external to which is the second posterior cell, without a number; *B*, posterior transverse vein; *C*, anterior basal vein; *V*, cubitus 1 and 2, or fifth longitudinal; *D*, posterior basal transverse vein; 10, posterior basal cell; 7, third posterior cell; *VI*, anal or sixth longitudinal.

and outwards to join with the posterior transverse vein, when it again turns and runs obliquely forwards to join the costal vein just in front of the tip of the wing. Between it and the radius 4 and 5 (third longitudinal) lie internally the first (anterior) basal cell, and externally the first posterior cell, separated by the anterior transverse vein, which is very oblique. The cubitus 1 and 2 (fifth longitudinal) joins the anterior basal vein, marking out the posterior basal cell, and then runs forwards to join the posterior transverse vein, marking out the discoidal cell, which is hatchet-shaped, with the handle running up to the anterior basal transverse vein. After this the vein turns backwards to join the margin of the wing, delineating the large second posterior cell. The anal (sixth longitudinal) is very short, being unchitinized after meeting with the posterior transverse basal vein, with which it marks out the posterior basal cell. The third posterior cell is, however, shown by its unchitinized trace. The posterior part of the wing shows an incrassation corresponding to anal 2 and 3.

The legs are simple, rather long, with long claws and pulvilli.

The abdomen is flattened, tapering to the apex, and clothed with short black hairs. The male genitalia are characteristic. The ventral plate of the sixth segment carries a patch of dark hairs on each side of the middle line, behind which is the hypopygium, which is oval, tumid, and marked by a vulviform median groove, the anus, running from its anterior margin backwards to beyond the middle.

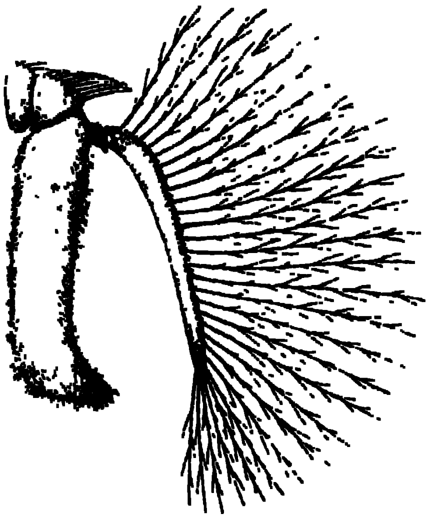

FIG. 433.—ANTENNA OF A GLOSSINA SHOWING THE ARISTA

(After Austen, from 'Tsetse-Flies.')

The proboscis shows the usual rostrum or conical head projection, the haustellum, or proboscis proper, and the labellæ.

The proboscis proper is composed of labrum, hypopharynx, and labium. The labrum arises from the basal bulb of the proboscis in the form of a tube, which is continuous posteriorly with the pharynx, while anteriorly it runs forwards, forming the dorsal wall of the proboscis. In this position it articulates by means of interlocking teeth with the labium, while, opening ventrally, it articulates with the hypopharynx, which closes the potential ventral opening. Farther forwards it separates from the labium, and ends in a point. The tube composed by the hypopharynx and the labrum is the afferent blood or pharyngeal tube. The hypopharynx starts below the pharynx surrounding the salivary efferent duct, and pierces the bulb of the proboscis, appearing on its dorsal aspect. Farther forward it lies in a groove on the labium, articulating laterally with the labrum. Finally it ends as a delicate chitinous tube just posterior to the labellæ. Its canal is the salivary tube or hypopharyngeal canal.

The labium, or second maxilla, starts from the ventral area of the head, and is first swollen to form the bulb. Anteriorly it is grooved dorsally to hold the hypopharynx and the labrum, while farther anteriorly it ends in the labellæ. These structures (labellæ) are joined together in the ventral line, except anteriorly, where there is a V-shaped notch, while dorsally they possess teeth which interlock.

In the ventral line the chitinous floor of the labium is prolonged forwards in the form of a fork, in front of which is a membranous area anteriorly to which the inner wall of each labellum becomes divided into dorsal, median, and ventral segments. Each segment is armed with a series of about ten rasps, composed of some thirty minute bars, in front of which are two pairs of teeth. Between the bases of the anterior pairs of teeth there projects a fan-shaped mass of spine-like scales. The segments are capable of eversion, when the muscles pull backwards the external walls of the labellæ. In this way the teeth would be brought in contact with the skin, and the wound necessary for blood-sucking made, probably by rotatory movements.

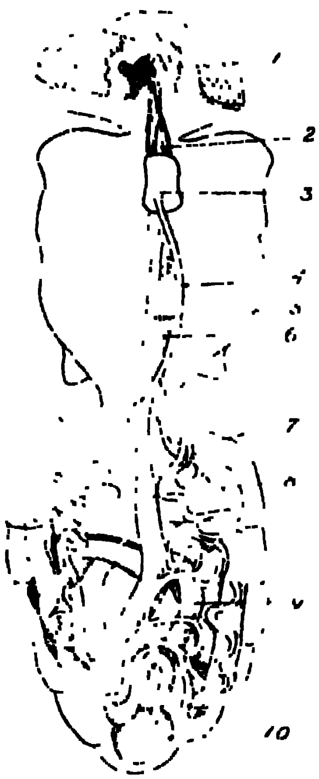

FIG. 431.—ANATOMY OF A TSETSE-FLY.

(After Minchin from Reports of the Royal Society.)

1, Pharynx; 2, œsophagus; 3, proventriculus; 4, thoracic intestine; 5, duct of sucking stomach; 6, salivary duct; 7, salivary gland; 8, sucking-stomach; 9, abdominal intestine; 10, rectum.

Internal Anatomy. The internal anatomy has been carefully studied by Minchin, and does not materially differ from that of *Stomoxys*.

The pharyngeal tube opens into the pharynx, which is situated mainly in the rostrum. Its walls are strongly chitinized, forming the fulcrum. The œsophagus runs upwards and then backwards to open into the proventriculus, and to be continuous via a long ventral duct with the crop, which lies in the first two segments of the abdomen. The chylific ventricle is narrow at first in the thorax, but becomes wider in the abdomen, where it coils several times. There are the usual ileum, colon, rectum, and Malpighian tubules.

The salivary glands are two long coiled tubes lying first in the abdomen, and then passing into the thorax, and probably opening finally on the hypopharynx, though this has not yet been worked out.

Life-History.—The species of *Glossina* live in jungles or bush, along the banks of streams or lakes. They appear to live principally upon the blood derived from big game, but Koch believed that *G. palpalis* lives on that of crocodiles, and Hodges, on that of hippopotami. According to Kinghorn, copulation in *G. morsitans* lasts for several hours. The female in due course produces a single larva, and may produce a second after fourteen to fifteen days. At the completion of intra-uterine life the larva almost completely fills the abdomen of the mother. Its extrusion takes place very rapidly, and it commences to crawl at once. The larvæ, which are yellow-coloured, are to be found as a rule near the roots of banana-trees. These larvæ are composed of twelve segments, the anterior of which carries the two minute mouth-hooks, and the posterior a dark hood or anal segment. The larvæ retire to some hole, and in a few hours become jet black pupæ from which the fully developed insects issue in about six weeks.

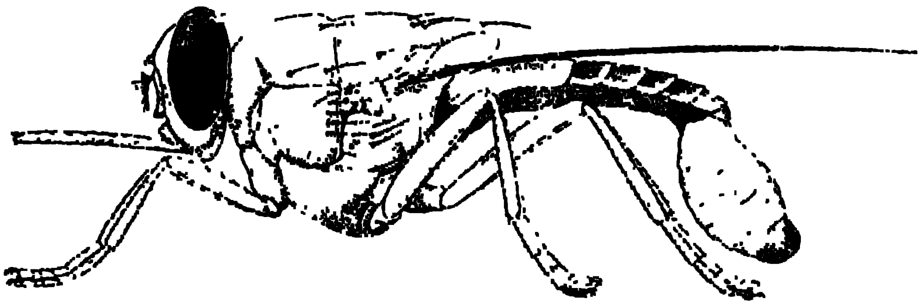

FIG. 135.—A GLOSSINA IN THE ACT OF GIVING BIRTH TO A LARVA. (Modified after Newstead.)

The pupa is 5·53 (5 to 6) millimetres long, and 3·2 (3 to 3·75) broad, according to an average of twenty measurements by Kinghorn, with twelve segments. The anterior four show the longitudinal seam, which bifurcates at the fourth segment, forming an opening through which the imago escapes. The first segment carries the mouth, and the twelfth two lateral tumid, tuberculated lips, connected by dorsal and ventral ridges enclosing a pit, in which the posterior stigmata can be seen.

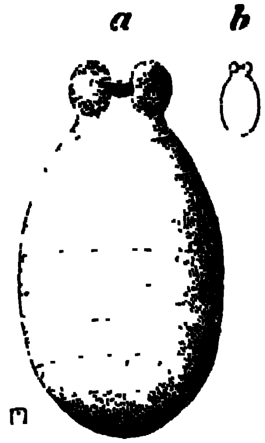

FIG. 136.—PUPA OF A TSETSE FLY. (After Austen, from 'Tsetse Flies.') *a*, Magnified; *b*, natural size.

The larvæ of *G. palpalis* measure 4·5 by 1·75 millimetres, and the pupæ 5 to 5·75 by 3 millimetres.

According to Kinghorn, forty-seven to fifty-three days elapse from the birth of the larva to the escape of the imago in *G. morsitans*.

Bionomics.—As *G. palpalis* is most probably the sole means of propagation of human trypanosomiasis, it is important to have some idea of what is known as to its bionomics, which have been carefully studied by Hodges and Bagshawe.

The main resort of the fly is to be found in bush near water, especially in the undergrowth composed of shrubs, bushes, vines, creepers, tall grass, cane-break tangle, and herbaceous plants. Tall trees alone will not afford the protection necessary for the fly unless they overhang the water, or their foliage reaches so low as to mix with the undergrowth.

The fly is, however, not met with behind a wide strip of papyrus, though it may be found on its water edge. This is explained by Bagshawe on the grounds that papyrus grows best in shallow water, which means that the ground is swampy, a condition which prevents the fly from depositing its larvæ. From a resort such as this a fly can travel for feeding purposes, or be carried by attraction or artificial means. It appears probable from Bagshawe's experiments that a single flight will not reach 70 to 80 yards, but flies can be carried to almost any distance by the agency of boats and floating islands of papyrus. Human traffic also increases the dissemination of the fly, as it is apt to pursue human beings for considerable distances.

Female flies appear to travel farther in search of food than males, probably because they more urgently require it. Bagshawe suggests that this can be made use of in finding the breeding-grounds, where he says plenty of males as well as females are to be found, while females alone may be met with at some distance therefrom. The feeding range, therefore, varies considerably.

Flies bite mostly during the middle part of the day, and not so much at dawn or in the late afternoon.

According to Hodges, the chief conditions required for a breeding-ground are loose, dry, friable earth, situate not more than 20 yards away from the high-water mark of a stream, and protected from sun and rain by the shade of trees and undergrowth.

Such conditions are found on steep banks along lakes, rivers, watercourses, etc., and the larvæ are to be looked for at the bases of shrubs and trees, in the undergrowth, and in earth-filled hollows in tree-trunks and branches at no great distance from the ground.

Bagshawe found the larvæ principally at the roots of bananas with scrub and water in the immediate neighbourhood; at the roots of a shrub called *Allophyllus*, belonging to the Sapindaceæ, especially in the dry season; at the roots of large figs and of the wild date-palm (*Phœnix reclinata*): while he also found a few pupæ in dry earth sheltered by overhanging rocks on wooded banks.

The breeding season appears to be at the commencement of the rains, as Bagshawe generally found empty pupal cases in the dry season.

The pupæ apparently have their enemies which eat them. These are minute winged insects probably belonging to the Chalcididæ, though this is not definitely known.

Pathogenicity.—*Glossina palpalis* is the carrier of *Trypanosoma castellanii*, and *G. morsitans* of *T. rhodesiense*, both of which are the causes of sleeping sickness in Africa.

Classification.—Newstead in 1911 revised the genus *Glossina*, and published a classification based on the male genital armature. This is a very excellent

classification, but requires the addition of female characters to complete it. We have, therefore, kept Austen's revised classification in 1911, which slightly modified, is as follows:—

A. Hind tarsi entirely dark (female of *Glossina tachinoides*), basal half of first and extreme bases of succeeding joints pale. **Glossina palpalis group.**

I. Ground colour of abdomen ochraceous buff, with interrupted dark brown deep transverse bands and sharply defined pale hind borders to segments. A very conspicuous square or oblong pale area in the centre of the second segment. Small species: Body length 7 millimetres—*G. tachinoides* Westwood, 1850.

II. Abdomen not so marked.

1. Third joint of the antenna dusky brown to cinereous black

(*a*) Dorsum of abdomen dark sepia brown, median paler area on second segment, broad, more or less quadrate or irregular, hypopygium of male buff or ochraceous buff—*G. caliginea* Austen, 1911

(*b*) Dorsum of abdomen blackish brown, median paler area triangular, hypopygium of male grey *G. palpalis* Robineau-Desvoidy, 1830.

2. Third joint of antenna pale *G. pallicera* Bigot, 1891.

B. Hind tarsi not entirely dark (except in *G. austeni*).

I Upper surface of abdomen with pale ground colour, drab grey, buff, or ochraceous buff, marked with very conspicuous dark brown or clove brown transverse bands interrupted in the middle line **Glossina morsitans group.**

(*a*) Last two joints of front and middle tarsi with sharply defined dark brown or black tips

(1) Large species: Wide head, darker anteriorly, abdominal bands deep *G. longipalpis* Wiedemann, 1830

(2) Smaller species: Narrower head *G. morsitans* Westwood 1850

(*b*) Last two joints of fore and middle tarsi very narrowly darker, and sometimes the colour is absent in the former *G. austeni* Newstead 1912

(*c*) Last two joints of fore and middle tarsi pale Body length 8 to 10 millimetres—*G. pallidipes* Austen 1895

II Upper surface of abdomen not so banded.

(*a*) Wings dull sepia coloured, palpi (except in *G. tabaniformis*) long and slender **Glossina fusca group.**

1. Third joint of antenna fringed anteriorly and posteriorly with hairs conspicuous when magnified 15 diameters.

(A) Longest hairs in front of third joint equal in length from one quarter to one-third of width of third joint; palpi moderately long—*G. tabaniformis* Westwood, 1850.

(B) Longest hairs in front of third joint equal in length from one-half to one-third of width of third joint; palpi noticeably long and slender *G. nigrofusca* Newstead, 1910.

2. Third joint antennae fringed anteriorly with five short hairs, scarcely noticeable when magnified 15 diameters

(A) Pleura drab grey, hind coxæ buff or greyish buff—*G. fusca* Walker, 1849.

(B) Pleura dark grey, hind coxæ mouse grey—*G. fusci-pleuris* Austen, 1911.

(*b*) **Wings pale, palpi short—Glossina brevipalpis group.**

(1) Dorsum of thorax with four sharply defined dark brown oval or elongate spots, arranged in a parallelogram, two in front and two behind the transverse suture proboscis bulb, with brown or dark brown tip *G. longipennis* Corti, 1895.

(2) Dorsum of thorax without such spots, and proboscis bulb not brown or dark brown at the tip.

- (i.) Wings with upper thickened portion of anterior transverse vein dark and distinct—*G. brevipalpis* Newstead 1910.
- (ii.) Wings with anterior transverse vein *G. medicorum* Austen, 1911

Recently Grunberg has described a new species, *G. ziemanni* Grunberg, 1912 but its position at present is not quite certain

Hæmatobosca Bezzi, 1911.

Stomoxydinæ resembling *Hæmatobia*, but with no bristles on the first and third longitudinal veins, and with fourth longitudinal vein almost as strongly bent as in *Musca*; therefore first posterior cell only very narrowly opens Distribution Southern Europe and China.

Type. *Hæmatobosca atripalpis* Bezzi, 1895.

European Species. -*H. atripalpis* Bezzi 1895.
Asiatic Species. *H perturbans* Bezzi, 1907, found at Tang-San, China.

Hæmatobia Robineau Desvoidy, 1830.

Synonym. *Siphona* Meigen, 1824.

Stomoxydinæ resembling *Stomoxys*, but with spatulate maxillary palps nearly as long as the proboscis: arista feathered dorsally and ventrally, and third longitudinal vein bristly proximally. Body robust, head broad and squat Distribution Europe, India, etc.

Type. *Hæmatobia stimulans* Meigen, 1824.

European Species.—*H. stimulans* Meigen
Asiatic Species. -*H. sanguisugens* Austen, 1909; *H rufipes* Brunetti, 1910, in India.

Bdellolarynx Austen, 1909.

Flies like *Hæmatobia*, but without sexual colour dimorphism. Arista with long hairs above and with six fairly long hairs below. No bristles on first and third longitudinal veins.

B. sanguinolentus Austen, 1909, is a blood-sucker found in India and Ceylon.

MUSCINÆ.

Musca Linnaeus, 1761

Musca putrida is the cause of *Myiase do Seio* in San Paulo

Calliphora Robineau Desvoidy, 1830.

These are the blow-flies or bluebottles, of which *C. erythrocephala* Meigen is the common species. It and the following have been found in the human intestine: *C. azurea*, *C. vomitoria*. *C. limensis* is a common cause of nasal myiasis.

Chrysomyia Robineau-Desvoidy, 1830.

Chrysomyia macellaria Fabricius, 1794.

Synonyms.—*Musca macellaria* Fabricius, 1794; *Lucilia macellaria* Robineau-Desvoidy, 1830; *L. hominivorax* Coquerel, 1858; *Calliphora infesta* Philippi, 1861; *C. macellaria* Jorge, 1878; *C. anthropophaga* Conil, 1878; *Compsomyia rubrifrons* Macquart; *Somomyia montevidensis* Bigot.

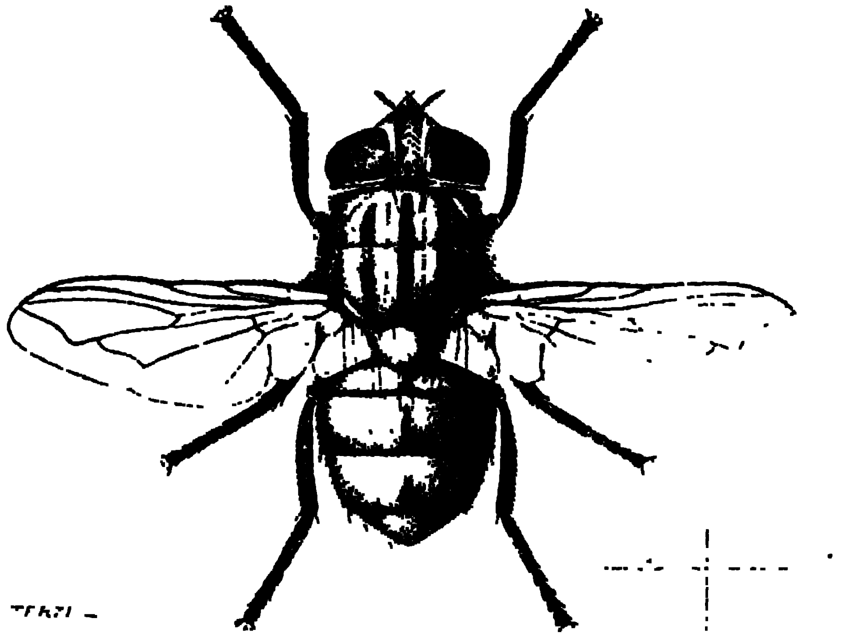

FIG. 437.—*Chrysomyia macellaria*: FEMALE. (× 4.)

In all this fly has twenty-six synonyms, largely due to Walker, Macquart and Robineau-Desvoidy, but these were all carefully consolidated by Arribálzaga.

Muscinæ with blue bodies, red front to the head, and three black lines on the thorax. The body, which is less than 10 millimetres in length, is covered with stiff black hairs.

Life-History.—The female deposits some three or four hundred eggs in a space of a few moments in some wound or decaying matter, but as the same fly may oviposit in different places at different times, the total number of eggs laid by one fly must number some hundreds, or perhaps even thousands. The eggs are white and cylindrical, 1 millimetre in length, and marked by a prominent unilateral ridge. They hatch in from one to nine hours, and produce a whitish footless larva, rather slender,

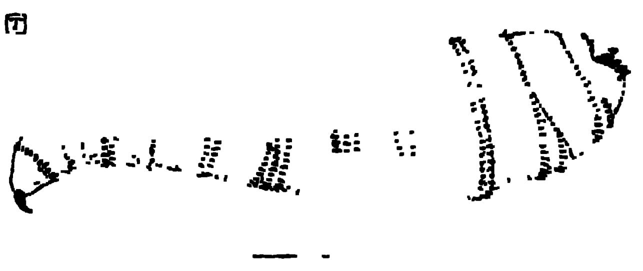

FIG. 438.—*Chrysomyia macellaria*: LARVA. (× 4.)
(After Blanchard.)

with twelve segments, armed with minute spines. It is most active, and burrows into the tissues of the affected animals or into the mass of putrid flesh or decaying matter. It grows rapidly and matures in from five to seven days, when it endeavours to escape from the wound or cavity on to the ground, when it wriggles off and buries itself in the ground at a suitable place, and becomes the brown cylindrical pupa with rounded ends. The pupa is about $\frac{3}{8}$ inch in length, and matures in some nine to fourteen days.

Habits.—It is a pest to man and animals.

Distribution.—America, from Canada to Patagonia, but most common in the tropical and subtropical belts. It is killed by cold winds. In the Southern United States it occurs from July to October. It is also found in the West Indies.

Pathogenicity.—It attacks cattle after castration, spaying, branching, dehorning, and when wounded by ticks or barbed wire. It will enter the uterus if there is placental retention, and will attack the navels and mouths of young calves. Horses and mules may be attacked in the sheaths and vaginæ, and in the navel in colts. Hogs are especially liable to be attacked, but sheep rarely, unless after being worried by dogs. Man is attacked when sleeping in the open air, and more rarely when driving. The symptoms produced in man will be detailed later under Nasal Myiasis in Chapter LXVII.

Treatment.—Injections of chloroform water are the best means of getting rid of the larvæ, but the frontal and other sinuses may have to be opened to remove them if in large numbers.

Prophylaxis.—The use of mosquito curtains and protection to the nose by handkerchiefs are important in man. Wounds of animals should be washed with weak carbolic lotion and dressed with pine tar or oakum and tar.

Chrysomyia viridula.

Causes nasal myiasis in Central America, and will attack ulcers.

Pycnosoma Brauer and Bergenstamm, 1893.

The larvæ of *Pycnosoma putorium* Wiedemann, 1830, are said to be parasitic in man and the domestic animals in Abyssinia, the Belgian Congo, and Lorenzo Marques.

This fly resembles *Chrysomyia,* but the three dark stripes on the dorsum of the thorax are wanting.

Pathogenicity.—It causes nasal myiasis in man, while other species—*e.g., P. megacephala* and *P. marginale,* etc.—are found in cattle.

Lucilia Robineau-Desvoidy, 1830.

Flies of this genus—*e.g., L. cæsar* Linnæus and *L. sericata*—deposit their eggs on ulcers. *L. nobilis* Meigen has been found in the auditory meatus. According to Peiper, *L. cæsar* Linnæus and *L. regina* Macy have been recognized as causes of intestinal myiasis.

Cordylobia Grünberg, 1903.

Cordylobia anthropophaga E. Blanchard.

Synonyms.—*Ochromyia anthropophaga* E. Blanchard, *Glossina grünbergi* Donitz.

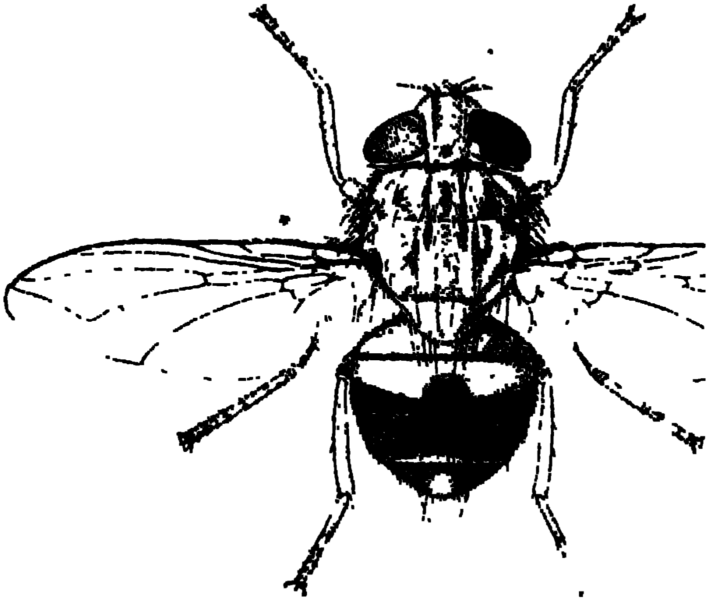

FIG. 439.—*Cordylobia anthropophaga* BLANCHARD: FEMALE. (× 4.)

The larva of this fly, which is called 'ver du Cayor,' because it was first noticed in Cayor, in Senegambia, burrows into the skin and causes a painful swelling. It extends from Senegal to Natal.

Life-History and Morphology.—It is not certain whether the fly lays its eggs upon the ground or upon the clothing of people and the skin of animals. Hence it is not known whether the larva creeps from the ground on to the human being or animal, or hatches in the clothing and simply enters the skin.

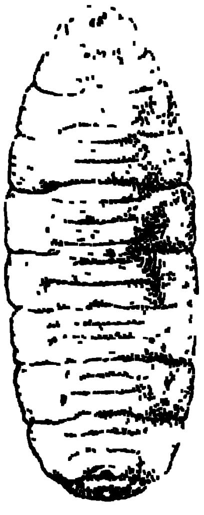

FIG. 440.—LARVA OF *Cordylobia anthropophaga*. (× 4.) (After Austen.)

The larva, which measures about 12 millimetres, is composed of twelve segments, of which the anterior or cephalic is bluntly pointed in front and truncated behind, and carries two black mouth hooklets on its ventral surface. External to these hooklets lie the antennal protuberances. On the third to the eleventh segments there are minute, rather characteristic, brownish, chitinous, recurved spines. The greatest breadth is at the level of the sixth to seventh segments, while the last segment has a flattened posterior surface which carries the posterior stigmata. It is parasitic in men, monkeys, and dogs. The pupa measures 10·3 by 4·6 millimetres, and looks like an ordinary muscid pupa.

The fly measures 9·5 millimetres, and has a yellowish-coloured head, body, and wing. The thorax is marked dorsally by longitudinal dark stripes, while the abdomen has also blackish markings, and the wings are of a brownish tinge. The female is distinguished from the male by the eyes being separated by a broad frontal stripe; in the black colour of the third and fourth abdominal (except the margin) segments: and in the blackish quadrangular median patch on the second abdominal segment. In the male the eyes join.

Cordylobia rodhaini Gedoelst, 1905.

Synonym.—Lund's larva.

Under this term a larva is described as occurring in the Congo Free State which possesses habits similar to those of *Cordylobia anthropophaga*.

The larva of this species also occurs at times under the skin of man in the Belgian Congo.

Auchmeromyia Schiner and Brauer Bergenstanum, 1819.

Auchmeromyia luteola Fabricius, 1805.

Synonym.—*Musca luteola* Fabricius, 1805, Ver de Case.

The larva of this fly is called the 'Congo floor maggot.' It was found by Dutton, Todd, and Christy, living in the floor of native huts to the depth of 3 inches. At night these larvae came out, and sucked the blood of persons sleeping on the ground, or on beds but little raised therefrom, but not on high beds.

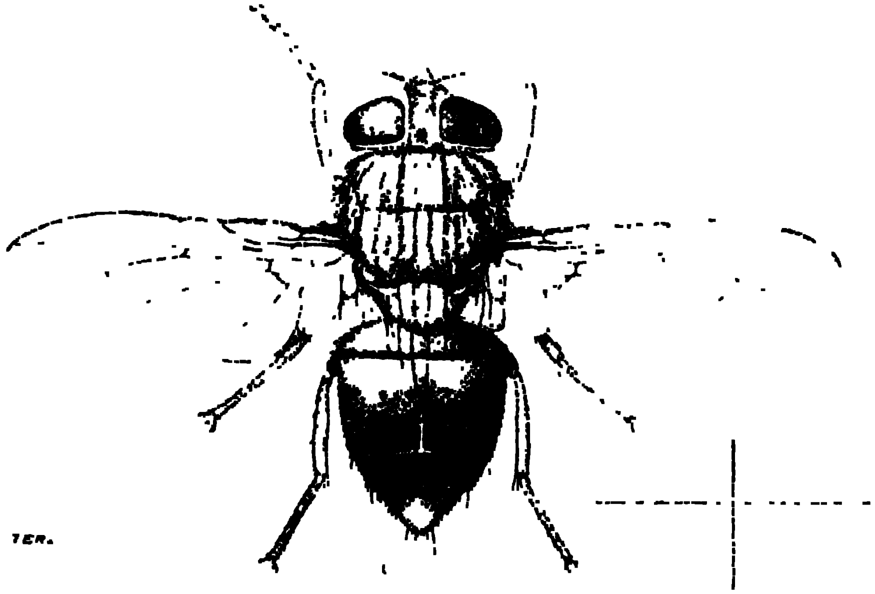

FIG. 441.—*Auchmeromyia luteola* FABRICIUS: FEMALE. (×3.)

The native names for the larvae are, 'Mabunzu,' 'Nchichi,' 'Ntunga,' 'Mvidi,' and 'Kiso.'

Morphology.—The fly is widely distributed in tropical and subtropical Africa. It is 10 to 12 millimetres in length, tawny in colour, with small black hairs giving it a smoky appearance. The head is large, as broad as the thorax. The eyes are separated by a considerable space. The proboscis is folded beneath the head into a deep groove. The palpi are club-shaped, with a long, yellow, flattened third joint, which carries an arista with black hairs on its upper and lower borders.

The dorsum of the thorax is marked by longitudinal black and brown stripes, and shows a well marked transverse suture. The squamæ are large, yellow in colour, and cover the halteres. The first abdominal segment has a narrow dark line posteriorly, the second a central median dark line, which joins with a posterior dark line. The third segment is dark brown, except for a narrow yellow anterior streak. The fourth segment is dark-coloured, with a posterior light brown band. The fifth segment is small, and contains the genital apparatus.

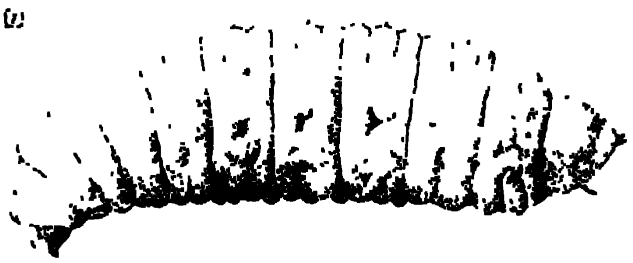

FIG. 412. *Auchmeromyia luteola*: LARVA (× 3.)

The legs are buff-coloured, with black hair and bristles. The fifth tarsal joint is jet black, and has a large cream-white pulvillus.

Life-History. The fly deposits its eggs on the ground of the hut, especially on spots on which urine has been voided. The larva is semitranslucent, of dirty white colour, acephalous and amphipneustic, and has eleven distinct segments. The first segment is divisible into two portions, of which the anterior carries the mouth parts. The broadest segments are the ninth and tenth. There are distinct dorsal and ventral surfaces, at the junction of which in each segment there are protuberances, with a spine and a pit. The ventral surface is flattened, and has three footpads transversely arranged at the posterior margin of each segment. The last segment is large, and carries the posterior spiracles and the anus.

The mouth, which is provided with teeth, leads into an œsophagus, which ends in a proventriculus, and has a dorsal diverticulum. The ventriculus is short. Malpighian tubules mark the commencement of the intestine. The hind gut is coiled. The salivary glands are well marked.

The larva becomes a dark brown or black pupa, 9 to 10·5 by 4 to 5 millimetres, with an anterior conical and a posterior rounded end, and marked by annular ridges. The pupal stage lasts two to three weeks.

Habits.—The fly does not bite man. The larva, as described above, attacks man and fills its dorsal œsophageal pouch with blood, and thus acquires a red colour.

Pathogenicity.—As far as is known it is non-pathogenic.

In 1911 Roubaud described a new genus, *Chœromyia* Roubaud 1911, of which the larvæ of two species, *C. boueti* Roubaud, 1911, and *C. chœrophaga* Roubaud, 1911, were blood-suckers attacking African wart-hogs and African ant-eaters.

Auchmeromyia prægrandis Austen, 1910.

A saffron-yellow fly. It occurs in South Africa.

Pollenia Robineau-Desvoidy, 1830.

The larvæ of *Pollenia rudis* Robineau-Desvoidy have been found in a case of gastric myiasis in man.

Bengalia depressa Walker.

By an error this fly was said to cause cutaneous myiasis in Natal, Rhodesia, British Central Africa, Uganda, and the Sudan, the true causal agent being *Cordylobia anthropophaga* Grünberg. The life-history of *B. depressa* is unknown.

FAMILY ANTHOMYIDÆ Latreille.

Diptera with arista naked or pectinate. Thorax with complete transverse suture. First posterior cell completely open. Abdominal bristles often absent.

This family includes a number of genera known to be troublesome to man—*Fannia* Robineau-Desvoidy, *Hylemyia* Macquart, *Hydrotæa* Robineau-Desvoidy—which may be recognized by the following characters: (*a*) Arista bare—*Fannia*; (*b*) arista plumose—*Hylemyia*; (*c*) arista pubescent—*Hydrotæa*.

Fannia Robineau-Desvoidy, 1830

Fannia canicularis Linnæus, 1761.

Synonyms.—*Homalomyia canicularis* Linnæus, *Anthomyia canicularis* Linnæus.

This species has frequently been reported as being passed in human fæces.

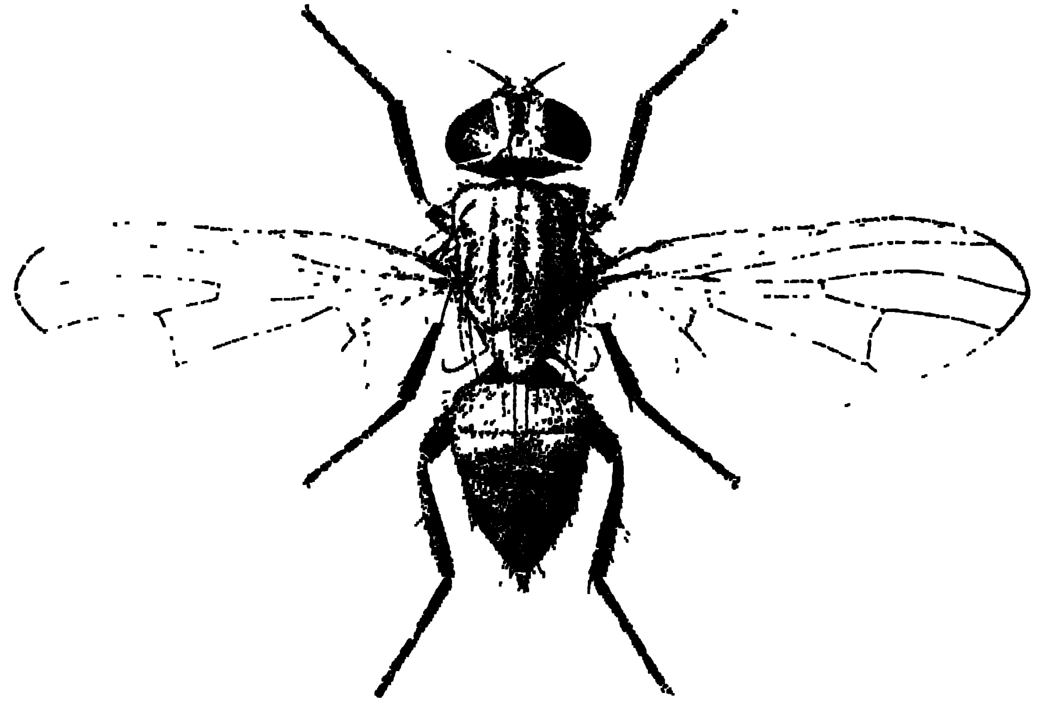

FIG. 443.—*Fannia canicularis* LINNÆUS: FEMALE. (×8.)

The fly is commonly found in houses in Europe and North America. The larvæ normally live in vegetables, by means of which they enter the human digestive tract. They are provided with branched processes on the segments.

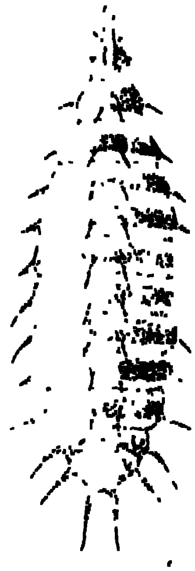

FIG. 444.—LARVA OF *Fannia canicularis*.

Pathogenicity.—Blankmeyer gives an account of a case of this infection which is said to have lasted some twelve years, being associated at first with abdominal pain, bloody diarrhœa, severe pains in the region of the liver. After the initial attack the pains continued, but instead of diarrhœa, constipation resulted, with severe headaches. The abdomen was distended.

The patient was treated with raw pumpkin seeds and then given a saline purge, and passed 1,000 to 1,500 *Fannia* larvæ. After this he still passed a few larvæ for some days, but eventually recovered. This is a curious case, in that the larvæ lived for years inside the man and because it is not clear how such an enormous infection was possible. Chevrel has collected and described seven authentic cases of myiasis of the urinary passages caused by the larva of this fly.

Fannia desjardensii Macquart

Synonyms. *Homalomyia desjardensii* Macquart; *Anthomyia desjardensii* Macquart.

Wellman describes cases of this myiasis in the alimentary canal of human beings in Angola who showed dysenteric symptoms, and which he successfully treated with castor-oil, then santonin, and then castor-oil again.

The disease is locally known as 'ovenvo,' a term which signifies maggots. The editors of the *Journal of Tropical Medicine* in 1907 asked for information

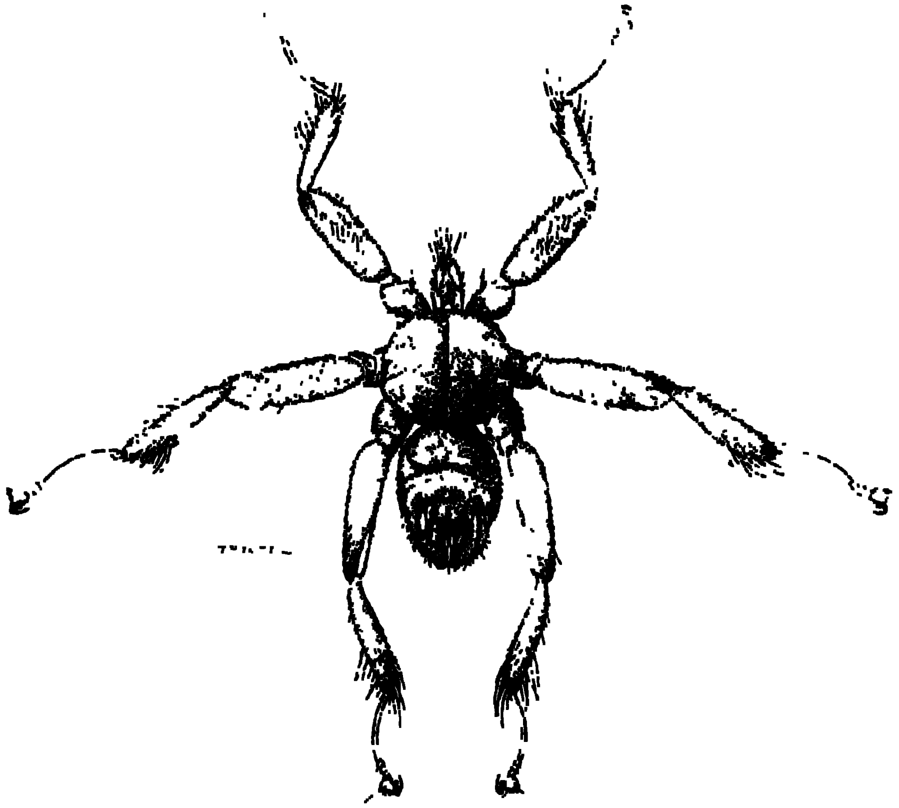

FIG. 445.—*Penicillidia dufouri* WESTWOOD FROM A BAT: FEMALE. (× 8.)

with regard to an African myiasis called 'muculo,' but as far as we know this disease has not been traced. Wellman says that the term is not used in Angola. In *F. desmidensii* the larvæ become pupæ in seven to nine days, and the pupæ insects in another thirteen to fifteen days.

Other Species.- Peiper also lists *F. scalaris*, *F. incisurata*, *F. manicata*, *F. saltatrix* as being causes of intestinal myiasis.

Hydrotæa Robineau Desvoidy, 1830.

Hydrotæa meteorica Linnaeus, which usually attacks animals' eyes and nostrils, is said to attack man also.

SUBORDER III. PUPIPARA.

FIG. 146. NYCTERIBIA SP. (?).

Synonym. *Eproboscidæ.*

The Pupipara are flies which appear to have become altered owing to their parasitic life. They possess a well defined proboscis, which is said by Austen to resemble that of the *Glossinæ* by being armed at its tip with teeth. Wings have been lost in several species, either entirely or after the imago has become parasitic though they may exist throughout life in other species. Their feet are provided with extra ungues to enable them to cling to the hairs, etc., of the host. They do not lay eggs but produce a larva, which soon becomes a pupa.

The suborder is divided into four families: (1) Hippoboscidæ, (2) Nycteribidæ, (3) Braulidæ, (4) Streblidæ.

The Nycteribidæ are parasitic on birds and bats. In this family comes *Penicillidia dufouri* Westwood, which is the carrier of *Ichromaticus vesperuginis* Dionisi, 1898. The Braulidæ are parasitic on bees, and the Streblidæ on bats, and therefore will not be considered further.

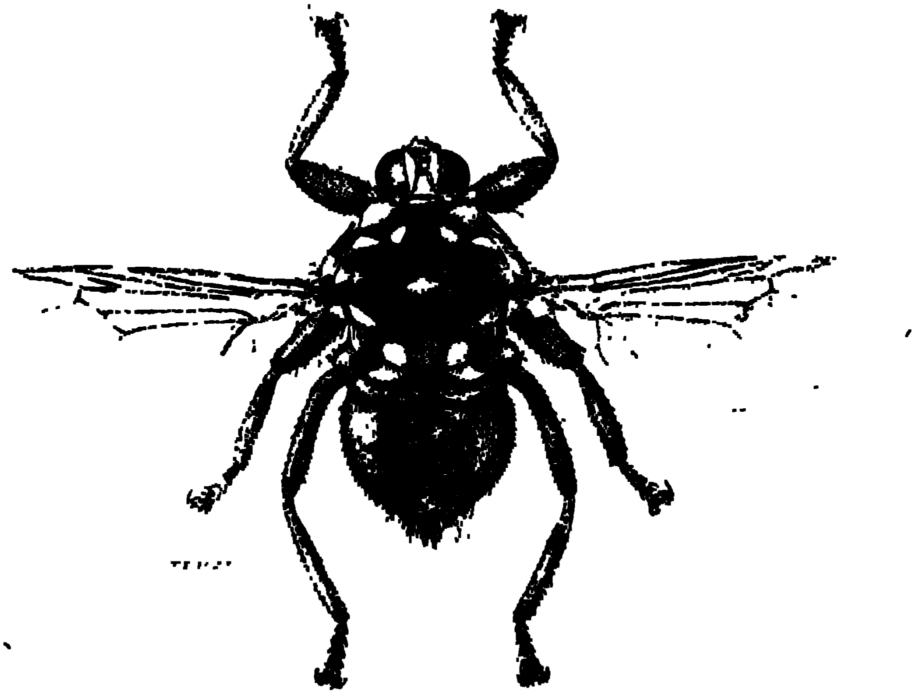

FIG. 147.—*Hippobosca rufipes* VON OLFERS: FEMALE (X 4.)

FAMILY HIPPOBOSCIDÆ.

Pupipara with horny flattened heads and bodies, and with one pointed antenna furnished with a terminal arista. The first joint of the tarsus is usually abbreviated in all, but certainly in the first two legs.

Wings may be well developed, or rudimentary, or entirely absent.

This family is composed of forms parasitic on mammals, and includes the following genera: *Hippobosca* Linnæus, 1761; *Allobosca* Speiser 1902; *Olfersia* Wiedemann, 1830; *Ortholfersia*, *Pseudolfersia* Coquillett, *Lipoptena* Nitzsch, 1818; *Melophagus* Latreille, 1802; *Ornithoctona* Speiser, 1902; *Lynchia* Weyenberg, 1881; and *Ornithomyia* Latreille, 1802.

Hippobosca is parasitic on cattle, horses, dogs, etc., all over the world; *Allobosca* is parasitic on lemurs in Madagascar, *Ortholfersia* on kangaroos in Australia; *Lipoptena* on deer all over the world; and *Melophagus* on sheep.

Hippobosca rufipes von Olfers is thought to be capable of transmitting *Trypanosoma theileri*.

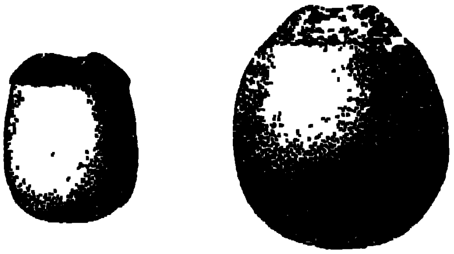

FIG. 448. LARVA AND PUPA OF *Hippobosca rufipes* VON OLFERS. (×4.)

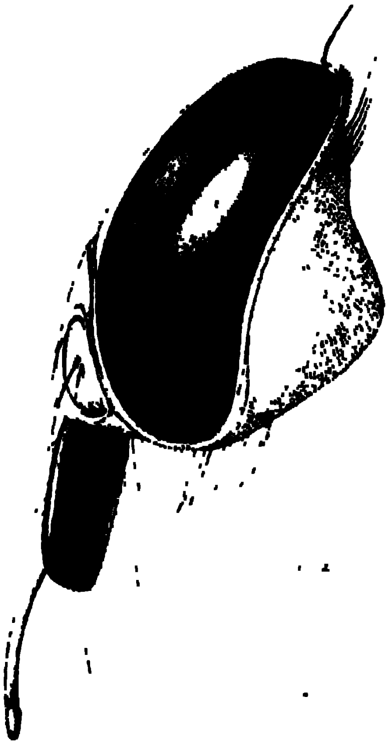

FIG. 449.—HEAD OF *Hippobosca rufipes*: FEMALE.

Hippobosca equina Linnæus is known on horses in the New Forest, England; *Hippobosca capensis* Leach on dogs in Africa, India, Persia, and South Europe; *H. camelina* Leach and *H. maculata* Leach are found in the Sudan and Egypt; and in addition to these *Melophagus ovinus* Linnæus is found all over the world.

CHAPTER XXXIV

SIPHONAPTERA AND COLEOPTERA

Siphonaptera—Sarcopsyllidæ—*Dermatophilus penetrans*—Pulicidæ—Pulicinæ—*Pulex irritans*—*Xenopsylla cheopis*—Coleoptera—Orthoptera—References.

SIPHONAPTERA Latreille, 1825.

Synonyms.—*Rophoteira* Schellenberg, 1798; *Aptera* Lamarck, 1801; *Aphaniptera* Kirby and Spence, 1826; *Pulicidæ* Stephens, 1829.

Definition.—Hexapoda with laterally compressed bodies and distinctly separated thoracic rings. Wings absent, except for two lateral plate-like appendages on the meso- and meta thorax.

The antennæ are three-jointed, and embedded in grooves. The third joint has nine more or less separated pseudo-joints.

Remarks.—Fleas have come into considerable prominence, owing to the work of the Indian Plague Commission and that of Dr. Verjbitski, of St. Petersburg, who have shown that they are to be looked upon as the main agents by which plague is spread from rat to rat, and from rat to man.

Fleas may also carry blood-parasites—as, for example, *Trypanosoma lewisi*—and, again, they may serve as intermediary hosts for the cysticercus of tapeworms, as in the case of *Dipylidium caninum*.

History.—The knowledge concerning fleas is of recent date. In 1758 Linnæus started with one genus and species, *Pulex irritans*; the second genus was that of the *Chigoe* in 1815, under the term *Rhynchoprion penetrans*; and the third genus was created by Curtis in 1832 under the heading *Ceratophyllus*. The first general systematic treatise was by Kolenati in 1863, the second by Taschenberg in 1880, and the third by Baker in 1904.

Recently much work has been done on these parasites by Rothschild and Jordan.

Morphology.—The head is small, and may or may not possess eyes, which, when present, are only simple pigment masses. Directly behind the head is the antennal groove, in which the antennæ, which are important organs to the flea, lie protected from harm. This groove is continued upwards to the mid-line of the vertex by an incrassation which divides the frons from the occiput. The groove may be open or closed by a process of the gena.

The antennæ are composed of three joints, of which the third, often called the club, may be unsegmented, segmented on the posterior border only, or completely segmented into nine more or less separate pseudo-segments.

The frons may carry a tubercle or notch, situate rather nearer the mouth than the centre of the head, while laterally the eyes, when present, are to be seen. The area of the head below the eyes and extending from the perioral ring to the antennal groove is the gena. A process of this area may be prolonged backwards, so as to meet the hind edge of the post-antennal part of the head, and so to close the antennal groove below in those species which possess a closed antennal groove.

The occipital area carries usually three rows of bristles, the first near the base of the antennae, the second in the middle, and the third near the hinder edge of the head, which are continued forwards on to the frons, and probably delineate the four segments of which the head is composed.

Anterior and ventral to the frons and gena lies the perioral ring, which carries the mouth appendages, which consist of a labrum (epipharynx), mandibles, maxillæ, and palps, hypopharynx, and labium with palps. There does not appear to be a separate clypeus.

The labrum (variously known as epipharynx, hypopharynx, and by other names) is a hollow prolongation of the dorsal wall of head and pharynx. In front it is closed, while behind it opens into the cœlom. Ventrally it shows a groove, converted into a canal when it is articulated with the mandibles laterally. The mandibles consist of basal segments attached to the sides of the mouth, and an anterior portion which projects freely forwards, and shows fine serrations anteriorly. The inner aspect of the mandibles pos groove, converted into a trilobed channel by articulation with the fellow of the opposite side and the hypopharynx.

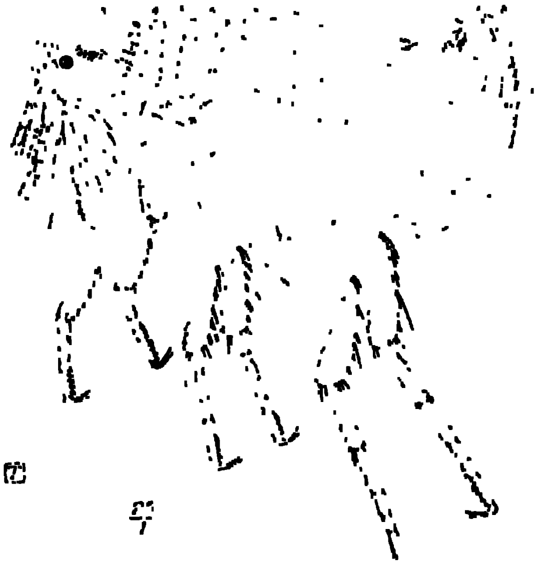

FIG. 450.—*Xenopsylla cheopis*: MALE. (After Jordan and Rothschild, *Journal of Parasitology*.)

1, Labrum, mandibles, and labial palps (at the junction of the last named with the head is seen the triangular maxilla); 2, maxillary palpi; 3, antenna; 4, pronotum; 5, mesonotum; 6, metanotum; 7-12, ordinary abdominal tergites; 13, seventh tergite with bristle (behind this is seen the small eighth tergite); 14, ninth tergite, with sensory plate; 15, tenth tergite; 16-24, sternites of abdominal segments; 25-27, metasternite, 8 mesosternite, 29, prosternite.

The maxillæ are triangular chitinous plates, each possessing a four-jointed maxillary palp. The labium (which, of course, represents the nd maxillæ with their palps) is gle posteriorly, where it is attached the perioral ring, while in front it divided into two one-to-thirteen jointed palps (labial palps), which form a sheath or um for th other mouth parts.

The hypopharynx consists of a basal portion, which is a chitinous plate concave ventrally, extending forwards in the head from the infra-œsophageal ganglion to the mandibulo-basal articulation and an anterior portion, which projects from the basal portion forwards, and contains the canal from the salivary pump.

This anterior portion of the hypopharynx articulates laterally with the mandibles, and its canal opening ventrally, forms the triradiate canal mentioned above, which is continuous with the salivary groove on the mandibles.

The thorax is composed of the usual three divisions, but there are no signs of scutellum or post-scutellum. There is generally one, but there may be two or three rows of bristles on each segment. The pronotum may have a comb. The metanotum may be dentate or serrate apically. Laterally the metathorax is typical, showing a sternite, episternite, and epimerite, while the mesothorax shows a sclerite, divided into two by an internal incrassation running from the coxa upwards. These two divisions represent the episternite and the epimerite. The episternite has the anterior and ventral portion separated off by an oblique incrassation to form a sternite. The posternite or sternite of the prothorax, is not divided. Generally these various sclerites show bristles.

With regard to the abdomen, the first to seventh segments are more or less normal, but the eighth to tenth are modified sexually. The tergites of the second to the seventh segments are normal, carrying bristles and combs in different species. The seventh tergite has a subapical bristle. The first segment has no sternal sclerite, hence the first visible sternite belongs to the second segment. The third to the sixth sternites carry a ventral row of bristles. The seventh has a considerable number of bristles. The sexually different segments must be considered according to sex. In the female the eighth tergite is very broad ventrally, but the sternite is reduced to an elongated plate lying between the ventral edges of the tergite

The ninth tergite carries the sensory plate, with usually fourteen (there may be more) setiferous grooves The ninth sternite is membranaceous laterally, and extends far ventrally where it is strongly chitinized, and lies

FIG. 151. ANATOMY OF A FLEA.

(From the *Journal of Hygiene*, 1906.)

1, Mouth; 2, pharynx, 3, salivary glands, 4, stomach, 5 Malpighian tubes, 6 intestine; 7 rectum

inside the seventh or eighth segment It forms the ventral wall of the vagina, which is joined just anterior to it by the duct of the receptaculum seminis.

The tenth tergite carries a short conical stylet, while the sternite which is triangular, carries a long bristle ventrally before the apex and shorter bristles at the apex.

The eighth tergite of the male is small, while its sternite is large, and from its cavity the copulatory organs project The accessory genital organs belong to the ninth segment the sides of whose tergite form the clasping organ laterally The internal ventral angle of the clasper is prolonged into a manubrium above which is a tubercle like projection The outer side of the clasper has three processes, which are different in *Pulex* and *Læmopsylla*. The ninth sternite has an internal vertical arm and a ventral horizontal arm The latter appears beyond the eighth sternite The penis can be seen between the ninth sternite and the claspers.

Internal Anatomy. - The mouth, which is situate below the base of the labrum, opens into the aspiratory pharynx, which communicates via a long œsophagus, with the stomach. Just before this organ the œsophagus is swollen into a bulb, which represents the proventriculus

At the junction of the stomach with the intestine are the openings of the four Malpighian tubes. The intestine is divided into small intestine, colon, and rectum, the last mentioned opening at the anus.

The salivary apparatus is, as usual, separate from the alimentary canal. It consists of two glands, on each side of the body, lying in the fat-body in front of the stomach. The duct from each gland joins, forming a common duct on each side, which runs forward to open into the salivary pump. This is a hollow, chitinous organ, supplied with powerful muscles, situated at the anterior end of the ventral surface of the hypopharynx.

The duct of this pump, running forwards through the hypopharynx, opens via the triradiate canal already mentioned as formed by the junction of the hypopharynx with the mandibles, into the groove of these organs.

The Act of Biting.—The flea apparently carefully selects the spot at which it is to bite, and then pierces a hole by means of the labrum. This hole is then enlarged by the mandibles, through whose grooves salivary secretion is pumped into the skin. This secretion irritates the vessels, causing a local rush of blood to the part, and this blood is drawn by the suction of the pharynx up a tube formed by articulation of the labium with the mandibles. This tube, of course, is embedded in the skin, which is pierced by its two component parts.

There are therefore two tubes in the mouth-parts of a flea—an efferent, carrying the salivary secretion, and an afferent, carrying the blood, which is taken to the stomach, and hæmolyzed and digested. It appears that the black residual mass is capable of further digestion by the rectal glands. Further bionomics will be given under *Xenopsylla cheopis*. In some people flea-bites may cause a local papular eruption—*e.g.*, ceratophyllus fasciatus.

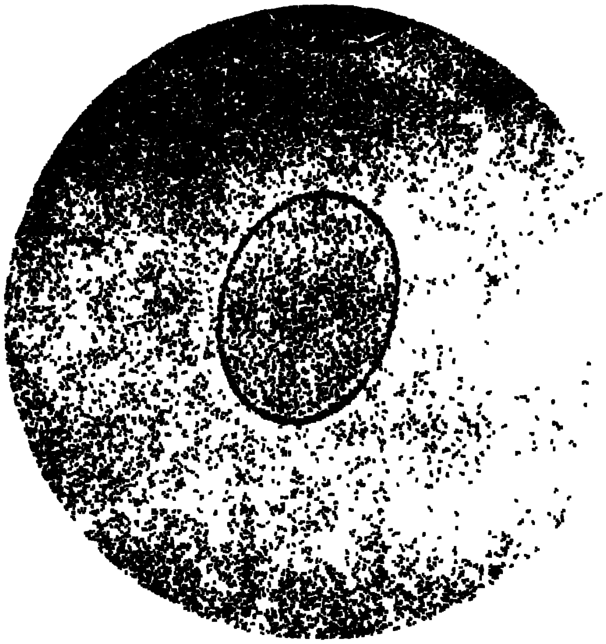

FIG. 452.—EGG OF THE DOG FLEA (× 50 DIAMETERS.)
(From a photograph by J. J. Bell.)

Life-History. The egg is oval, waxy white or opaque porcelain in appearance, smooth, and with a length of about 0·5 millimetre. It is generally deposited between the hairs of the host, and falls off on to the ground. In two to four days the larva is hatched. This larva is an elongated worm-like little creature with fourteen segments. The head is well developed, and has strong mandibles suitable for biting. It lives on dead organic matter, and moults three times as a rule—*i.e.*, three to four days, and again six days, and again seven to fourteen days after hatching. It then spins a cocoon, inside which the pupa becomes the imago in about five days, the whole time required for development being fourteen to thirty-three days.

Dispersal.—Fleas are dispersed mainly by their host travelling about. Such a host as a rat may, of course, be carried by merchandise, and, again, merchandise itself can spread fleas.

Capture of Fleas.—If it is desired to capture fleas, allow a suitable animal to remain in the place, when the fleas will gather on it. Then chloroform the animal, and comb the stupefied or dead fleas on to white paper.

Remedies.—The remedies for fleas are, first and best, a clean house—*i.e.*, plenty of soap and water applied to the floors, etc. Otherwise naphthalene, pyrethrum powders, tobacco leaves and infusions, and benzene may be used.

A flea cannot jump more than 4 inches—an important fact to be noted.

Flea larvæ are delicate little things, and cannot stand disturbance; hence fleas will not be found in houses kept well swept and dusted, but will abound in infected empty houses.

Classification.—The Siphonaptera are classified by Rothschild into three families: (1) Sarcopsyllidæ, (2) Pulicidæ, (3) Ceratopsyllidæ. Only the first two are of importance, the last named being found on bats.

FAMILY SARCOPSYLLIDÆ Taschenberg, 1880.

Synonym.—*Rhynchoprionidæ et Hectopsyllidæ* Baker, 1905.

Siphonaptera without ctenidia. Labial palps rather long, but very weak and fragile; pale, slightly chitinized, formed of one or two segments. Small maxillæ little prominent. Piercing apparatus very developed; mandibles large and strong. Genal extremity always prolonged below and in front into a process, placed behind the insertion of the mandibles. Nota of thoracic segments shorter than that of the first abdominal.

Genera.—*Echidnophaga* Olliff, 1886; *Hectopsylla* Frauenfeld, 1860; *Dermatophilus* Guérin, 1838 or 1839, which, according to Jordan and Rothschild, may be recognized in the following manner:—

I. Hind coxa with patch of spines on inner side—*Echidnophaga*.
II. Hind coxa without such a patch of spines:—
    (*a*) Hind femur with large basal tooth-like projection—*Hectopsylla*.
    (*b*) Hind femur simple—*Dermatophilus*.

We need only consider *Dermatophilus*.

Dermatophilus Guérin, 1838

Synonyms.—*Rhynchoprion* Oken, 1815, *nec* Hermann, 1804; *Sarcopsylla* Westwood, 1836.

This genus contains the species *Dermatophilus penetrans* Guérin, distinguished by having a distinct eye, and *D. cæcata* Enderlein, 1901, with a rudimentary eye. The latter species was found behind the ear of *Epimys rattus* in Brazil.

Dermatophilus penetrans Guérin, 1838.

Synonyms. -*Pulex minimus cutem penetrans* Catesby, 1743; *Pulex minutissimus nigricans* Barrère, 1743; *Acarus fuscus sub cutem nidulans proboscide acutiore* P. Brown 1756; *Pulex penetrans* Linnaeus, 1767; *Rhynchoprion penetrans* Oken, 1815.

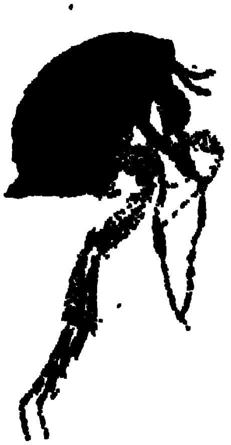

FIG. 453. *Dermatophilus penetrans*: MALE. (MICROPHOTOGRAPH.)

This is the insect variously known as the *Chigoe*, or jigger, and believed to have been discovered by Oviedo in 1551. The home of this little insect appears to be South America, especially Brazil, from which it was conveyed to West Africa about the middle of last century, arriving on the West Coast at Loanda from Rio Janeiro by a ship, the *Thomas Mitchell*, in 1872, whose crew was suffering from jiggers. It was probably noted on the Gold Coast for the first time in the early seventies. It appears to have spread across Africa by Stanley's Expedition and by trade routes, arriving in East Africa in 1895, and from East Africa it spread to India in 1899 by the 4th Bombay Infantry, but luckily the infection did not spread beyond Bombay. In 1900 it reached Madagascar. It affects not merely man, but domestic and wild animals. Perhaps the most noted feature is the way in which it attacks pigs. On the Gold Coast it appeared to be largely kept in existence by these animals. It is very easily captured in the free state by taking a little pig with a pale abdomen, and placing it on its back on the ground on which infected pigs are living. After watching a few moments, a black speck will appear

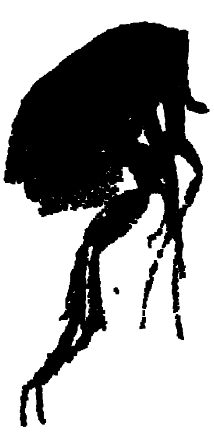

FIG. 454. *Dermatophilus penetrans*: FEMALE. (MICROPHOTOGRAPH.)

on the pig's abdomen, and quickly another and another. These black specks are jiggers, which can easily be transferred to a test-tube. On examination, they will be found to be males and females in about equal numbers. It appears likely that a number of different species, if not genera, are included under the term *D. penetrans*, and there is without doubt room for investigation into jiggers taken from wild and domestic animals and man.

If the reader will look at the list of synonyms, it will be clear that, by the law of priority, the name of this little insect should be *Rhynchoprion penetrans*, and not *D. penetrans*, as the name *Rhynchoprion* Oken is dated 1815; but Rothschild has recently pointed out that *Rhynchoprion* was applied in 1804 by Hermann to a tick, and also by Oken to other ticks in 1815.

Geographical Distribution.—It occurs in Mexico, West Indies, Central and South America, through the whole of tropical Africa, and as far south as Mashona—*i.e.*, 30° N. to 30° S. In Asia it does not appear to flourish; it has only infected Bombay, and will probably not become naturalized, as the monsoon conditions do not appear good for it, for it flourishes in a warm, dry, sandy soil.

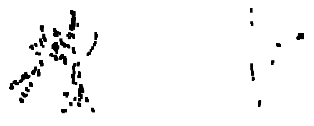

FIG. 455. *Dermatophilus penetrans*. PREGNANT FEMALE.

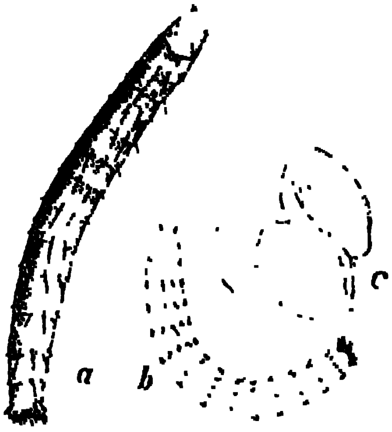

FIG. 456. *Dermatophilus penetrans*. (After Newstead, *Annals of Tropical Medicine and Parasitology*.)

a, Larva; *b*, younger larva; *c*, empty cuticles of eggs.

The female only becomes endoparasitic, and when it first arrives in a place, and is unknown, may cripple people, and cause loss of one or more toes.

Morphology.—The general account already given of the morphology of fleas and the special characters indicate the morphology sufficiently for the purposes of this book.

Life-History.—The males and females live in dry, sandy soil as reddish-brown little insects about 1 millimetre in length, and are very active. They live by sucking the blood of warm-blooded animals. When impregnated, the female burrows into the skin of a warm-blooded animal, whether bird or mammal. The abdomen now swells enormously into the size and appearance of a small pea. If one of these small peas is examined, it will be seen to show the head and thorax anteriorly, and the two last abdominal segments posteriorly. The head is in the bottom of the burrow in the skin, and the posterior abdominal segments block the opening.

The eggs are expelled through the opening in the skin, after which the female jigger is expelled by ulceration. The egg develops into a larva with thirteen segments. This larva spins a cocoon, inside which is the pupa, which gives rise to the imago in about eight to ten days.

Pathogenicity. -This will be described later (Chapter XCVI.), but it may be mentioned that it includes irritation, pus formation, ulceration, and formation of a sore, which may become infected with bacteria, and cause loss of a toe or a leg, or even tetanus may develop.

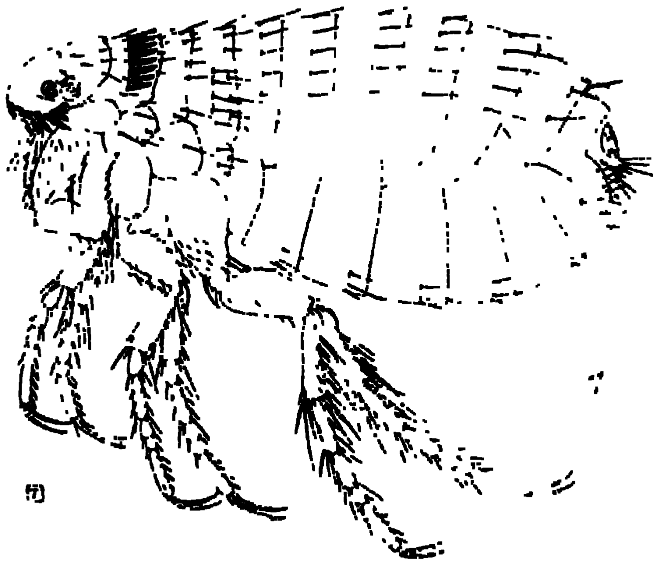

FIG. 457. *Ctenocephalus felis* BOUCHÉ.
This drawing shows the combs on the head and prothorax.

FAMILY PULICIDÆ
Stephens, 1829.

Siphonaptera with body compressed or elongated, always larger than in the preceding family. Head, in comparison to the rest of the body, small; top round; venter protected with hairs; often no eyes. The antennal groove is at times covered by a chitinous plate. The end segment of the antenna is either segmented or unsegmented. Thorax wide; pronotum often with ctenidia. Abdomen never so swollen that the original form is lost. Female never endoparasitic.

There are three subfamilies: *Pulicinæ* Tiraboschi, *Typlopsyllinæ* Tiraboschi, *Hystrichopsyllinæ* Tiraboschi.

SUBFAMILY PULICINÆ.

Pulicidæ with eyes.

The more important genera of the Pulicinæ may be arranged as follows (modified after Jordan and Rothschild):-

A. Ctenidia on prothorax and head -*Ctenocephalus*.
B. Ctenidia on prothorax and only two teeth on cheek at genal angle—*Chiastopsylla*.
C. Ctenidia on prothorax only.
  I. Pygidium freely projecting behind—*Pygiopsylla*.
  II. Pygidium not freely projecting behind
    (1) Club of antenna completely segmented—*Ceratophyllus*.
    (2) Club of antenna incompletely segmented—*Hoplopsyllus*.

D. Ctenidia absent on prothorax and head.

- I. Terminal segment of antennæ short, only distinctly segmented posteriorly. Hind coxa with a comb, fifth tarsal segment with four lateral and one subapical bristle.
  - (1) Forms with small mesial tubercle—*Moeopsylla*.
  - (2) Forms without small mesial tubercle:
    - (A) Mesosternite with internal rod-like incrassation from insertion of the coxa upward.
      - (*a*) Anterior angle of genal edge prolonged backwards into a triangular lobe; pronotum stronger than metanotum—*Pariodontis*.
      - (*b*) Anterior angle of genal edge not produced into triangular lobe—*Xenopsylla*.
    - (B) Mesosternite without internal rod-like incrassation from insertion of the coxa upward—*Pulex*.
- II. Terminal segment of antennæ segmented all round; hind coxa without a comb, fifth tarsal segment with four lateral bristles and one subapical hair.
  - (1) Terminal segment of antennæ symmetrical, genal process with a number of bristles—*Parapsyllus*.
  - (2) Terminal segment of antennæ asymmetrical, proximal segments sloping backwards. Genal process with only one to two bristles—*Rhopalopsylla*.
- III. Terminal segment of antennæ segmented all round, symmetrical. Hind coxa without comb. Fifth tarsal segment with five lateral bristles at least and subapical hair.
  - (1) Antennal groove open behind.
    - (*a*) Abdominal tergites with one row of bristles, except first, which bears two. First hind tarsal segment shorter than second—*Coptopsylla*.
    - (*b*) Abdominal sternites with very numerous short bristles. First mid tarsal segment longer than second—*Goniopsyllus*.
  - (2) Antennal groove closed behind.
    Abdominal tergites with one row of bristles—*Lycopsylla*.

SUBFAMILY TYPHLOPSYLLINÆ.

Pulicidæ with eyes absent or very rudimentary. Head rounded in front. Body thin.

Genera.—*Ctenopsylla* Kolenati; *Ctenophthalmus* Kolenati, 1857; *Typhlopsylla* Wagner; *Neopsylla* Wagner; *Typhloceras* Wagner. Ctenophthalmus can be recognized by having movable ctenidia in front of the ocelli, and the rest can be differentiated as follows:—

- I. Third tarsal with five lateral bristles on each side—*Typhloceras*.
- II. Third tarsal with four lateral and two accessory bristles—*Ctenopsylla*.
- III. Third tarsal with four lateral and no accessory bristles—*Neopsylla*.
- IV. Third tarsal with three lateral and two accessory bristles—*Typhlopsylla*.

SUBFAMILY HYSTRICHOPSYLLINÆ.

Abdominal tergites with one or more ctenidia; posterior tibial spines in numerous short, close-set, transverse rows on posterior border, with about four spines in each row; female with four antepygidial bristles on each side.

Genera. *Hystrichopsylla* Taschenberg, *Macropsylla*.

THE FLEAS OF RATS AND MICE.

The following table gives the fleas observed on rats, mice, and field-mice, by Tiraboschi and Rothschild.

Pulicidæ	Pulicinæ	Pulex	P. irritans L.
		Xenopsylla	X. cheopis Roth. X. brasiliensis Baker.
		Hoplopsyllus	H. anomalus Baker.
		Ctenocephalus	Ct. felis Bouché. Ct. canis Dugès.
		Ceratophyllus	Cer. fasciatus Bosc. Cer. londiniensis Roth. Cer. anisus Roth. Cer. niger Fox. Cer. penicilliger Grube. Cer. walkeri Roth. Cer. pinnatus Wag. Cer. gallinæ Sch. Cer. abantis Roth. Cer. lucifer Roth. Cer. pollionis Roth. Cer. agilis Roth. Cer. californicus Baker.
		Odontopsyllus	Od. charlottensis Baker. Od. telegoni Roth.
		Pygiopsylla	P. colossus Roth. P. hilli Roth. P. rainbowi Roth.
	Typhlopsyllinæ	Ctenopsylla	Ct. musculi Dugès. Ct. spectabilis Roth. Ct. taschenbergi Wag. Ct. aganippes Roth. Ct. ellobius Roth. Ct. pectiniceps Wag. Ct. selenis Roth.
		Stephanocircus	St. thomasi Roth. St. dasyuri Skuse. St. simpsoni Roth.
		Ctenophthalmus	Ct. agyrtes Heller. Ct. assimilis Tasch.
		Typhlopsylla	Typhl. pseudogyrtes Baker. Typhl. prosuma Wag.
		Chiastopsylla	Ch. rossii Waterst.
		Neopsylla	N. bidentatiformis Wag. N. pentacanthus Roth. N. isacanthus Roth.
		Typhloceras	Typhl. poppei Wag.
	Hystrichopsyllinæ	Hystrichopsylla	Hystr. tripectinata Tirab. Hystr. talpæ Curtis. Hystr. narbeli Galli-V.
		Macropsylla	Macr. hercules Roth.
	Sarcopsyllinæ	Dermatophilus	D. penetrans L. D. cæcata Enderlein.
		Echidnophaga	Ech. murina Tirab. Ech. gallinacea Westw. Ech. myrmecobis Roth. Ech. liopus Roth.

Epimys norvegicus Erxleben, 1777.

Pulex irritans Linnæus, *Xenopsylla cheopis* Rothschild, *Ctenocephalus felis* Bouché, *C. canis* Curtis, *Ceratophyllus fasciatus* Bosc, *C. londiniensis* Rothschild, *C. penicilliger* Grube, *Ctenocephalus musculi* Dugès, *Neopsylla bidentaliformis* Wagner.

Epimys norvegicus is the true host of *Ceratophyllus fasciatus*.

Mus musculus Linnæus, 1758.

Ceratophyllus fasciatus Bosc, *C. londiniensis* Rothschild, *C. walkeri* Rothschild, *Odontopsyllus charlottensis* Baker (?), *Ctenocephalus serraticeps* Taschenberg, *C. musculi* Dugès, *Typhlopsylla assimilis* Taschenberg, *C. agyrtes* Heller, *Hystrichopsylla tripectinata* Tiraboschi

Epimys rattus Linnæus, 1758.

Pulex irritans Linnæus, *Xenopsylla cheopis* Rothschild, *Ctenocephalus felis* Bouché, *C. canis* Curtis, *Ceratophyllus fasciatus* Bosc, *C. londiniensis* Rothschild, *Ctenopsylla musculi* Dugès *Dermatophilus caecata* Enderlein, *Echidnophaga rhynchopsylla* Tiraboschi, *E. gallinacea* Westwood.

Of all these fleas, the most important with regard to plague are:

A. Spreading the disease from rat to rat—*Xenopsylla cheopis* Rothschild and its allies; *Ceratophyllus fasciatus* Bosc and its allies; *Ctenopsylla musculi* Dugès; *Ctenocephalus felis* Bouché; *C. canis* Curtis.

B. Spreading the disease from rat to man *Pulex irritans* Linnæus, *Xenopsylla cheopis* Rothschild, *Ctenocephalus felis* Bouché, *C. canis* Curtis *Ceratophyllus fasciatus* Bosc.

Of all these, the most important is *Xenopsylla cheopis* Rothschild and it is believed that its true host is *Epimys rattus*.

Citellus beecheyi Richardson.

This is the ground squirrel of California, which has been proved to play an important part in the plague infection of that country, and its fleas have been recently studied, and it has been found that *Hoplopsyllus anomalus* Baker is capable of carrying the bacillus, and according to McCoy *Ceratophyllus acutus* Baker can also convey the disease from squirrel to squirrel.

Arctomys bobæ Schreb.

This is the tarbagan, and its common flea is *Ceratophyllus silantieri* Wagner, 1898.

Pulex Linnæus, 1758.

Pulicinæ with head without notch on the frons; antennal groove closed behind by a genal process. Strong incrassation separating occiput and frons. Eye large, a little pointed below, with two bristles beneath it, and one on the oral edge. Anterior angle of genal process projecting somewhat downwards, and usually bearing a small tooth (remains of a comb). Anal coxa is pear-shaped, carrying a number of hairs on the inner posterior portion, as well as in front, and carrying a row or patch of short spines near apex. Greatly reduced thorax, the tergites being short, each with a row of bristles, but without subapical spines on the mesonotum. Mesosternite characteristic, very narrow, with ventral edge close before apex, stigmata not being entirely covered. No internal rod-like or cariniform incrassation from the insertion of the coxa to the dorsal edge.

Male with eighth tergite with small manubrium; clasper with very large flap on inside of which are two processes, forming a kind of claw. Manubrium of clasper large, curved. Ninth sternite boomerang-shaped, with its upper end pointed. Internal wire-like spring of ninth sternite and penis making several coils.

Female No hairs above stigma of eighth stergite. Stylet with long apical bristle and short bristle near apex. Anal sternite truncate, bristles confined to the apical edge.

Species *P. irritans* Linnæus.

Pulex irritans Linnaeus, 1758.

Synonyms *Pulex vulgaris* Raius, 1710; *P.* [illegible] Linnaeus, 1746; *P. hominis* Dugès, 1832; *P. simulans* Baker, 1895; *P. dugesi* Baker, 1904.

This, in a much restricted sense, is the *P. irritans* of Linnaeus, which included all fleas, but now the term is restricted to the parasite of man. It is essentially an Old World flea, those of America being but distantly connected, but has become now

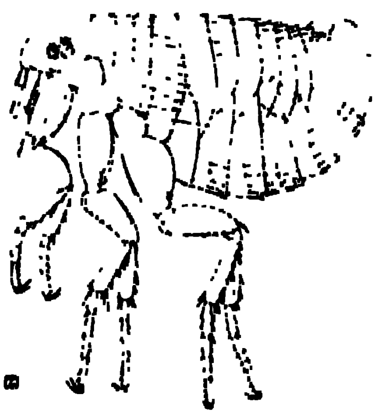

FIG. 458.—*Pulex irritans*: MALE.

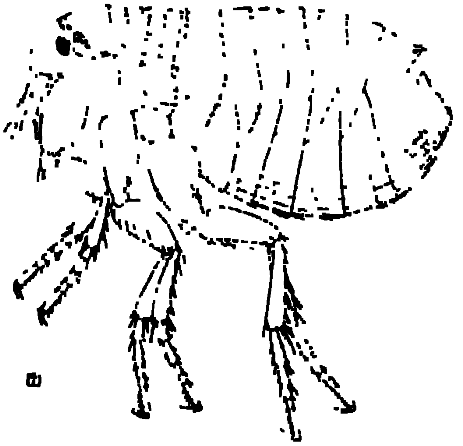

FIG. 459.—*Pulex irritans*: FEMALE.

cosmopolitan through trade. It appears to have been introduced into the eastern tropics by European trade. It is absent from the Sahara and the Haussa countries south of it, but it abounds all through Africa where there are European settlements.

The question whether there are different varieties on the different races of mankind is not settled. Baker described a *Pulex dugesi* or *P. irritans dugesi* from West Mexico on *Citellus macrourus* and man, but is the only person who indicates this.

P. irritans is also found on animals, particularly the badger (*Meles taxus*) in England: on dogs, cats, rats, and other animals in various parts of the world.

Xenopsylla Glinkiewicz, 1907.

Synonym.—*Laemopsylla* Jordan and Rothschild, 1908.

Pulicinæ with third segment of antennæ distinctly segmented only on posterior side. Eye round; one bristle below, one in front of eye, third at oral edge. Frons without tubercle, four-segmented labial palpus; closed antennal groove. Pleura of the mesosternite divided by a suture into an episternite and an epimerite, with the dorsal apical bristle of the seventh abdominal tergite remote from the edge of the segment, with short spines on the inner surface of the coxa of the third leg, with a rod-like incrassation on the inside of the coxa of the second leg; fifth tarsal segment with four lateral bristles besides the subapical hair.

Male with clasper provided with two or three small processes, manubrium narrow: upper internal portion of the ninth sternite not very sharply defined.

Female with the stylet bearing, besides the long apical bristle, a short bristle situated in a notch before apex.

Type.—*Xenopsylla cheopis* Rothschild. This genus is found in Africa and Central Asia in particular.

At the time of writing there are some twenty four species known

Xenopsylla cheopis Rothschild, 1903.

Synonyms. *Laemopsylla cheopis* Rothschild, 1903; *Pulex cheopis* Rothschild 1903; *P. brasiliensis* Baker, 1904; *P. murinus* Tiraboschi, 1904; *P. philippinensis* Herzog, 1904.

This is the rat-flea in all parts of the tropics, and is believed to be the principal transmitter of bubonic plague from the rat to man. Its home is believed to be the Nile Valley, where it lives on various hosts, but it has spread from there by the agency of the rats.

It is often referred to in literature by the name *P. pallidus* Taschenberg, which is really a different species.

Jordan and Rothschild report it on man or animals from the Egyptian Sudan, Pretoria, Beira in East Africa, Entebbe, Uganda, Benguella, Angola, Réunion, Marseilles, Plymouth, Aden, Bombay, Agra, Arabia, Japan, West Australia, New South Wales, Colombia, Paraguay.

They have found it on man, *Epimys norvegicus, E. rattus, Mus chrysophilus*, and several other animals.

Morphology.—Episternum of metathorax separated from sternum. The latter carries a bristle as long as that on the former. Hind femur angulate ventrally at the widest part. Fifth segment of fore- and mid tarsi, with three spine-like bristles ventrally at apex: lateral ones very stout in male. Clasper with two distinct free processes; manubrium long. Penis without a brush near apex.

Life-History.—The eggs are round, waxy-white or pearly in colour, and number one to five at each oviposition. They hatch in Bombay in two days, and produce the little larvæ, which at once hide themselves away from the light. In about a week's time these larvae, which at first are very active, become sluggish, and, ceasing to eat, spin cocoons composed of fine white silk-like fibres. The cocoon becomes covered with rubbish, and is hard to see. In about seven to fourteen days the imago escapes from the cocoon. The total development, therefore, requires about twenty-one to twenty-two days.

Bionomics. The young flea is capable of living without a feed of blood for some seven to fourteen days, but if not fed then it dies. The length of life of a flea is difficult to ascertain, but *Xenopsylla cheopis* will live forty-one days on a rat and twenty-seven days on a man. Therefore, the whole life of a rat-flea from birth to death is about sixty-three days. A rat flea is more readily attracted by a rat than by a man. It breeds at all temperatures, but has one optimum temperature above and below which it does not thrive so well. Dampness is injurious to the flea, killing the larva and hindering development.

X. cheopis is the commonest rat-flea, being probably the flea of *Epimys norvegicus* in India, while in Western Europe *Ceratophyllus fasciatus* is the flea of the same rodent. It is found on *E. norvegicus*, *E. rattus*, and *Nesokia bengalensis*, also on musk-rats, guinea-pigs, cats, rabbits, antelopes, kangaroos, and men.

The infection with plague bacilli does not appear to affect the flea's health, for it has an immunity dependent, apparently, on phagocytosis.

Hoplopsyllus Baker.

Closely related to *Pulex*, but distinguished at once by the ctenidia on the prothorax. *Hoplopsyllus anomalus* Baker is the plague carrier of the Californian ground squirrel

FAMILY CERATOPSYLLIDÆ Baker, 1905.

Siphonaptera with ctenidia present on the metathorax and abdomen; eyes rudimentary or absent.

Genus.—*Ceratopsylla* Kolenati

The species of this genus are found on bats

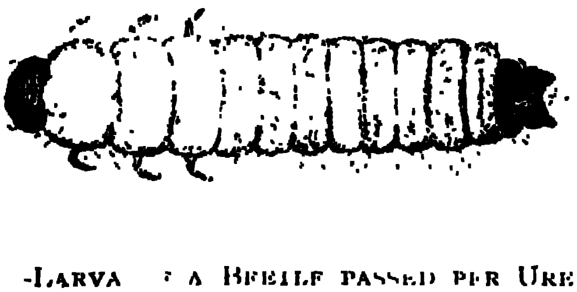

FIG. 460.—LARVA OF A BEETLE PASSED PER URETHRAM.
(After King.)

COLEOPTERA.

Hexapoda with biting mouth-parts. Anterior wings altered to form cases for the thin posterior wings.

Remarks.—The larvæ of beetles have rarely been recorded as parasites of the alimentary canal, or found in abscesses in man in the temperate and tropical regions. *Silvanus surinamensis* Linnæus bites people at night.

ORTHOPTERA.

The bite of *Enyaliopsis durandi* Lucet causes a nasty eruption (according to Wiggins, 1910, in man in Uganda), with high fever and general illness, and finally sloughing at the site of the bite.

E. petersi Schaum, the nantundua of Nyassaland, according to Stannius, can cause ulceration by the action of a yellow fluid which it emits.

The *Phasmidæ*, or stick insects, are said to eject a fluid which may cause blindness if it gets on to the conjunctiva.

CHAPTER XXXV

THE ANIMAL CARRIERS OF DISEASES

Preliminary—Historical—Protozoal diseases—Helminthiasis—Myiasis—Bacterial diseases—Diseases of unknown causation—Chance transmission—Imperfect carriage of parasites—Terms—References.

PRELIMINARY.

THE present chapter is an attempt to put in concrete form the rôle of the 'animal carrier' of disease.

Animals can produce traumatisms by their bites, and can cause disease by injecting chemical substances manufactured in their bodies—e.g., American and Australian tick paralysis—but these questions do not now concern us. The problems which we are about to consider are those associated with the spread of diseases known or suspected to be parasitic. Such diseases are divisible into those caused by animal and those caused by vegetal parasites. The latter are the simpler, as their carriage does not involve any great morphological changes in the parasite, such as often accompanies the carriage of an animal parasite, which, as it is the more complex, we will consider first.

A given animal parasite apparently has some form of *sexual generation* in some stage of its life-history, and it is probably merely our lack of knowledge which prevents us from acknowledging this as a proven fact.

The host in which the sexual generation takes place is called the *definitive host*, and is probably the original host, in which, as a rule, the parasite does not produce severe forms of disease and may produce no ill effects at all. This shows that it and its host have become so adjusted that it does not overproduce itself in the host, which on its part does not poison or otherwise attack the parasite.

It is certainly not the object of the parasite to kill its definitive host, but to leave it by some route which causes no great disturbance of its tissues or functions. Hence intestinal parasites leave by means of the fæces, but in so doing they are flung into new dangers, and therefore require protection by encystment. These cysts may be eaten by another individual of the same species as the original definitive host, and the cycle may begin again; but the dangers of the outer world may be guarded against by entering some animal's body in which no development occurs. Such an animal would be a protective ***intermediary host***, and such a cycle can be exemplified by the amœba of dysentery and house-flies.

This extremely simple carriage is also shown by animals which convey bacteria, but some of these undergo multiplication in the gut of the intermediary host—as, for example, the plague bacillus—and may even have their virulence raised—as, for example, Eberth's bacillus. Returning again to the animal parasite, this may grow and multiply in this second host, and may invade its tissues and dwell therein for a length of time. This is quite different from the short passage of an amœbic cyst in the flies' intestines. The second host now becomes a true *intermediate host*, but it is something relatively new interposed in the life cycle of the parasite, which has not yet adjusted itself to its new host, nor has this host adjusted itself to the parasite; and the result is that the parasite almost invariably causes disease in the intermediate host, which may be a vertebrate or an invertebrate, *e.g.*:

The Definitive Host.

Parasite.	*Definitive Host.*	*Intermediate Host.*	*Nature of Parasitism.*
Filaria bancrofti.	Man but little affected pathologically.	Culex and Stegomyia mosquitoes severely affected by infection.	True parasitism of the vertebrate.
Plasmodium malariæ.	Anopheline mosquitoes unaffected pathologically.	Man suffers from malarial fever.	True parasitism of the mosquito.

It is therefore obvious that these two diseases, from the point of view of evolution, have two quite different origins. The first is originally a parasite of man, and, as Hindle has pointed out, Manson's original idea of water infection may be the true method, and that *ab initio* the 'Larvofilaria' lived in water and pierced the human skin, as it does to-day on leaving the mosquito, and requires, as Bahr has shown, dampness in order to live while it pierces the skin. The mosquito carrier is therefore a relatively new acquisition, and the mosquito, not having adjusted itself to these conditions, often dies, as Bahr has shown. On the other hand, *Filaria bancrofti*, barring accidents, causes no symptoms in man, but if there are accidents the disease ensues.

It is quite otherwise with the malarial parasites, in which the anopheline mosquito is the definitive host and man the intermediate host. Here the mosquito is not affected pathologically, but man suffers from malarial fever. Here the malarial parasite must have been originally a sort of coccidioform parasite of the mid-gut of the mosquito, and may have spread from mosquito to mosquito by hereditary infection, as Schaudinn suggested, the sporozoites—*i.e.*, the infective agent—going all over the body, and so entering the salivary glands, and subsequently, when the evolution of warm-blood animals took place, becoming blood parasites, at first accidentally.

The passage from the *intermediate host* to the *definitive host* we call *transmission*.

It is never directly inoculative, like infection, but it may be—

1. Ingestive, via the alimentary canal.
2. Penetrative, via the unbroken skin and mucous membranes.

In the first it is the arthropod which ingests the parasite; in the second the parasites come in contact with the unbroken skin or mucosæ, through which they force their own way, and so enter the body of the intermediate host, which is usually the vertebrate in this case.

Following our life cycle, we come to the passage from the definitive to the intermediate host, and this may be called 'infection,' because it is so often followed by disease in the intermediate host This generally takes place by the agency of the product of the sexual generation—*i.e.*, some descendant of the *zygote*, using this term in the widest sense to mean the product of the fusion of male and female elements.

Infection of the vertebrate is usually *inoculative*, and may be performed in two ways:

(*a*) *The Direct.* In this the blood-sucker simply transmits the parasite unchanged after holding it for a short time.

(*b*) *The Indirect.*—In this the parasite undergoes development in the blood-sucker.

INFECTION AND TRANSMISSION.

Parasite	*Definitive Host.*	*Infection*	*Intermediate Host.*	*Transmission.*
Plasmodium malariæ	Anopheline mosquitoes	Sporozoites from zygote. — Inoculative	Man.	Micro- and macro-gametocytes. — Ingestive.
Filaria bancrofti.	Man.	Microfilaria from egg. — Ingestive.	Culicine mosquitoes.	Larvofilariæ. — Penetrative.

The direct is unusual, as a blood-sucker as a rule takes a full meal from one individual, and does not feed again for a day or so, but it may take place—as Edmond and Étienne Sergent have shown to be the case of the tabanid flies, which bite camels in North Africa, and which spread the trypanosome disease, 'el debab'—by this method, because they acquire a full meal from several individuals, and because the camels resent their attentions.

Infection may also be *contaminative*. In this method the parasite, escaping with the carrier's fæces, enters the new host via wounds, either pre-existing or caused by the carrier itself.

In the case of the Arthropoda infection is generally *ingestive*, as it sucks the blood of the vertebrate and so obtains the blood parasite.

Finally, just as the fly is an *intermediary or temporary host* for the amœba of dysentery, so blood-sucking flies may take up some blood-containing parasites and immediately pass them on to a healthy animal in a second feed: but while biting through the skin they inject this second animal with the parasite, and infection results.

We will now assume that the definitive and intermediate hosts have been living together for long periods undisturbed, and that they have adjusted themselves to the parasite and the parasites to them. Under circumstances such as these there will be little or no sign of disease in the intermediate host, which has now become a 'reservoir' for the parasite.

Assuming that the definitive host is a blood sucking arthropod, and that man enters such an area as a new comer, and is bitten by the blood-sucker, then several things may happen to the parasite.

A. It may be killed off and no infection follow.
B. It may find in man a suitable intermediate host, and cause—
  (1) Acute epidemic disease.
  (2) Chronic endemic disease.
  (3) No disease, only infection.

The second is obviously better for the parasite than the first, and the third than the second.

Therefore, in studying the carriage of an animal parasite of man by some other animal, we must know

1. The parasite.
2. The definitive hosts:
   (*a*) Reservoirs.
   (*b*) Non-reservoirs.
3. The method of infection.
4. The intermediate hosts.—
   (*a*) Reservoirs.
   (*b*) Non-reservoirs.
5. The method of transmission.

But there is another question which it is necessary to consider when man is the definitive host. This question is whether the intermediate host is new, and if so, whether any trace of the old original life-cycle still persists. It should be remembered that man evolved later than blood-sucking insects, as evidenced by tsetse flies found in geological formations in America— so Sambon informs the writers.

Therefore, in order that man may be the definitive host and the blood-sucker a pathologically affected intermediate host means a comparatively recent evolutionary change. Therefore an old original life cycle may still be discoverable, if sought for, and may be of value in prophylaxis, which is the end and aim of the study of the animal carrier.

With these preliminary remarks we may now turn to the history of the subject.

Historical. The history of the animal carrier of disease may be divided into three periods by the dates 1878 and 1898, *i.e.*, by Manson's and by Ross's discoveries, and these periods will be:

I. Early views.
II. Manson's period.
III. Ross's period.

I. *Early Views.*—This period is characterized by gropings in search of truth, mainly by suggestions and by theories, but also by the first experiments with bacteria.

In 1577 Mercurialis suggested that *plague* might be spread by house flies, and in 1666 Sydenham opined that the autumnal diseases of England were due to the flies of summer. In 1769 Bancroft advanced the theory that *Frambœsia tropica* was a fly-borne disease, and in 1808 Crawford believed insects to be carriers of infection. In 1848 Nott of Alabama brought forward reasons to support the insect origin of *yellow fever*. In 1853 Moore referred to flies as possible carriers of *cholera, typhoid, tuberculosis, anthrax*, and *leprosy*, to the last named of which Linnæus had already invited attention, while Raimbert in 1869 performed the first actual experiments to try to prove that flies carried anthrax.

In 1853 Beauperthuy argued that mosquitoes spread *yellow fever*.

II. *Manson's Period.*—This opens with the publication of Manson's epoch-making discoveries of the carriage of *Filaria bancrofti* by mosquitoes, and it must never be forgotten that he grasped at once that this was a new infection of the mosquito, and that water was the original method; and thus he discovered two great truths, of which so far only one has been properly appreciated, because the insect carriage laid the foundation of Ross's great work.

In 1881 Findlay definitely accused mosquitoes as being the transmitters of yellow fever, and conducted experiments in which he is considered to have been successful in transmitting the disease experimentally by their bites.

In 1883 King formulated the theory that malaria was spread by mosquitoes, and in the same year Thomas demonstrated the carriage of *Fasciola hepatica* by snails, while Grassi and Stiles showed that parasitic worms were carried [illegible]

In 1895 Bruce discovered that *Trypanosoma brucei* was spread by a tsetse-fly, a fact which led eventually to clearing up of the carriers of trypanosome diseases.

During the closing years of this period Ross in India was hard at work dissecting mosquitoes in the face of much difficulty, thus opening the way for the last period of our history.

III. *Ross's Period.*—Just twenty years ago (1898) the new stage of research into the animal carrier in disease was opened by Ross's most important, careful, and laborious work into the causation of malaria, and the carriage of its parasites by the anopheline mosquitoes.

This discovery was followed in 1899 by the classical paper by Nuttall, on 'Insects as Carriers of Disease,' while in 1900 Reed, Carroll, and Agramonte showed that *Stegomyia (ædes) calopus* was the carrier of yellow fever.

The rest of this period has been referred to in the opening chapter of this book, and need not be recapitulated, and we will now pass on to study the results of this work, by considering the parasites in the zoological order followed in the preceding chapters.

A. PROTOZOAL DISEASES.

Amœbic Dysentery.—We have already seen that amœbiasis in man is principally caused by *Loeschia histolytica*, which, escaping as *cysts* in the fæces, is taken up by house flies—that is to say, flies belonging to the genera *Musca*, *Fannia*, *Calliphora*, etc.

The cysts do not undergo development in the fly, which serves merely as a carrier and protector for them, which, escaping with the flies' fæces on to human food, afford a means of infection.

This carriage is interesting, indicating that the environment of the alimentary canal of the fly is not suitable for the development of this amœba, though it is known that there are amœbæ passing their whole life-cycle in insects—*e.g.*, *Endamœba blattæ*.

With regard to *L. histolytica*, it is believed that the sexual life-cycle occurs in man, but it is not definitely known whether gametes are formed in the human intestine, or whether autogamy takes place in the cyst, which is improbable, but in either case the life-cycle does not require more than one host, and infection can take place by direct contamination of the food, without passing through the fly.

Animals can be infected with amœbic dysentery, but there is no evidence at present of any animal, other than man, acting as a reservoir, but this does occur in human carriers.

To demonstrate what we mean we give the following table:—

AMŒBIC DYSENTERY.

Parasite.	*Definitive Host.*	*Reservoir.*	*Transmission.*	*Intermediary Host.*	*Infection.*	*Incidental Host.*
Loeschia histolytica.	Man in carrier stage.	Man in carrier stage.	Cyst Ingestive.	Flies.	Cysts ingested from contaminated food or drink.	Man in acute and chronic infections.

Flagellate Diarrhœa and Dysentery.—Whatever may be the views of zoologists, medical men have little doubt that some of the flagellates, such as *Giardia intestinalis*, produce diarrhœa; and Wenyon and O'Connor have shown that their cysts have been found in flies, and that in general the process of infection is much the same as in man, but the reservoir is different. There is little doubt in our minds that man is more or less accidentally infected with many of these parasites, and certainly with *Giardia intestinalis*, which appears to us to be a true parasite of the rat.

If there is a sexual cycle, it takes place either in the cyst or in the vertebrate.

FLAGELLATE DIARRHŒA AND DYSENTERY.

Parasites.	*Definitive Host.*	*Reservoir.*	*Transmission.*	*Intermediary Host.*	*Infection.*	*Intermediate Host.*
Giardia intestinalis and others.	Man in chronic cases and as carriers, and rat	Rats	Cysts ingested.	Flies.	Cysts ingested with contaminated food or drink	Man in acute cases.

Sleeping Sickness. We have already indicated that we think that there are several forms of this disease—viz., that caused by—

1. *Trypanosoma gambiense.* Synonym: *T. nigeriense.*
2. *Trypanosoma castellanii.* Synonyms: *T. ugandense, T. gambiense pro parte.*
3. *Trypanosoma rhodesiense.*
4. *Other Forms of Trypanosomes.* (*a*) Some type of *T. brucei* in the laboratory infection of Professor Lanfranchi; (*b*) some type of *T. vivax* found by Macfie

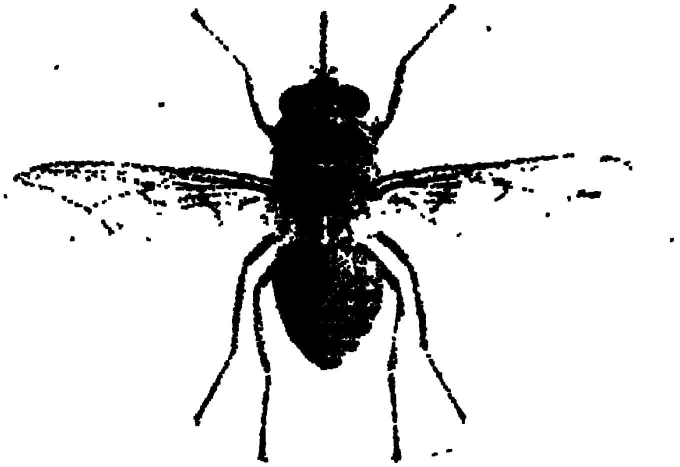

FIG. 401.—*Glossina palpalis* ROBINEAU-DESVOIDY, 1830: THE CARRIER OF THE TRYPANOSOME OF THE CASTELLANI TYPE OF SLEEPING SICKNESS.

(From a photograph by J. J. Bell.)

The carrier of the first (*T. gambiense*) has never been properly studied. Possibly it is not *Glossina palpalis*, and as nothing can be said definitely, we will not pursue this subject further, except to say that Yorke and Blacklock consider man to be the principal reservoir, with domestic cattle as a secondary reservoir.

With regard to *T. castellanii*, we have noted that Miss Robertson's researches have shown that it never multiplied in the vertebrate in cells of the liver, spleen, or lungs, and that there was no schizogony, and that division was simple and longitudinal, taking place always in the circulating blood and producing ***transmission forms***, which are her ***short blood forms***.

These forms can be ingested by *Glossina palpalis* (but one has to be sure that it is really *palpalis*, as flies apparently of this species have been found by King, using Newstead's more accurate methods of classification, not to be this species), first establishing themselves in the posterior part of the mid-gut and then multiplying and forming many types therein, but moving on the tenth to twelfth day to the proventriculus in the form of *long, slender, non-infective trypanosomes*, from which they find their way via the hypopharynx to the salivary glands after the sixteenth day. In these glands they assume a crithidial form, from which after multiplication ***small infective trypanosomes*** appear after the eighteenth to twenty-first day—*i.e.*, some two to five days after infection of the salivary glands.

Miss Robertson never saw any signs of conjugation or of sexual forms, as described by Minchin, Gray, and Tulloch, but considers the cycle in the fly has this significance, and if so the fly is the *definitive host*, and susceptible animals can be infected by its bite.

Is there hereditary infection of the fly via the ova, as shown by O'Farrell to take place with a crithidia in a tick? This question is so far answered in the negative

Is there an animal reservoir for *T. castellanii*? Perhaps there is, but notwithstanding Duke's experiment with an antelope, we believe that no such reservoir has been proven, and this is supported by the very small numbers of wild glossinæ which have been found to contain *T. castellanii*. One suspects that if there is a reservoir, it must be in man himself when he becomes more or less immune to the disease

The possibility of direct infection during sexual intercourse must be remembered, in addition to insect carriage.

There appears to be no doubt that the fly at present labelled *Glossina palpalis* is the carrier of the disease, as all experiments tend to show.

CASTELLANI TYPE OF SLEEPING SICKNESS.

Parasite.	*Definitive Host.*	*Definitive Reservoir.*	*Infection.*	*Intermediate Host.*	*Intermediate Reservoir.*	*Transmission.*
Trypanosoma castellanii.	*Glossina palpalis.*	Hereditary infection of tsetse flies (?)	Short salivary trypanosomes.	Man.	Game animals (?).	Short blood trypanosomes.
			Inoculative.			Ingestive.

Rhodesiense Type of Sleeping Sickness.—Kinghorn and Yorke have described short blood trypanosomes in man, and, judging by Miss Robertson's Castellanii experiments, these must be the transmission agents which infect *Glossina morsitans*, in the salivary glands of which short trypanosomes occur, which infect the vertebrate, which is the intermediate host.

We now come to the very important question of the intermediate reservoir of this trypanosome. Bruce says that *T. brucei* and *T. rhodesiense* are one and the same parasite. Assuming this to be true, the intermediate reservoir would be the African antelopes —*e.g.*, *Catoblepas gnu*, the wildebeest: *Strepsiceros capensis*, the koodoo: *Tragelaphus scriptus* var. *sylvaticus*, the bush-buck. But there are doubts about this, because—

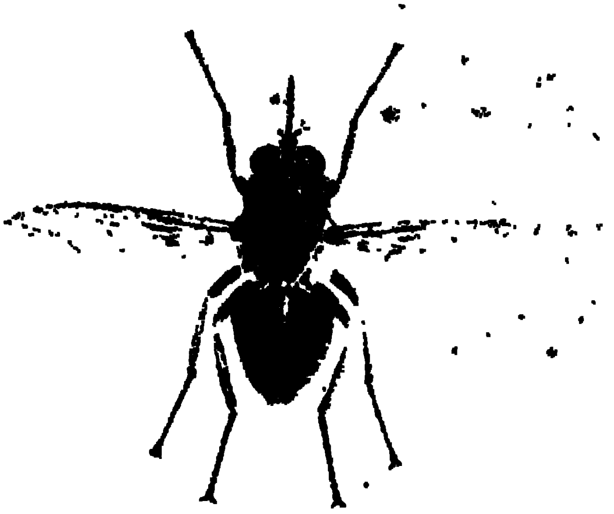

FIG. 462.—*Glossina morsitans* WESTWOOD, 1850: THE CARRIER OF THE TRYPANOSOME OF THE STEPHENS AND FANTHAM TYPE OF SLEEPING SICKNESS.

(From a photograph by J. J. Bell.)

1. Stephens and Blacklock have shown that two distinct trypanosomes have been called *T. brucei*—viz.:—

(*a*) *Monomorphic.*—This is the original strain of *brucei* discovered by Bruce in cattle suffering from nagana in Zululand.

(*b*) *Polymorphic.*—This is a posterior nucleated form from Uganda, where the Rhodesiense form of sleeping sickness is unknown.

2. Chalmers and O'Farrell, working with a posterior nucleated trypanosome, sent to them in dogs inoculated from a case of sleeping sickness in the Bahr-el-Ghazal province of the Anglo-Egyptian Sudan, found it to differ markedly in serological experiments and animal inoculations from the original strain of *T. rhodesiense*. This shows that merely obtaining a posterior nucleated trypanosome in a sleeping sickness area does not prove that it is *T. rhodesiense*, or, indeed, has anything to do with sleeping sickness.

3. Laveran's cross immunity experiments mentioned in Chapter XIX. show that *T. brucei* and *T. rhodesiense* are quite different from an immunity point of view.

4. Taute has injected himself with 2 c.c. of blood from a dog infected with *T. brucei*. He did not become infected, and suffered no bad effects.

5. Taute fed *Glossina morsitans* upon animals infected with *T. brucei*, and after waiting the necessary time these flies were allowed to feed upon two men, with negative results, although control animals became infected and died.

Thus the chain of evidence is strengthening which tends to show that *T. brucei* is not *T. rhodesiense*, and if this is so, then we do not know the intermediate reservoir of this trypanosome, and its chart becomes:—

STEPHENS AND FANTHAM TYPE OF SLEEPING SICKNESS.

Parasite.	*Definitive Host.*	*Definitive Reservoir.*	*Infection.*	*Intermediate Host.*	*Intermediate Reservoir.*	*Transmission.*
Trypanosoma rhodesiense.	*Glossina morsitans.*	Hereditary infection of tsetse flies (?).	Short salivary trypanosomes. — Inoculative.	Man.	Game animals (?)	Short blood trypanosomes. — Ingestive.

With regard to the other forms of sleeping sickness due to trypanosomes allied to *T. vivax*, etc. (*vide* p. 1280), too little is known about them and their carriers, and therefore it is impossible for us to discuss the means of infection and transmission. *G. tachinoides* is suggested as a possible carrier.

Chagas' Disease.—Chagas has shown that *Trypanosoma cruzi* in the vertebrate intermediate host finally enters the lungs, where it loses its flagellum, while its two extremities join, and it becomes a sphere, inside which eight daughter spheres arise, which, elongating and entering red blood cells, become male and female trypanosomes. These are the transmission agents which carry on the life-cycle of the parasite in *Lamus megistus* (*Triatoma megista*) when it sucks infected blood.

In this insect the trypanosome lives and multiplies in the gut of the insect, and gives rise to crithidial forms in the mid-gut. These eventually develop into small trypanosomes, which pass into the salivary glands, and from there are injected into the intermediate host when the insect bites.

He considers that the armadillo, *Dasypus novemcinctus*, may be the intermediate reservoir, and that *Lamus geniculatus*, which lives with this animal, may also be a definitive host, as may *Lamus infestans* and *L. sordida;* while Brumpt has shown that *T. cruzi* can develop in *Clinocoris lectularius* and in *Leptocimex boneti.* (It must be remembered that Triatoma can be infected naturally with a trypanosome.)

There is no evidence of hereditary infection in these insects, but there is some evidence that at times infection may be contaminative from the insect fæces via the bite, but this requires more investigation.

The chart of this disease would be:—

CHAGAS' DISEASE.

Parasite.	*Definitive Host.*	*Infection.*	*Intermediate Host.*	*Intermediate Reservoir.*	*Transmission.*
Trypanosoma cruzi.	*Lamus megistus* (synonym, *Triatoma megista*).	Short salivary trypanosomes. — Inoculative.	Man	*Dasypus novemcinctus.*	Male and female trypanosomes. — Ingestive.

Leishmaniasis. The nature of the carrier and the reservoir is very uncertain at the present moment. Judging by the more marked resistance of the dog to experimental infection in India and the Sudan, we may assume that there are at least two kinds of kala-azar. It is believed by certain authorities that a flea is the transmitter of the Mediterranean type, whereas the Indian and Sudan type are not so transmitted. Patton's incrimination of the bug has not stood the test of time. Archibald has suggested and brought forward evidence that, at least in regard to the Sudan, infection is probably due to the ingestion of cysts from water arthropods.

The development of generalized kala-azar in Archibald's monkeys, after the successful inoculation of Oriental sore, points to a close relationship between the two diseases, as suggested long ago by Manson.

There is no complete evidence at present that the espundia parasite is essentially different from that of kala-azar, but it may prove in the long run to be different, because of its marked different clinical results.

The present state of our knowledge, which is unsatisfactory, may be summarized as follows:—

TROPICAL KALA-AZAR.

Parasite.	*Inter-mediate Host.*	*Intermediate Reservoir.*	*Trans-mission.*	*Definitive Host.*	*Method of Infection.*
Leishmania donovani.	Man.	(?)	Parasites passed in faeces. — Ingestive (?).	Water insect (?) Biting insects (?)	Cysts in drinking-water (?). — Ingestive (?). Inoculative (?).

MEDITERRANEAN KALA-AZAR.

Parasite.	*Inter-mediate Host.*	*Inter-mediate Reservoir.*	*Trans-mission.*	*Host Nature Doubtful.*	*Method of Infection.*
Leishmania infantum.	Man.	Dogs (?).	Blood-sucking insect (?) — Inoculative (?)	Fleas (?).	Blood-sucking insect (?). — Inoculative (?). Contaminative (?).

Coccidiosis.—The discovery of a coccidial oöcyst in a fly's intestine by Wenyon and O'Connor suggests that possibly this is the method of infection of man by these parasites, the fly only acting as an *intermediary host,* as in the case of *Loeschia.* Perhaps this ought to be included with chance infections.

Malaria.—The three well-recognized malarial parasites have as their *definitive host* various species of anopheline mosquitoes. The classification of the Anophelinæ is as follows:—

A. Costa with less than four main dark spots—*Protoanopheles.*
B. Costa with four main dark spots:—
  I. Sixth vein with not more than three dark spots—*Deuteroanopheles.*
  II. Sixth vein with more than three dark spots—*Neoanopheles.*

The Neoanopheles have no malarial carriers.

DIVISION I.: PROTOANOPHELES CHRISTOPHERS, 1911.

The division contains the following genera:—

A. *Costa without pale areas* :—
  I. Female palps with second segment disproportionately long—*Stethomyia.*
  II. Female palps with second segment not disproportionately long—*Anopheles.*

B. *Costa with at least one pale area* :—
- I. Mesothorax without true scales.
    - (*a*) Wing scales mixed dark and light—*Patagiamyia.*
    - (*b*) Wing scales not so mixed:—
        - 1. Wing scales not inflated—*Myzorhynchus.*
        - 2. Wing scales inflated—*Cycloleppteron.*
- II. Mesothorax with true scales—*Arribalzagia.*

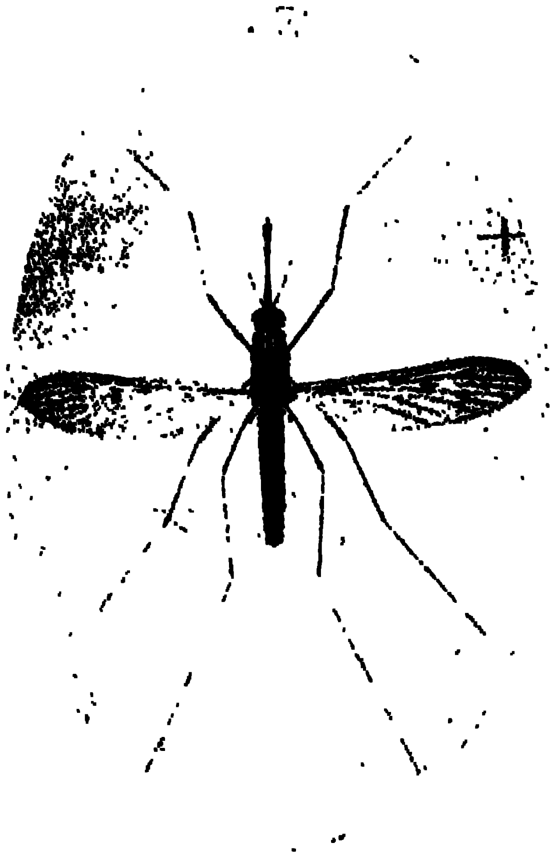

FIG. 403. — *Anopheles maculipennis* MEIGEN, 1818 A CARRIER OF THE MALARIAL GERMS.

(From a photograph by J J Bell.)

James distinguishes between *true scales*, which are broad and have distinct striations, and *false scales*, which are hair-like and have indistinct striations.

The question whether any of these serve as *definitive reservoirs* by infection of the ova, as suggested by Schaudinn, has never been proved, but we doubt whether much research has been attempted in this direction.

The anopheline mosquitoes known definitely to transmit malaria, arranged according to recent methods of classification and following Hindle and our previous lists, are as follows:—

I. Anophelines definitely known to be able to carry the malarial parasites through the complete cycle of quartan, tertian, or subtertian infections, or only as far as zygotes:—

(*a*) ANOPHELES CARRIERS.

Number.	*Mosquito*	*Observer.*	*Observation.*	*Habitat.*
1	*A. algeriensis* Theobald, 1903	The Sergents.	To sporozoites.	North Africa.
2	*A. bifurcatus* Linnæus, 1758.	Grassi.	Tertian.	England.
3	*A. maculipennis* Meigen, 1818.	Many.	Quartan, tertian, malignant tertian.	Europe.

(*b*) PATAGIAMYIA CARRIER.

Number.	*Mosquito.*	*Observer.*	*Observation.*	*Habitat.*
4	*P. pseudopunctipennis* Theobald.	Darling.	Malignant tertian.	Panama Canal Zone.

(*c*) CYCLOLEPPTERON CARRIERS.

Number.	*Mosquito.*	*Observer.*	*Observation.*	*Habitat.*
5	*C. mediopunctatum* Theobald.	Cruz.	Tertian.	Brazil.
6	*C. nolotrichum*—*A. intermedius* Chagas.	Cruz.	Tertian.	Brazil.

(*d*) ARRIBALZAGIA CARRIER.

Number.	*Mosquito.*	*Observer.*	*Observation.*	*Habitat.*
7	*A. pseudomaculipes* Chagas.	Cruz	Tertian.	Brazil.

DIVISION II.: DEUTEROANOPHELES CHRISTOPHERS, 1911.

This division may be classified as follows:—

- A. Terminal segment of female palpi less than half length of penultimate. Tarsi not broadly banded:—
  - I. Mesothorax without true scales—*Myzomyia*.
  - II. Mesothorax with true scales—*Pyretophorus*.
- B. Terminal segment of female palpi at least half length of penultimate. Tarsi broadly banded:—
  - I. Mesothorax not completely covered with true scales *Pseudomyzomyia*.
  - II. Thorax completely covered with true scales:—
    - (*a*) Abdomen without lateral scale tufts:—
      - 1. Palpi moderately shaggy—*Nyssorhynchus*.
      - 2. Palpi markedly shaggy—*Myzorhynchella*.
    - (*b*) Abdomen with lateral scale tufts—*Cellia*.

Most of these genera possess malarial carriers.

(e) Myzomyia Carriers.

Number.	*Mosquito.*	*Observer.*	*Observation.*	*Habitat.*
8	*M. albirostris* Theobald.	Staunton	Malignant tertian zygote.	Malaysia.
9	*M. culicifacies* Giles	Stephens and Christophers	All forms.	India and Ceylon.
10	*M. formosaensis* I. and II. Tsuzuki = *M. aconita* Dönitz = *Anopheles kochii* Dönitz.	Tsuzuki	Malignant tertian.	Formosa.
11	*M. funesta* Giles = *M. kumassi* Chalmers.	Many, including Chalmers, in Kumassi.	Malignant tertian, including Kumassi zygote and sporozoites.	Tropical Africa.
12	*M. hispaniola* Theobald.	Sergents.	Tertian	North Africa, South Spain
13	*M. listoni* Liston.	Kinoshita, Stephens, and Christophers	Tertian.	India.

30	*M. arabiensis.*	Patton.	Sporozoites.	Aden Hinterland.

II. Anophelines believed to be malarial carriers for epidemiological reasons:—

Number.	*Mosquito.*	*Observer.*	*Habitat.*
31	***Stethomyia aitkeni*** James.	Daniels, Christophers.	Malaysia, India.
32	***Pyretophorus chaudoyei*** Theobald.	Billet.	Algerian Oases (saline waters).
33	***Mysomyia d'thali*** Patton.	Patton.	Aden.
34	***Myzomyia kochi*** Dönitz =***M. aconita***= ***M. formosænsis***.	Daniels.	Malaysia.
35	***Myzomyia lutzi*** Theobald.	Lutz.	Brazil.
36	***Nyssorhynchus karwari*** James and Liston.	Staunton.	Malaysia, India.
37	***Anopheles*** (?) ***martini*** Laveran.	Laveran.	Cambodia.
38	***Myzorhynchus mauritianus*** Grandpré (?=***M. paludis***= ***M. aconita***).	Ross.	Mauritius, Madagascar.
39	***Anopheles*** (?) ***pursati*** Laveran.	Laveran	Cambodia.

III. Malarial carriers in Lists I. and II. under synonym names. (The nomenclature is in such confusion that it is quite impossible to be certain whether these synonyms are correct):—

(*a*) ***Myzomia funesta*** (Giles, 1900); ***Anopheles kumassii*** Chalmers, 1900.

(*b*) ***Myzomia formosænsis*** :—

1. ***Anopheles constance*** Laveran, Madagascar.
2. ***Anopheles jamesi*** Theobald, India.
3. ***Anopheles jeporensis*** James, India.
4. ***Anopheles kochii*** Dönitz, Malaysia.
5. ***Anopheles mauritianus*** Grandpré, Mauritius.
6. ***Anopheles paludis*** Theobald, West Africa.

(*c*) ***Stethomyia atkeni*** :—
Anopheles vincenti Laveran, Tonkin.

(*d*) ***Myzomia listoni*** :—
Anopheles cohæsus, Doune Japan.

IV. Probably not carriers:—

(*a*) ***Myzorhynchus barbirostris*** Van der Walp, India, Ceylon, Malaysia, China.

(*b*) ***Myzomia rossi*** Giles, India, Ceylon, China.

(*c*) ***Pyretophorus sergenti*** Theobald, Algeria.

(*d*) ***Myzomia sinensis*** Wiedemann, India, Malaysia, China.

V. Said to be a carrier, but reason unknown to us:—
Cycloleppteron grabbami Theobald, West Indies, South America.

An infective mosquito, when biting a man, injects the salivary sporozoites into his blood and gives him the infection.

When a mosquito bites a suitable human carrier it receives the macrogametocytes and microgametocytes, which enable the parasites to undergo sexual development in its body.

The scheme is:—

MALARIA.

Parasites.	*Definitive Hosts.*	*Definitive Reservoir.*	*Infection.*	*Intermediate Host.*	*Intermediate Reservoir.*	*Transmission.*
Plasmodium malariæ, ***Plasmodium vivax,*** ***Laverania malariæ.***	Anopheline mosquitoes.	Unknown.	Salivary sporozoites. — Inoculative.	Man.	Human carriers.	Macrogametocytes and microgametocytes from blood. — Ingestive.

B. HELMINTHIASIS.

Trematode Infections.—The trematode infections of man have as their intermediate host a mollusc. The definitive host is a vertebrate, from whom the eggs escape in the urine, the fæces, or the respiratory secretions. These eggs hatch in water, producing a ciliated, actively swimming miracidium, which will enter and develop in some definite genus of mollusc. Chalmers and Pekkola, watching the miracidia of schistosoma, noted that they rapidly entered the known susceptible molluscs, rejecting other genera.

It would appear that the mollusc is liable to disease and death if too heavily infected.

It is therefore necessary to note the classification and method of recognition of the known carriers.

PHYLUM MOLLUSCA Cuvier.

Synonyms.—*Palliata* Latreille; *Malacozoa* de Blainville.

Definition.—Metazoa with no sign of primitive segmentation, with well-developed distinct cœlom (gonad and pericardial), enteron, and hæmocœl, with (or has lost) a radular sac, with periœsophageal ring; dorsal moiety is the cerebral commissure, and the ventral the labial commissure; and with a dorsal and a ventral nerve trunk. Body wall differentiated into an antero-dorsal, ***cephalic*** portion, with the sense organs, a postero-dorsal, the ***pallium or mantle***, which secretes externally a calcified cuticle, ***the shell***, and develops the ***ctenidia***, or respiratory organs, on its lower surface, and a ventral portion, ***the foot***, or organ of locomotion. A ***veliger***, or free trochosphere larva, is nearly always present.

Classification.—The phylum so defined is divided into three grades as follows:—

A. Gonadial and reno-pericardial cavities communicate—*Isopleura, Siphonopoda*.

B. Gonadial and reno-pericardial cavities separate—*Prorhipidoglossamorpha*.

The Isopleura contains the 'Chitons', and the Siphonopoda the 'Cephalopods, with which we are not concerned.

Grade Prorhipidoglossomorpha Grobben.

Definition.—Mollusca in which the gonadial and reno-pericardial cavities are separate, the foot is wholly posterior to the head, and a visceral commissure is present.

Classification.—The Prorhipidoglossomorpha are divided into three classes as follows:—

A. *Body bilaterally symmetrical* :—
  I. Mantle united ventrally to form a tube. No ctenidia—Class I., *Scaphopoda* Bronn.
  II. Mantle not so united; ctenidia present—Class II., *Lamellibranchia* de Blainville
B. *Body asymmetrical*—Class III., *Gastropoda* Cuvier.

We are only concerned with the third class.

Class Gastropoda Cuvier.

Definition.—Prorhipidoglossomorpha with asymmetrical organization, with well-developed head, with shell formed in one piece and spirally coiled, at least in the larva.

Classification.—The class may be divided into two subclasses:—

A. Visceral commissure twisted into a figure of eight, mostly diœcious—*Streptoneura*.

B. Visceral commissure not so twisted, with shortened visceral commissure monœcious—*Euthyneura*.

Subclass I.: Streptoneura Spengel.

Definition.—Gastropoda, diœcious, with a few aberrant genera; maximum torsion of visceral mass and commissure. Head with only one pair of tentacles.

Classification.—The Streptoneura are divided into two orders:—

A. Nervous system not concentrated. Infraœsophageal commissure present. Ctenidia bipectinate and free at their distal ends—*Aspidobranchia*.

B. Nervous system somewhat concentrated. Intraœsophageal commissure present. Ctenidium monopectinate and attached to mantle along its whole length—*Pectinibranchia*.

Only the last concerns us.

Order Pectinibranchia.

Definition. Streptoneura as defined above.

Classification. The Pectinibranchia are divided into two suborders:—

A. Without proboscis, pallial siphon, or Leiblein's unpaired œsophageal poison gland—*Tænioglossa*.

B. With proboscis, pallial siphon, and Leiblein's poison gland—*Stenoglossa*.

Only the Tænioglossa are of importance to us.

Suborder Tænioglossa.

Definition.—Pectinibranchia with the characters given above, with three teeth, one lateral and two marginals, on each side of the median tooth of the radula.

Classification.—There are two tribes:—

A. Creeping forms, with foot flattened ventrally—*Platypoda.*

B. Free-swimming forms, with foot flattened laterally -*Heteropoda.*

We are concerned with the Platypoda.

Tribe Platypoda.

Definition.—Tænioglossa with the characters given above.

Classification.- There are some fifty-five families, of which we are interested in the Melaniidæ only.

Family Melaniidæ Gray.

Definition.—Platypoda with spiral shell and elongated spire. Operculum horny. Foot short. Mantle border fringed. Viviparous. Fluviatile.

Classification.—Several genera.

A. Shell long:- -

I. Shell turriculated, aperture enlarged anteriorly—*Melania.*

II. Spiral very long, aperture notched anteriorly—*Faunus.*

B. Shell short, thick, and aperture rounded - *Other genera.*

Melania Lamarck.

Synonyms. *Thiara* Mergele: *Pyrgula* Crist.

Definition. -Melaniidæ with turreted shell, acute apex, whorls ornamented with striæ or spires; aperture oval, pointed above; outer lip sharp, sinuous. Operculum subspiral.

Type Species.- -*Melania hastula* Leach.

Remarks.- Some 400 or more species distributed throughout Southern Europe, India, the Philippines, Japan, and the Pacific Islands. Distinct groups in the Southern United States.

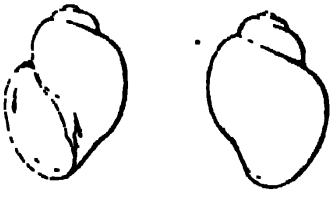

Fig. 464.- *Bulinus contortus* (p. 893).

According to Nakagawa, *Melania obliquegranosa* Smith and *M. libertina* Gould are intermediate hosts of *Paragonimus ringeri* Cobbold, but Kobayashi believes that the cercariæ seen by Nakagawa in these molluscs are not those of *P. ringeri.*

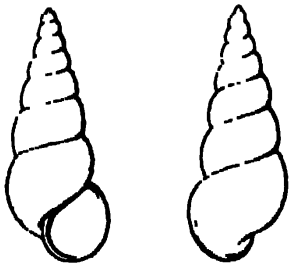

Fig. 465.- -*Blandfordia japonica* Adams, 1861. The Carrier of *Schistosoma Japonicum.*

Blandfordia Adams, 1863.

Definition. -Melaniidæ with ovate conical shell, apex truncated. Aperture elliptical, peristome continuous, operculum subspiral. Rostrum elongated. Tentacles very short, eyes sessile. Foot large; divided into two parts by a transverse sulcus.

Type.—*Blandfordia striatula* Menke.

Other Species.- *B. bensoni* Adams: *B. japonica* Adams; *B. pyrrhostoma* Cox: *B. viridescens* Carpenter.

We are only concerned with *B. japonica,* which is the carrier of *Schistosomum japonicum.*

Subclass II.: Euthyneura Spengel.

Synonym. *Platymalakia* von Jhering.

Definition. Gastropoda monœcius with radula possessing uniform teeth on each side of the median tooth. Head usually with two pairs of tentacles. Detorsion of organization when adult.

Classification.—

A. Marine forms with aquatic respiration—*Opisthobranchiata*.
B. Aerial or fresh-water (exceptionally marine) forms, with pallial cavity, but no ctenidium. No free larval form—*Pulmonata*.

Order Pulmonata Cuvier.

This order is divided into two suborders:—

A. Aquatic forms, with a single pair of tentacles—*Basommatophora*.
B. Terrestrial forms, with two pairs of tentacles—*Stylommatophora*.

Suborder Basommatophora.

Definition.—Pulmonata with an external shell and a single pair of well-developed contractile but not invaginable tentacles, at the bases of which lie the eyes.

Classification.—There are some eleven families, but only the following concern us:—

A. Shell thin, dextral; no inferior pallial lobe—*Limnæidæ*.
B. Shell sinistral, inferior pallial lobe prominent—*Planorbidæ*.

Family Limnæidæ Broderip.

Definition.—Basommatophora with shell thin, horn coloured, and capable of retaining the whole animal when retracted. Aperture single; lip sharp, No inferior pallial lobes. Tentacles angular and flat.

Remarks.—These molluscs are found in fresh water all over the world.

Type Genus—*Limnæa* Lamarck.

Genus Limnæa Lamarck.

Definition.—Limnæidæ with spiral shell, more or less elongated, thin pointed spire translucent; body whorl large; aperture rounded; columella obliquely twisted.

Type Species.—*Limnæa stagnalis* Linnæus.

Other Species.—The hosts of *Fasciola hepatica* are:—*L. truncatula* Müller, Europe, Asia, Africa; *L. oahuensis*, Eyd, Sandwich Isles; *L. viator*, D'Orbigny, South America; *L. humilis*, Say, North America.

Family Planorbidæ Adams.

Definition.—Basommatophora with sinistrally coiled shell. Inferior pallial lobe very prominent, transformed into a branchia; tentacles tapering.

Classification.—

A. Shell discoid, branchia not folded—*Planorbis*.
B. Shell ovoid, with prominent spire. Branchia not folded—*Bulinus*.

Genus Planorbis Guettard.

Definition.—As above. Shell discoidal, dextral, many whorled; aperture crescentic. Peristome thin, incomplete; upper margin projects.

Type.—*Planorbis corneus* Linnæus.

Planorbis boissyi Potiez and Michaud, 1838.

Synonym.—*P. laurenti* Bourguignat.

Remarks.—This is the intermediate host of *Schistosoma mansoni* in Egypt and the Sudan, as discovered by Leiper.

Planorbis olivaceus Spix.

This is the carrier of *S. mansoni* in Brazil.

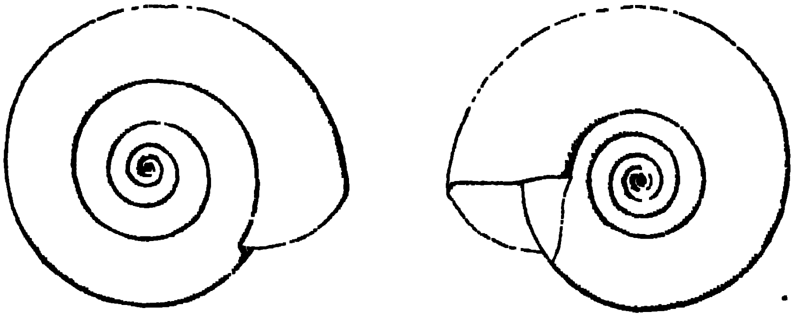

FIG. 466.—*Planorbis olivaceus.* THE CARRIER OF *Schistosoma mansoni* IN BRAZIL.

Genus Bulinus Adamson.

Synonyms.— *Nauta* Leach; *Aplexa* Fleming. Often spelt *Bullinus.*

Definition.—Planorbidæ with ovoid shell, prominent spire, branchia folded.

Type.—*Bulinus hypnorum* Linnæus.

Classification.—The species of importance to us are:—*Bulinus contortus* Michaud, 1829; *Bulinus dybowski* Fischer, 1891; *Bulinus alexandrina* Innes; *Bulinus innesi* Bourguignat.

The above are the hosts of *Schistosoma hæmatobium* in Egypt.

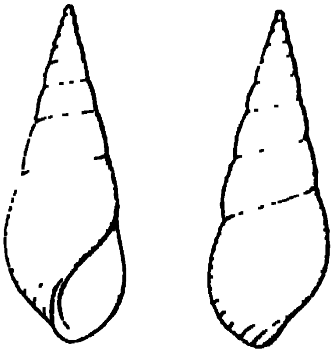

FIG. 467.—*Physa* (*Physopsis*) *africanus* KRAUSS. A CARRIER OF *Schistosoma Hæmatobium.*

Family Physidæ Dall.

Definition.—Basommatophora with visceral mass and shell sinistrally coiled. Shell thin, with a narrow aperture; tentacles cylindrical. No inferior pallial lobe.

Type Genus.—*Physa* Draparnaud.

Remarks.—*Physopsis* is distinguished from *Physa* by the spire not being at all exserted, and having the columella truncated at the end.

Phya or *Physopsis africanus* is the carrier of *S. hæmatobium* in Brazil.

TREMATODE INFECTIONS.

Trematode.	*Definitive Host.*	*Definitive Reservoir.*	*Transmission.*	*Intermediate Host.*	*Infection.*
Fasciola hepatica.	Man.	Sheep.	Miracidium in water. - Penetrative.	Species of Limnæa.	Cercaria encysted on weeds. — Ingestive.
Fasciolopsis buski.	Man.	Pig.	Miracidia in water.	Shrimps (?).	(?) - Ingestive (?).

Echinococcus.	Dog, jackal.	Dog, jackal.	Eggs on fur.	Man, sheep.	Cysticerci in muscles. — Ingestive.

C. MYIASIS.

Myiasis comprises the infestation of the vertebrate body with the *larvæ of diptera*, and the disorders which arise in the body of the host therefrom.

The vertebrate is an *intermediate host*, because not merely is it protective to the fly larva, but in it the larva grows and develops until it is about to pupate.

There is no doubt that this is an advantage to the fly, and that this method of protection is in process of evolution. In Chapter XXXIII. we have written upon the change in habits of flies, and will merely remind the reader that there is ample evidence that within quite recent years a scatophilous fly has so changed its habits that

NEMATODE INFECTIONS.

(These are on the same lines as trematode and cestode as a rule.)

Nematode.	*Definitive Host.*	*Definitive Reservoir.*	*Infection.*	*Intermediate Host.*	*Transmission.*
Filaria bancrofti.	Man.	Man.	Microfilaria in blood. — Ingestive.	Culex and Stegomyia.	Larvofilaria. — Penetrative.

Ascaris lumbricoides.	Man	Pig.	Eggs. — Ingestive	Rats.	Larvæ on food. — Ingestive.

it has deposited its larvæ on the skin of sheep and become a producer of myiasis thereon.

Myiasis will form the subject-matter of Chapter LXVII. (p. 1619), and here it is only necessary to say that the larvæ may be deposited in the natural cavities of the body, placed in neglected wounds, live in the subcutaneous tissue, or pass through the alimentary canal.

In this chapter we are merely concerned with the method by which the larva reaches man, and it would appear that it is always, or nearly always, due to the direct action of the mother fly; but there is a curious observation, which is that an ***intermediary animal carrier*** exists, at all events, in the case of *Dermatobia cyaniventris*, which has been studied by Blanchard, Surcouf, Rincones, Tovar, Zepeda, and Sambon.

According to the last-named observer, *D. cyaniventris* lives in Trinidad and Central and South America, and its young produce cutaneous myiasis in man, monkeys (the brown howler and the capuchin), pumas, agoutis, cattle, goats, pigs, and birds (the toucan and the turkey).

Man is most liable to be infected while working in the mahogany forests of Honduras and Columbia, as many as a hundred maggots being found in a single patient. These maggots are called by the natives 'mosquito worms,' because they are deposited by a culicine mosquito, *Janthinosoma lutzi*.

The history is as follows:—

The female *J. lutzi* lays its eggs in water; these hatch and produce the imago, which is then seized by the *D. cyaniventris* (according to Kudi), and some eight to eighteen long, pale, yellow eggs are glued one after the other to the velvet surface of the gnat's first second to third abdominal segments.

The eggs are quite ready to hatch, and Sambon says that some of them quickly become uncapped, and that the anterior part of the larva is protruding. The mosquito now goes off to get a meal of warm vertebrate blood, and while it is so doing the larvæ drop out of their shells and enter the skin via the hole made by the mosquito. This much is known, but we may well ask whether this happens with any other insects. Sambon says that the common house-fly spreads the book-scorpion, *Chermes nodosus*, in this way, and says that he has seen *Pediculus capitis* do the same thing. If this be so, then the study of entomology, applied to man and animals, has still much work in front of it.

Restricting our attention to *Dermatobia cyaniventris*, the chart of its carriage is as follows:—

DERMATOBIA MYIASIS.

Parasite.	*Intermediary Hosts.*	*Infection.*	*Intermediate Host.*	*Intermediate Reservoir.*	*Transmission.*	*Definitive Stage.*
Larva of *D. cyaniventris.*	*Janthinsoma lutzi.* Carries eggs. Only female.	Mosquito sucks blood; larva enters wound. — Penetrative.	Man.	Warm-blooded vertebrates.	Larva escapes from skin.	Free living.

D. BACTERIAL DISEASES.

The spores of bacteria enable them to spread from host to host with a degree of protection during the passage, but non-sporing forms will be benefited by the aid of a carrier, which not merely affords protection, but also a means of dissemination. We will divide the discussion into flies, fleas, and lice.

1. FLIES.

This 'intermediary host' is often a non-blood-sucking fly of the nature of the 'common house-fly,' which is a potential carrier of disease, because it and its kind frequent decaying matter and excreta for the purpose of laying the eggs, while both it and its larvæ are filth feeders.

If it and its allies only fed upon filth, there would be but little harm, but, unfortunately, they are attracted to many articles of human food, cooked and raw, such as milk, meat, butter, sweets, etc.; and the distances within reason to which flies travel is limited by the necessities of food and shelter, but they go to the nearest place, and if both exist at hand they do not travel.

Nicholls, working in St. Lucia, has shown that the fly *Limosina punctipennis* Wiedemann lives and breeds almost exclusively upon human excrement, and that it is a carrier of *Bacillus coli communis*. In Africa flies belonging to the genus *Pycnosoma*—*e.g.*, *P. marginale*—do the same as do other species in India and China.

These flies one and all are great feeders, and are accustomed to vomit frequently, while they pass a considerable amount of excrement. Graham Smith records 1,102 vomit marks and nine fæcal deposits on an area of a cupboard window 6 inches square. Bearing this in mind, it can readily be appreciated how well they contaminate food and what efficient disseminators of germs they may be.

Graham Smith describes fæcal deposits as round, opaque, often raised, spots of a yellowish, brownish, or whitish colour, while vomit spots have an opaque centre and a clear periphery bounded by a darker zone.

But the body of the fly is thickly clothed with hairs or setæ, and as it walks over filth, particles containing bacteria are apt to cling to these hairs.

We therefore have to consider:-

A. The external carriage of germs.
B. The internal carriage of germs.

With regard to the former, Graham Smith's experiments with *B. prodigiosus* show that this bacillus can be cultivated from the legs and wings of infected flies for eighteen hours after infection. It must be remembered that flies are everlastingly cleaning themselves, and it is a matter of common knowledge how the proboscis is rubbed by the anterior pair of legs, which become contaminated therefrom.

Therefore the external carriage of germs from filth to food is possible, provided that it takes place within a relatively short time.

With regard to the internal carriage, the same observer has shown that, though there is no evidence that *B. prodigiosus* multiplies therein, it can live in the alimentary canal of flies for four to five days.

The investigation of the presence of *B. typhosus* in a fly is most difficult, because there are non-lactose fermenters present as normal denizens of the fly. Faichnie has shown that it tends to be present in the intestine, and not on the legs, but Cochrane's experiments show that it may be recovered from the external washings of flies. The bacilli so obtained were tested with typhoid serum, and gave positive reactions, and even by immunizing animals therewith and testing the serum so obtained against stock *B. typhosus*, positive results were obtained.

With regard to the spread of *B. typhosus* and *B. paratyphosus A* and *B* via the larva to the fly, the only experiments of real moment are those of Faichnie, who worked with uncultivated germs, the flies being bred in infected fæces. He showed that this was highly probable, though other workers have failed with cultivated material. Faichnie, however, did not say that he separated the larvæ which had fed upon the excrement therefrom, and therefore did not say that he had excluded the possibility of the newly hatched flies feeding upon the excrement. Hence the subject of the carriage from the larva to the imago is *sub judice* at present.

Finally, as far as is known, flies do not suffer in health from the carriage of germs pathogenic to man.

Is the fly, with its non-lactose fermenters, the original home of the enteric fevers of man? We have not sufficient knowledge at present to discuss this subject, but we have said enough to demonstrate its importance.

For epidemiological reasons, supported by bacteriology, it appears probable that 'epidemic or summer diarrhœa' is due to Morgan's bacillus spread by flies.

For epidemiological reasons it seems possible that flies may infect food with the germs of the choleras.

There is no doubt that flies can obtain the tubercle bacillus from sputum, keep it alive in the crop for three days, and in the intestine for twelve or more days, and thus can contaminate food by the fæces up to the fifth day, and sometimes up to the sixth to fourteenth day.

Anthrax spores remain infective in flies for twenty days, being found in the fæces, while in dead flies the period is indefinite; moreover, they can pass via the larva to the imago.

At this stage we may point out that the infection of wounds produced by biting flies may be carried out by the agency of non-biting flies. Patton was the first to point out that non-biting flies—*e.g.*, *Musca pattoni*—suck the blood which exudes from the bites made by tabanids, stomoxys, etc. As *M. pattoni* breeds in bovine excrement, the possibility of bacterial infection of the wound is to be remembered.

The possibility of the Klebs-Loeffler bacillus and allied organisms being spread by flies must not be forgotten, though there is no evidence that this is the usual form of infection; still, judging from a case of conjunctival diphtheria seen in Khartoum by Chalmers, it is possible that it may occur as the means of infection of unusual sites, as Graham Smith has shown that the germ can live in the crop and intestine for twenty-four hours and longer, and, further, that the vitality may be *under-estimated*.

Ophthalmia, for epidemiological reasons, especially the Egyptian ophthalmia, is believed to be spread by flies, and Perry and Castellani have shown that *Microneurum funicolum* de Meijere, 1905—the eye-fly of Ceylon and Java—is a possible carrier of the Koch-

Weeks bacillus and a spreader of the severe forms of ophthalmia found therein.

Flies can also carry the plague bacillus in living virulent form in their alimentary canal for forty-eight hours, but they do not play any great part in the dissemination of the disease.

They also may be regarded with suspicion as spreaders of coccal infections, as these germs have been found in their alimentary tracts, as well as externally.

Flies are therefore of great importance as intermediary hosts of bacteria, and as such are worthy of study.

We require to know the house-flies of the tropics, but these are little investigated, though Nicholls at St Lucia has found the following breeding in human fæces:—

Drosophila melanogaster Meigen.
Limosina punctipennis Wiedemann.
Sepsis species.
Sarcophaga aurifinis Walker.
Sarcophaga species.
Sarcophagula species.

In Africa and the East generally:—

Pycnosoma marginale Wiedemann.
Pycnosoma chloropyga Wiedemann.

In India by Patton:—

Musca domestica Linnæus.
Musca domestica var. *determinata* Walker.
Musca nebulo Fabricius.
Musca pattoni Austen.

In England the investigation is much more complete—*e.g.*:—

Musca domestica Linnæus
Musca corvina Fabricius.
Calliphora erythrocephala Meigen
Calliphora vomitoria Linnæus.
Lucilia cæsar Linnæus.
Pollenia rudis Fabricius.
Fannia canicularis Linnæus.
Fannia scalaris Fabricius.
Anthomyia radicum.
Sarcophaga carnaria Linnæus.
Sepsis punctum Meigen.
Piophila casei Linnæus.
Scatophaga stercoria Linnæus.
Drosophila fenestrarum.

Also *Scenopinus fenestralis* and species of Stomoxys and of Psychoda; but these two last have already been described, and now it behoves us to look at the classification and structure of the non-biting flies.

We have already given the classification of the Diptera in Chapter XXXIII., and need only consider that of the families.

Family Phoridæ.

Phora femorata occurs occasionally in houses. *Aphiochæta ferruginea* Brunner causes intestinal myiasis.

Family Scenopinidæ.

Scenopinus fenestralis Linnæus is the so-called window fly, which is probably the only household fly which is not injurious to health.

FAMILY EMPIDÆ.

Orthorrhapha brachycera with medium or small bodies and small heads. Antennæ with the first two joints very small and hardly distinct, the third joint annulated, often with terminal bristle. Wings with three large complete basal cells, of which the third is shorter than the second. The posterior basal transverse vein is parallel to the border of the wing. Empodium membranaceous.

It is doubtful whether these insects attack man. As a rule they live on the juices of other insects and plants.

SUBORDER II. CYCLORRHAPHA.

Section 1: Aschiza.—This group includes the family Syrphidæ, of which no species is known to bite man.

Section 2: Schizophora.—This group includes the true flies characterized by a distinct frontal lunula and a frontal suture; antennæ with three simple segments, and an arista which is generally dorsal. They may be classified into—

Muscoidea.

Synonym.—*Eumyidea.*

This superfamily is divided into:—

TRIBE 1: *Muscoidea acalyptratæ*, without squamæ covering the halteres.

TRIBE 2: *Muscoidea calyptratæ*, with squamæ covering the halteres.

MUSCOIDEA ACALYPTRATÆ.

A large number of families are grouped together under this division, of which the most important for our purposes are—

1. Sepsidæ.
2. Oscinidæ.
3. Drosophilidæ.
4. Borboridæ.

These families can be recognized as follows:—

A. Subcostal (auxiliary) vein present. Radial 1 (first longitudinal) terminates near or beyond the middle of the wing.

  I. With a distinct bristle on each side of the face near the oral margin.

   Front never bristly near antennæ; abdomen somewhat elongate, cylindrical, usually narrowed near base. Small black flies found about decaying matter—*Sepsidæ*.

B. Subcostal vein absent, vestigial, or incomplete. Radial 1 usually ends in the costa before the middle of the wing. Head not produced into lateral processes.

  I. Hind metatarsi incrassate and usually shorter than the second joint—*Borboridæ*.

II. Hind metatarsi not incrassate and always longer than the following joint.
   (a) Discal and basal cells united: anal cell absent: front bare, or at most bristly above; small, usually light-coloured flies—*Oscinidæ*.
   (b) Discal and second basal cells separated: anal cell complete, though small. Scutellum not elongate and triangular, and without spines on margin. Oral vibrissæ present. Arista long plumose—*Drosophilidæ*.

FAMILY SEPSIDÆ.

The Sepsidae include the genus *Piophila*, of which the species *Piophila casei* Linnæus may cause intestinal myiasis. *Sepsis violacea* is a dung-fly often found in houses.

FAMILY OSCINIDÆ Latreille, 1804.

Muscoidea acalyptratæ with front without bristles: crown with only a few short bristles, border of mouth without vibrissæ. Middle tibia with small spurs: costa of wings without bristles. Subcostal vein absent. Anterior of two small basal cells united with discal cell: posterior wanting.

The genera with which we are concerned are *Microneurum* Becker, 1903, and *Hippelates* Loew, 1863.

Microneurum Becker, 1903.

Microneurum funicola de Meijere, 1905.

Synonym.—*Siphonella funicola* de Meijere, 1905.

This little fly is the common 'eye-fly' of Ceylon and Java, which causes great annoyance by hovering in front of the eyes, especially when reading or writing indoors.

It is said to suck blood, but our experience is quite opposed to this. It chiefly attacks the eyelids and the ears, and since the experiments performed by Sir Allan Perry and Castellani it has been suspected as a possible carrier of the Koch-Weeks bacillus, which is the cause of severe attacks of conjunctivitis. It objects to the odour of such substances as Odol, which may be used to drive it away.

Hippelates Loew, 1863.

Some authorities consider this genus not well founded, and state that a revision of the genera of the Oscinidæ is urgently required.

The species *Hippelates flavipes* Loew, *H. plebejus* Loew, and *H. pusio* Loew, attack men and domestic animals by darting at the eyes and other parts of the body in search of moisture or perspiration. They also attack wounds, sores, scratches, ulcers. Their life-history is unknown. In habits they are diurnal, frequenting open and sunny places. They are found in the southern United States, in Florida, Alabama, and Texas. Veils can be used as a protection, and eucalyptus oil or a menthol spirit lotion can be sprinkled on the coat collar to drive them away.

FAMILY DROSOPHILIDÆ.

This family includes the species *Drosophila ampelophila* Loew, commonly called the fruit-fly, and found hovering over fruit in houses; and as it is attracted by excrementum it must be regarded as dangerous. There are a large number of species of *Drosophila* known.

FAMILY BORBORIDÆ.

This family includes *Borborus equinus*, a small fly sometimes found in houses.

MUSCOIDEA CALYPTRATÆ.

MUSCINÆ.

Musca Linnæus, 1761.

Musca domestica Linnæus, 1761.

Musca: face in its lower part silky yellow; shot with blackish-brown. Median stripe black; antennæ brown, palpi black.

Thorax dusty grey, with four equally broad longitudinal stripes.

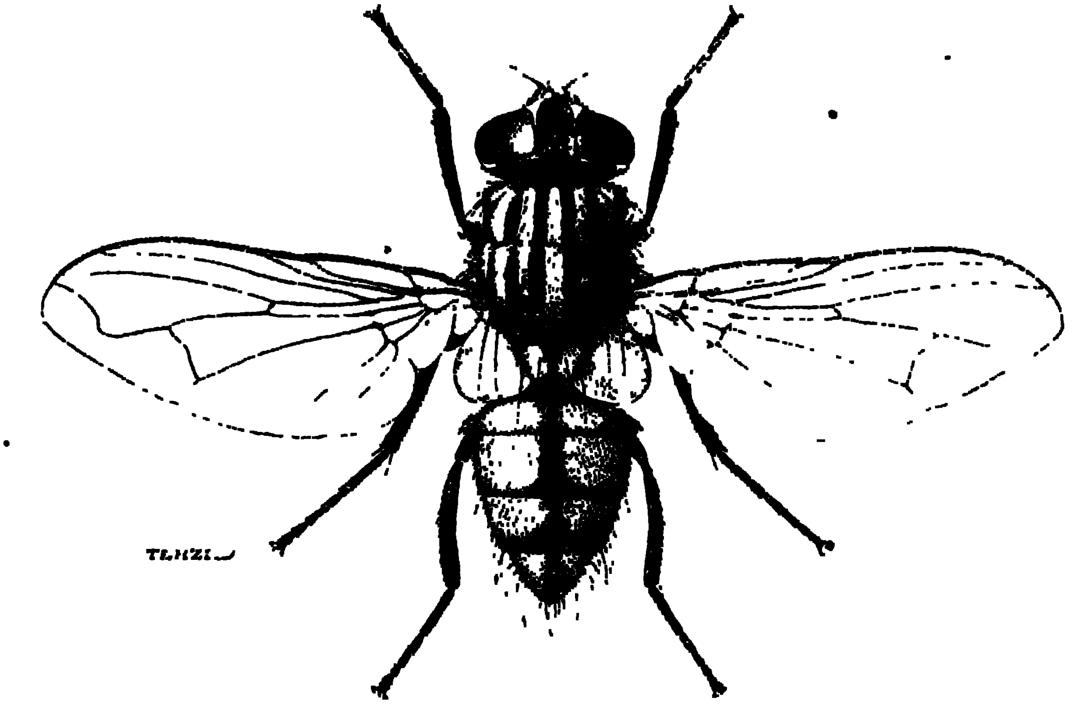

FIG. 468.—*Musca domestica* LINNÆUS. (×6.)

Scutellum grey, with black sides. Wings tinged pale grey with yellowish base. Legs blackish-brown. Abdomen yellowish, with dorsal blackish-brown line, except the last segment, which is entirely blackish-brown. Eyes separated by a wide frontal stripe in the female, and near together in the male. Length, 6 to 7 millimetres; wing breadth, 13 to 15 millimetres.

Remarks.—It has been known for many years that flies can carry micro-organisms on their legs. In 1888 Celli proved that flies, fed upon pure cultures of typhoid bacilli, were able to transmit virulent bacilli with their excrement. Early observations also proved that flies were capable of transmitting cholera. In the Spanish-American War, in the Army Concentration Camps of 1898, flies were found to be spreaders of typhoid. Lime was sprinkled on the fæcal pits, and the flies on the soldiers' mess-table were noticed to have their legs whitened with the lime.

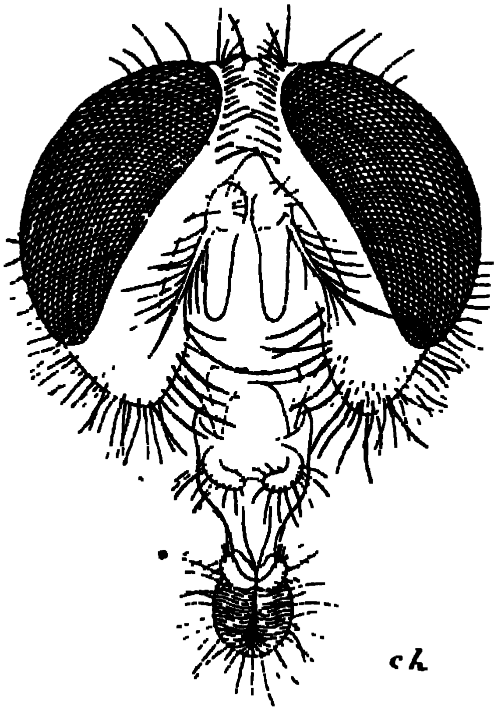

FIG. 469.—HEAD OF *Musca domestica* LINNÆUS: FEMALE. (After C. J. Martin.) *ch.*, Pseudo-tracheæ.

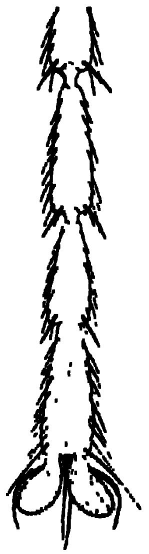

FIG. 470.—LEG OF *Musca domestica*. (After C. J. Martin.)

The flies which breed in human excrement in America are: (1) *Musca domestica*, house-fly; (2) *Drosophila ampelophila*, fruit-fly; (3) *Fannia canicularis*, little house-fly; (4) *F. brevis*, little house-fly; (5) *Stomoxys calcitrans*, stable-fly; (6) *Phora femorata*; (7) *Sarcophaga trivialis*.

Of these the most common are the house and the stable flies. The house-fly is 98 per cent. of all flies infesting houses.

In the Boer War of 1900-02 flies were held to be great spreaders of typhoid. In 1902 a paper, entitled 'An Inquiry into the Influence of Soil, Fabrics, and Flies in the Dissemination of Enteric Infection,' was published by Firth and Horrocks in the *British Medical Journal*, and they showed that the ordinary house-fly (*Musca domestica*) can convey enteric infective matter from excreta or polluted materials, or objects on which they may walk, rest, or feed. Such infective matter appears to be attached to their heads (mandibles), legs, wings, and bodies. Klein has grown the typhoid bacilli from flies caught in an infected area.

Flies have long been accused of being the spreaders of dysentery, and recently this view has been experimentally proved by several authors, including one of us. Other diseases, including intestinal myiasis, are said to be spread by flies.

The flies found by Newstead in houses in Liverpool, or bred from refuse and excreta, were *Musca domestica* in quite 90 per cent. of all flies, while the other species met with were—*Calliphora erythrocephala*, the blow-fly; *Scatophaga stercoraria*, the dung-fly; *Borborus equinus*, a small fly; *Stomoxys calcitrans*, the stable-fly; *Fannia canicularis*; *F. scalaris*; *Anthomyia radicum*, the root-fly; *Psychoda phalænoides*, the owl-midge.

Morphology.—The vertex shows three ocelli, situated on a slightly raised ocellar triangle, which is surrounded by another triangle, the vertical triangle.

Between the upper and lateral edges of the clypeus (face) and the lower edge of the epicranium can be seen the crescentic opening of the ptilinum.

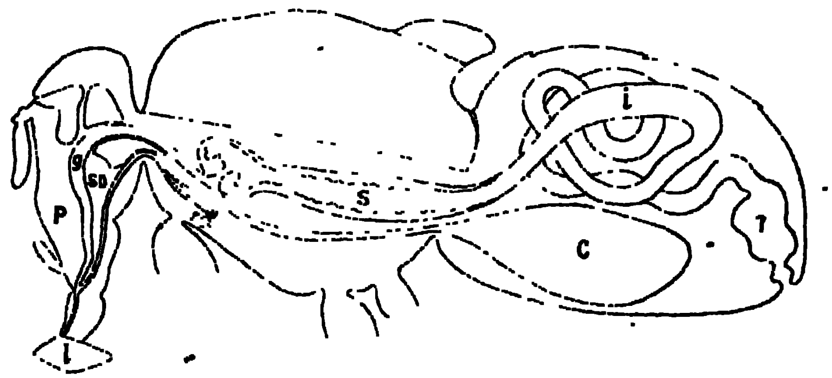

FIG. 471. -ANATOMY OF *Musca domestica*.
(After C. J. Martin.)

l., Labella; *P.*, proboscis; *S.D.*, near salivary duct; *g*, gullet; *S*, mid-gut; *i.*, intestine; *C*, sucking stomach; *T*, rectum.

The proboscis consists of the rostrum, the haustellum (proboscis proper), and the labellæ. The rostrum is a truncated cone containing the pharynx; the haustellum is grooved anteriorly to contain the labrum, epipharynx, and the hypopharynx. Posteriorly it is strengthened by a sclerite called the 'theca,' which distally carries the fork (*furca*).

The labrum and the epipharynx, with the hypopharynx, as is usual, form the pharyngeal tube, while the hypopharynx contains the salivary or hypopharyngeal tube. The labellæ are complicated organs with a number of channels (pseudo-tracheæ) on their distal surface.

Each labella has lobes anterior, middle, and posterior, with respectively twelve, twenty-one, and three channels, which eventually run to the oral aperture, which lies at the base of the oral pit. This pit is kept open by two discal sclerites. In the oral pit the pseudo-tracheæ cease, and the sides of the channels are covered by overlapping teeth.

The pro- and meta-thoraces are much reduced, while the mesothorax is well developed, and shows a typical structure. The venation of the wings may be briefly described by saying that the costa and subcosta are well marked, and the usual costal and first costal cells are present. Radius 1 cuts off the subcostal cell; R. 2 and 3 the first radial, and R. 4 and 6 the third radial; while media 1 and 2 bound the radial and fifth radial cells, which are separated by the radio-median nerve. Median 3 and cubitus 1 cut off the median and second median cells, which are separated by the medio-cubital vein. The anal vein is incomplete, and therefore does not separate the cubital and anal cells.

The abdomen consists of eight segments in the male, and nine in the female. The first segment in both sexes is rudimentary, and fused with the second. The second, third, fourth, and fifth are well developed. The sixth, seventh, and eighth in the male are atrophied, and surround the anal and genital orifices. The sixth, seventh, eighth, and ninth in the female form the long ovipositor, which can be retracted into the abdomen.

The pharyngeal tube mentioned above ends in the pharynx, which has a chitinous wall, the fulcrum. The œsophagus runs into the thorax, where it opens into the proventriculus, and sends a long duct to the trilobed crop which lies in the abdomen. The proventriculus is really a valve which leads to the chylific ventricle. This tube is narrow in front and wide behind, and much coiled. At the junction with the Malpighian tubes it becomes the intestine, which runs to the rectum. There are the four usual rectal glands.

The salivary glands are two long tubes whose ducts unite in the head and open into the salivary duct of the hypopharynx. The labial glands lie in the proboscis at the base of the labellæ, and by their secretion keep the tip moist.

The reproductive organs consist in the female of ovaries, spermathecæ, accessory glands and ducts, and the ovipositor. In the male they consist of testes, vasa deferentia, an ejaculatory duct, and penis.

Life-History. This was first studied by de Geer in 1752-78, next by Bouché in 1834, Packard, junior, in 1873, and more recently by ourselves and a number of other people. The most recent works are those by Newstead in Liverpool and Hewitt in Manchester.

The house-flies lay their eggs by preference in human fæcal matter when somewhat decomposed, in horse-manure, goat-manure, cow-dung, and in fermenting vegetable substance, on which the larvæ can feed when hatched.

But these grubs can eat textile fabrics and paper when in need of nourishment. Usually the fly works its way into the rubbish-heap or loose earth to lay its eggs, but this is not invariable.

FIG. 472.—EGG, LARVA, AND PUPA OF *Musca domestica*.
(After C. J. Martin.)

The time required for the development to be gone through depends upon the temperature of the air, being most rapid from 22° to 35° C.; upon the food, being more rapid when animal food is available; on moisture, which is most necessary; and upon fermentation, which is also necessary. The egg takes from one to three days to hatch into the larva, which lives rather less than a week, and then turns into the pupa, which produces the imago.

The whole time required is usually twelve to twenty days, and never less than eight days.

Aldridge gives the following table for India :—

Stage.		Hot weather.		Cold weather.
Eggs	..	One day	..	Two days.
Larvæ	..	Five days	..	Fourteen days.
Pupæ	..	Three days	..	Five days.

In Colombo, Ceylon, we found the development to be quick, and to resemble the times given in Aldridge's hot-weather table.

Egg.—The imago becomes sexually mature in ten to fourteen days, and eggs are laid as soon as the fourth day after fertilization, usually 120 to 150 eggs laid being in a batch. The egg is cylindrically oval, being broader posteriorly, and has two curved ribs along its dorsal aspect. It hatches by splitting at the dorsal portion of the anterior end.

Larva.—The larval life is divided into periods or instars by the ecdyses.

First Instar.—The larva is 2 millimetres in length, with a slender body, the head being at the narrow end, with a spiny area on the anterior ventral edge of each segment, and posteriorly two stigmatal openings. This stage lasts twenty-four to thirty-six hours.

Second Instar.—The larva develops a pair of anterior spiracles. This stage lasts twenty-four hours.

Third Instar.—The larva eats vigorously for the first two days, and then, ceasing to feed, still increases in size. This stage lasts three to four days, and ends in pupation. The larva has a well-developed alimentary canal.

Pupation.—Pupation takes place in three to four hours, and consists of the larva contracting (especially anteriorly) inside its own skin, from which a puparium with rounded ends is formed. Length about 6·3 millimetres, which is at first creamy-yellow, but later becomes dark brown. This is a typical coarctate pupa, around which the spiral locomotory pads may be seen.

Pupa.—The pupal stage lasts about three to five days, when the imago, dilating its frontal sac, ruptures the anterior end into dorsal and ventral portions, the whole separating by a circular split at the sixth segment.

Fly.—The young fly is at first underground or in the middle of a rubbish-heap, through the interstices of which it makes its way to the surface by the aid of its ptilinum or frontal sac. When first hatched it is rather grey in colour, and has to allow its wings to dry before it is able to fly.

Habits.—After hatching the fly sets about to obtain food, and on this point it is not particular as to the kind, as anything, from typhoid fæces and dysenteric fæces to a pudding, are quite agreeable to its oral lobes. It also has a liking for human sweat, much to the annoyance of a person desiring a rest on a tropical afternoon. It works all day, but rests at night in any place which is dark. It is not known whether it has a particular preference for the spots on which to defæcate, as fly-specks are abundant. It is believed to defæcate about fifty times in twenty-four hours. A number of experiments have been performed to see how far *Musca domestica* can fly, but they are not satisfactory. It is believed that a female fly becomes sexually mature and deposits ova in ten days after leaving the pupal case, that she lays four batches of eggs at intervals of ten to fourteen days, and that then she dies, but these figures must be received with great caution. Jephson believes that the limit of life of an adult fly is three weeks, but a hibernating or æstivating fly must live much longer. Indeed, a fly has been known to live sixteen weeks.

Enemies.—The enemies of the house-fly are numerous, and include fungi (*e.g.*, *Empusa muscæ*), protozoa (?), nematode worms (?), mites (*i.e.*, larvæ of *Trombidium muscarum* Riley, *T. muscæ* Oudemans, the genus *Pigmeophorus*, nymphs of *Tyroglyphus*), spiders, pseudo-scorpions, centipedes, larvæ of beetles, ants, wasps; also members of Cynipidæ, insects which produce galls on plants (*e.g.*, *Figites anthomyiarum* and *F. scutellaris* attack the maggots, while *Spalangia niger* of the Pteromalidæ lays its eggs in the pupæ); and *Stenomalus muscarum* is also a pupal parasite, as is *Nasonia brevicornis*, *Pachycrepoideus dubius*, and *Muscidifurax raptor*. Toads, lizards, and rats are expert fly-catchers.

Pathogenicity. It is a carrier of the bacilli of enteric fever, dysentery, cholera, infantile diarrhœa, framboesia tropica, anthrax, tuberculosis, ophthalmia, oriental sore, and parasitic worms (*e.g.*, *Ascaris lumbricoides*).

Calliphora Robineau-Desvoidy, 1830.

These are the blow-flies or bluebottles, of which *C. erythrocephala* Meigen is the common species.

Bacillus typhosus.	Man.	Man. · Typhoid carriers.	Bacilli in urine and fæces. — Ingestive.	Flies.	Bacilli on to human food. — Contaminative.

2. FLEAS.

These insects have been accused of spreading leprosy and tuberculosis, but only one bacterial disease of man has really been proved to be carried by them, and this is the plague.

The Plague.—The ætiology of plague has been placed on a sure footing by the labours of Kitasato, Yersin, Cantlie, Simpson, Thompson, Kolle, Martini, and the Special Committee already mentioned, together with the Second Indian Commission.

It is caused by the *Bacillus pestis* of Kitasato and Yersin, which is found in the fluid of the initial cutaneous vesicle, the buboes, the spleen, the blood, and the sputum in cases of pneumonia. When inoculated into monkeys, cats, rats, guinea-pigs, squirrels, mongooses, bats, jerboas, etc., it causes the typical disease, while in bovines and equines it only causes local reactions. Canines, birds, and reptiles appear to be immune. It causes a natural epizoötic in rats, which apparently is the true disease, from which that of man must be looked upon as an offshoot. In rats it produces either as acute or a chronic attack, the post-mortem appearances of which are different.

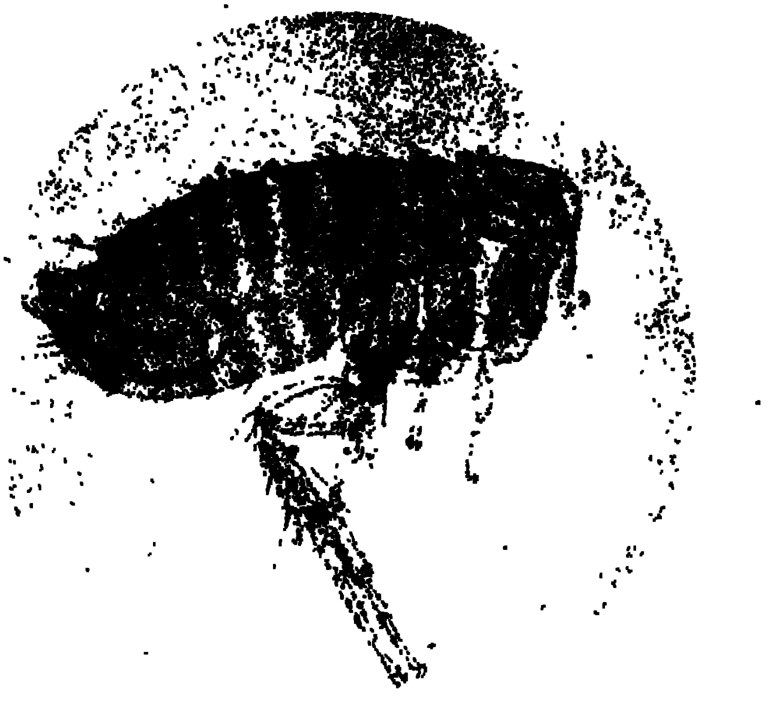

FIG. 473.—RAT FLEA.

In the acute type a bubo is found in 85 per cent. of infected rats, being present usually in the neck or axilla. If the bubo is absent, a plague rat can be recognized by the subcutaneous congestion, the purplish-red appearance of the muscles, the waxy, mottled, or finely granular appearance of the liver, the hæmorrhages, and the pleural effusions. The diagnosis can be confirmed by finding the bacilli in the bubo, the spleen, or the blood.

The chronic type of the disease consists of encapsuled caseous foci, or abscesses containing bacilli, and found in the spleen and other organs. This form plays no part in the spread of the disease.

The epizoötic does not continue with equal virulence all the year round, for it appears to be profoundly altered by the temperature, being diminished in the hot weather of the tropics and the cold weather of the Temperate Zone. Thus in Bombay the Plague Commission found 1,766 plague-infected rats in one week in the season December to May, and only 20 to 30 in the season June to November. The cause of this variation has already been given.

But all rats are not equally infected, for it was found in Bombay that there were two principal species, *Epimys norvegicus* and *E. rattus*, and that during the epizoötic period no less than 1,334 of the 1,766 belonged to the former species, while in the non-epizoötic period it alone carried on the disease. The reason assigned for this difference was that the numbers of the flea population of the two rats were very different, *E. norvegicus* possessing about double the number of *E. rattus*. Further, it was noticed that the curve of *E. norvegicus* infection began to rise about ten days before that of *E. rattus*, which points to the origin of the infection of the latter from the former in the first instance.

E. norvegicus, which is not nearly so numerous in Bombay as *E. rattus*, lives outside houses, for the most part in sewers, drains, and stables, and has a great facility for burrowing, and is a good climber. It, however, has never been found above the third floor of a house. It forms its nest in one of its burrows, and breeds all the year round, but has two special seasons, one in March and one from June to October, the average family being eight.

E. rattus is more common in Bombay than *E. norvegicus*, especially in houses, where it increases, relatively to the other, up to the third floor, but above that level it alone infects the house. It is not so common in gullies, compounds, stables, go-downs, and food and tea shops as *E. norvegicus*. The common meeting-ground of the two species appears to be the lower floors of houses, gullies, and go-downs. Though a domesticated rat, it can climb and burrow. It forms its nest in cupboards, heaps of firewood, etc., and breeds all the year round, but especially from June to October, the average family being five.

The spread of the plague from *E. norvegicus* to *E. rattus*, according to the experiments of the Commission, is neither by direct contact nor by air, soil, or food, but solely by the flea. Contact was excluded by placing healthy rats in the same room with plague-infected animals from which the fleas had been removed, when it was found that none of them developed plague. The experiment was kept up for a long time, replacing dead infected rats with freshly infected rats, and, further, the room was never cleaned out, so that the healthy animals lived in contact with the infected urine and fæces, and even ate food polluted therewith, and yet not one contracted plague, thus excluding transmission by contact, soil, and food.

Again, when healthy animals were suspended in cages 2 feet from the ground, so that the fleas could not get to them, or placed on the ground, and surrounded by 6 inches of tangle-foot, over which a flea cannot pass, as it is said to be incapable of jumping more than 4 inches, or surrounded by a curtain of wire gauze so fine that a flea could not penetrate it, and exposed to infection, they escaped, though others not so protected became infected, thus disproving aerial infection. Further, the transmission by the rat-flea was proved by constructing a glass box, inside which two wire cages were placed at a little distance, but side by side, each standing in a tray filled with sand. Each cage had a lid, through which rats, food, water, etc., could be introduced, and the whole apparatus was covered in with fine muslin to prevent the escape of the fleas. A plague-infected rat and a number of rat-fleas were placed in one cage. When this rat died, a healthy rat was placed in the other cage, and after some time the dead body of the infected rat was removed, when it was found that the new rat became infected with plague, and fleas containing plague bacilli were found upon it. This experiment was repeated many times, 15 per cent. of the exposed rats taking the disease. Further, fleas infected by biting plague rats, when placed upon healthy rats, produced the disease in 55 per cent. of the experiments.

The Commission calculated that the blood of an ordinary plague rat in two-thirds of the cases contains more than 100,000,000 bacilli per cubic centimetre, and that a flea's stomach could hold 0·5 cubic millimetre of blood. Therefore, when the flea gorged itself on the average plague-stricken rat it received at least 5,000 bacilli. These bacilli are found only in the stomach and in the alimentary canal posterior to that viscus, especially the rectum, and escape from the flea solely with the faeces. It was proved, however, that the bacilli multiplied in the body of the flea by allowing infected fleas to feed solely on uninfected rats, a fresh one being supplied each day, when abundant bacilli were found up to the twelfth, and once to the twentieth day, thus proving that multiplication must have taken place, otherwise the original number of bacilli would have become much diluted by the feeds with fresh blood. Further, it was discovered that the proportion of fleas in whose stomach multiplication took place was six times greater in the epidemic than in the non-epidemic season. In the former season the bacilli could be found easily up to the fourth and even to the twelfth day, while in the latter never after the seventh day. Infected fleas were found to transmit the disease for seven to fifteen days.

The method of infection probably is in one of two ways—either faecal pollution of the proboscis, or else faecal pollution of the wound made by the proboscis, which was found quite large enough for the purpose of introducing the bacilli into the skin. Both males and females can transmit the disease, but it was found that one infected flea alone was unlikely to do so. The flea most commonly found on rats, and the one by which the infection in these experiments was usually spread, was *Xenopsylla cheopis*, but others—*e.g.*, *Ceratophyllus fasciatus* and *Pulex irritans*—were found also capable of causing the disease.

Bacot and Martin have proved the inoculative method of infection in *Ceratophyllus fasciatus*, which, when blood-sucking, injects the bacilli, when they are present in its stomach in such numbers as to cause temporary obstruction at the entrance to that organ.

With regard to the spread of the disease to man, the Commission believes that the infection generally comes from *Epimys rattus*, because the habits of that rodent bring it into close relationship with man, and because the curve of its epizoötic begins to rise ten to fourteen days before that of the epidemic. This period is calculated to be made up of three days, during which the flea leaves the dead rat, to which is added another three days, which is the incubation period of plague in man, and five and a half days, which is the average duration of the fatal illness in man.

Xenopsylla cheopis appears to be the flea by which plague is spread from *Epimys rattus* to man. This rat-flea will not merely bite man when it cannot get rat's blood, but is capable of living for three to four weeks on man's blood, and is often found on human beings after inspection of plague-stricken houses.

Further, it is believed that the spread of plague is due, not to migration of rats, but to the carriage of infected rats on ships, and of fleas in merchandise or on human beings. The Commission apparently consider the last to be the most important method.

Pneumonic plague, which occurs only in 2·5 per cent. of cases during bubonic epidemics, spreads from man to man by bacilli carried by the air, for Strong and Teague demonstrated that the sputum in invisible droplets containing viable plague bacilli was frequently to be found in the air near a patient. Teague and Barber have shown that the fine droplets of sputum disappear very quickly unless there is a considerable amount of aqueous vapour in the atmosphere, as is found in very cold climates, and hence the tendency for pneumonic plague to spread in those rather than in warm climates. On the other hand, the bubonic or septicæmic is not spread from man to man, but from rats to man. The epizoötic is the real disease, and the epidemic is only an offshoot.

The above ætiology explains fully the predisposing causes of sex, women staying more in the house than men; of house, of season, of climate, and also the carriage of the disease from one place to another by people, fodder, grain, bales of cotton and clothing, rags, etc.

Verjbitski in 1908 showed that bugs could act as carriers of the bacilli, and this has been confirmed by Jordansky and Kladnitsky, while Walker considers *Clinocoris rotundatus* to be one of the carriers of plague in India, having found 22 per cent. infected with *B. pestis* when collected from infected native huts. Moreover, he successfully transmitted the disease from man to the rat by means of *C. rotundatus*.

In California, Wherry, McCay, and others have shown that the ground-squirrel (*Citellus beecheyi*) is subject to plague, and that its commonest flea, *Ceratophyllus acutus* Baker, is the vector from squirrel to squirrel, and, further, that this flea will bite man Further, they record a subacute case of plague in a boy where the infection was believed to be acquired by contact with ground squirrels. With regard to the outbreak in Manchuria and North China, Gray suggested that it started among men who handled the tarbagan (*Arctomys bobæ* Schreb), which is susceptible to epizoötic plague, and that these men on returning to their homes introduced the disease into three provinces, as pneumonic and septicæmic plague, while it was spread by the agency of the breath and personal contact of clothes and belongings by coolies travelling in parties and sleeping together in overcrowded insanitary inns, especially as the cold of the winter induced an indoor existence. These travelling parties infected adult males who stayed at the inns or were travelling, and so it spread to the ordinary population. No infected rats could be found, in 20,000 examined, while isolation of the patients and their contacts, together with efficient disinfection, were sufficient to diminish the death-rate. Further researches, however, tended to show that, though the tarbagan suffers at times from plague, the epizoötic is not extensive, and its direct relationship to human plague negligible. The pneumonic form of plague may be in epidemics, especially in cold weather, but it is also to be noted that, although it starts from association with an epizoötic, it tends to die out without being succeeded by a bubonic outbreak, but it may infect rats and so cause a bubonic outbreak. The marmot (*Spermophilus citellus*), which is common around Mukden, was susceptible to the infection. There has been an epizootic in Suffolk, and a few cases of bubonic plague in man.

We therefore have to consider the rôle of the flea and the role of the vertebrate in plague, and with regard to the latter there does appear to be some such sequence as this:—The *enzoötic*, the *epizoötic* ; and these become in man:—The *endemic*, the *epidemic*, the *pandemic*.

The fleas we have described in Chapter XXXIV. (p. 857), but it is necessary to say a few words with regard to the rats.

CLASS MAMMALIA.

SUBCLASS EUTHERIA.

ORDER GLIRES Linnæus, 1758.

Definition.—Eutheria with toes armed with claws. Size usually small or medium. Front teeth chisel-shaped and separated from the grinding teeth by a wide space.

Classification.—This classification is taken from Swenk:—

A. Upper front teeth two, both large (suborder *Simplicidentata*).

- I. *Fur not sprinkled with quills.*
  - (*a*) Tail very broad, flat, scaled; hind feet webbed; size large—*Castoridæ*.
  - (*b*) Tail round or compressed; hind feet not webbed; size small to medium.

1. **Fore feet modified for digging, their claws very large; eyes and ears very small; form stout and short; large external cheek pouches**—*Geomyidæ*
2. Fore feet not modified for digging; their claws normal, eyes and ears generally large; form slender.
    - (A) Grinding teeth at least four in each jaw, tail long-haired, generally bushy, not scaled—*Sciuridæ*.
    - (B) Grinding teeth not more than three in each jaw, or if four (Perognathus and Zapus), the tail closely haired, sometimes scaly.
    - (C) With large external cheek pouches—*Heteromyidæ*.
    - (D) Without external cheek pouches:—
        - (1) Hind feet not greatly elongated, little if any longer than front feet, tail not longer than rest of body—*Muridæ*
        - (2) Hind feet greatly elongated, much longer than front feet; tail much longer than rest of body—*Zapodidæ*

II. *Fur thickly sprinkled with sharp, stiff, spine-like quills*—*Erethizontidæ*.

B. Upper front teeth four, the second pair minute and placed directly behind the first pair; hind legs much longer than front legs; ears very large, tail very short (suborder *Duplicidentata*)—*Leporidæ*

FAMILY SCIURIDÆ GRAY, 1821.

Squirrels and Marmots.

The genera of the Sciuridæ, which concern us, may be recognized by the following table taken from Swenk:—

A. Sides without a furred membrane (subfamily *Sciurinæ*, true squirrels and marmots).
- I. Tail long, much over one half of length of body; form slender, coloration usually spotted or streaked.
    - (*a*) Cheek pouches absent, tail bushy, the hairs growing outward, arboreal (squirrels)—*Sciurus*.
    - (*b*) Cheek pouches present, large; tail well haired, but not bushy, mainly terrestrial
        - 1. Nail of thumb well developed; back conspicuously striped lengthwise with five dark and two or four white stripes.
            - (A) Premolars in upper jaw one on each side; back with two white stripes; rump rufous; tail with hairs shorter than rest of body (eastern chipmunks)—*Tamias*
            - (B) Premolars in upper jaw two on each side; back with four white stripes; rump greyish; tail with hairs as long as rest of body (western chipmunks)—*Eutamias*
        - 2. Nail of thumb rudimentary, back striped lengthwise with seven lines alternating with six rows of spots, or irregularly and indistinctly spotted with whitish, or plain without either distinct spots or streaks (ground squirrels)—*Citellus*.
- II. Tail short, less than one-half of length of body; form stout, coloration always plain.
    - (*a*) Skull highly arched, causing the head to appear convex above, tail very short, flattened; thumb-nail well developed, normal, fur short and full (prairie dogs)—*Cynomys*.
    - (*b*) Skull nearly straight, causing the head to appear flat above; tail short, bushy, not flattened; thumb-nail broad and flat; fur long, coarse, and heavy (woodchucks)—*Marmotta*.

B. Sides with a densely furred membrane joining front and hind legs (subfamily Pteromyinæ, flying squirrels)—***Sciuropterus***.

Genus Citellus Oken, 1816.

Synonym. -*Spermophilus* F. Cuvier, 1825; *Citellus* Lichtenstein.
Definition. -As above.
Type Species. - *Citellus citellus* Linnæus, 1766.
We are, however, concerned with *C. beecheyi* and with *M. bobak*.

Citellus beecheyi Richard, 1829.

Definition. Citellus of large size with large prominent ears. Tail more than two-thirds of body-length. Colour above mixed black and pale yellowish brown.
Remarks. This is the ground squirrel of California mentioned above.

Genus Marmotta Blumenbach, 1779.

Synonym. - *Arctomys* Storr, 1780.
Definition. As above
Type Species. -*Marmotta marmota* Linnæus, 1758.

Marmotta bobak Muller, 1776.

Definition. Marmotta of medium size resembling the type, but of uniform colour, being above yellowish brown, overlaid with black.
Remarks. This is the tarbagan of Mongolia and Central Asia.

FAMILY MURIDÆ Gray, 1821.

Rats and Mice.

The genera of the Muridæ, which concern us, may be recognized as follows: —

- A. Crowns of grinding teeth, with tubercles arranged in transverse rows.
  - I. Rows of tubercles in grinding teeth three, very distinct in upper jaw; tail long and scaly. Subfamily *Murinæ* (Old World rats and mice).
  - II. Rows of tubercles in grinding teeth two, tail generally hairy Subfamily *Cricetinæ* (American rats and mice)
- B. Crowns of grinding teeth divided into raised loops or triangles of enamel, not tubercular.
  - I Upper front teeth narrow, compressed each one thicker than wide at base; body not clumsy; tail always long; eyes and ears large and prominent Subfamily *Neotominæ* (wood rats and cave rats) *Neotoma*
  - II. Upper front teeth broad, each one wider than thick at base; body clumsy; tail short; eyes and ears small and inconspicuous. Subfamily *Microtinæ* (voles and lemmings)

Subfamily Murinæ Baird, 1857.

Definition. As above.
Remarks. The Murinæ comprise the genus *Epimys* Trouessart, 1857, to which belong the rats and mice, of which two are of great importance in the spread of plague viz., *Epimys rattus* and *E. norvegicus*.

Genus Epimys Trouessart, 1857.

Definition. Murinæ with first and second upper molars, with two tubercles on inner side. Upper incisors with outer cutting edge entire.

Epimys rattus Linnæus, 1758.

Synonym. -*Mus rattus* Linnæus.
Slender rats with very pointed muzzles and large out-standing ears, large prominent eyes, long tail, and greyish-black fur.

The tail, which is 25 per cent. longer than the length of the head and body together, is brown and regularly annulated. Feet medium-sized, but comparatively long and slender.

Body variable, 14 to 19 centimetres in length. Colour variable: light rufescent, brown on the dorsum, white or grey on the venter, but may be darker or lighter. Mammæ two to three.

There are two varieties of this rat: ***alexandrinus***, which is larger and heavier; and ***rufescens***, which is smaller and redder; but there are any number of intermediate species. It breeds frequently throughout the year.

It is essentially a house rat, living in the tiles or thatch of the roof, or in holes and recesses in the floor, but it will live in the crowns of cocoanut trees.

Its pathogenicity is important, for it is the plague rat of Upper India. It is supposed to have entered Europe with the Asiatic invasion.

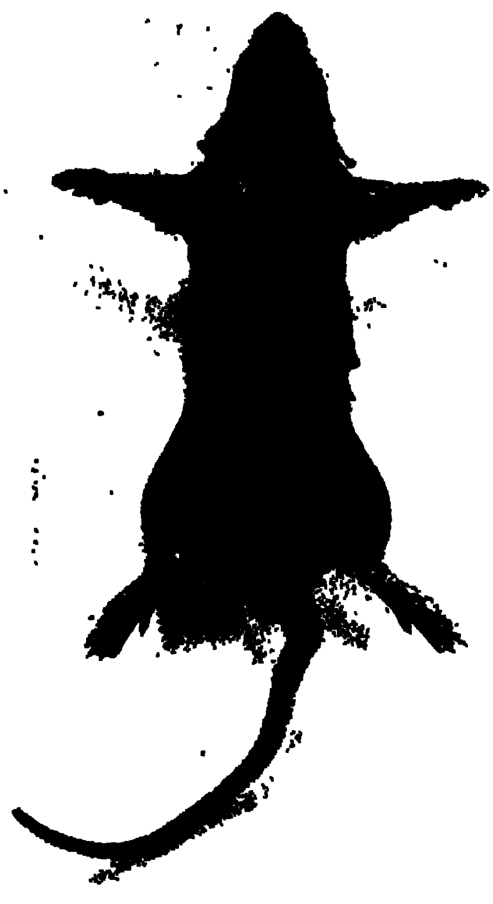

FIG. 474.—RAT. PLAGUE RESERVOIR.

Epimys norvegicus Erxleben, 1777.

Synonym. *Mus decumanus* Pallas, 1778.

Large, heavy rats, with heavy, uniformly tapering tails; dark coloured dorsally, lighter coloured ventrally; only 89 per cent. of the length of the head and body. Heavy, flesh-coloured feet, short round ears, and broad heavy snout.

Colour brown on the dorsum and dirty white on the venter. Footpads large; heart-shaped mammæ ten to twelve in number.

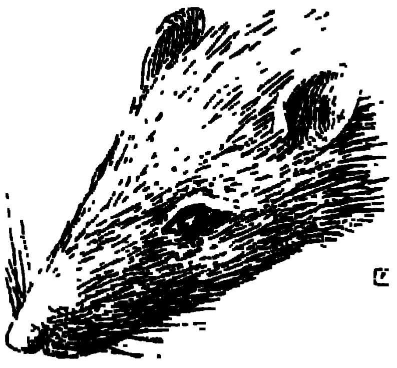

FIG. 475.—HEAD OF *Epimys rattus*.
(After Hossack.)

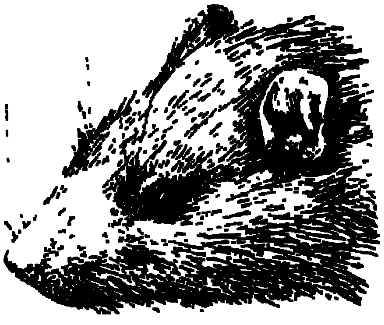

FIG. 476.—HEAD OF *Epimys norvegicus*.
(After Hossack.)

This is the brown sewer or ship rat, which is supposed to have come from China to Europe, and from Europe to India. It is the plague rat of Bombay It is very prolific, producing several litters of eight to ten young per annum.

The chart of plague is as follows:—

PLAGUE.

Organism.	*Infected Host.*	*Infected Reservoir.*	*Transmission.*	*Propagative Host.*	*Infection.*
Bacillus pestis.	Man.	Murinæ.	Bacilli obtained by blood-sucking. — Ingestive.	Fleas.	Bacilli in fæces into wound by bite. — Contaminative. More rarely inoculative.

3. LICE.

Relapsing Fevers.—With the downfall of Schaudinn's views many authorities consider spirochætes to be bacteria—*e.g.*, Dobell considers them to be such because the longitudinal division is said to be based on imperfect observation, and hereditary transmission can occur with *Bacillus cuenoti* in the germ cells of the cockroach.

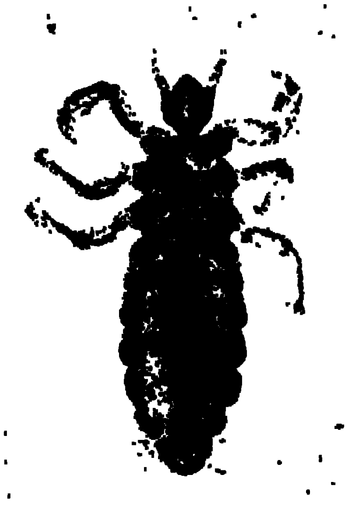

FIG. 477.—*Pediculus corporis* DE GEER, 1778: MALE. CARRIER OF TYPHUS, ETC.

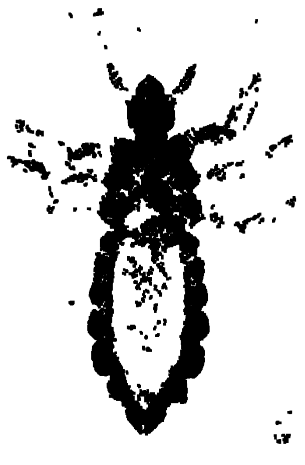

FIG. 478.—*Pediculus corporis* DE GEER, 1778: FEMALE. CARRIER OF TYPHUS, ETC.

(From a photograph by J. J Bell.)

Many of them are said to be flagellate; their nucleus is diffuse, like bacteria, and there is no conjugation, sex formation, or encystment known, and it would appear as though a coccoid-like infective granule was the important method of their infection of the host.

They therefore behave more like the bacteria than like animal parasites in the carrier.

For our present purpose relapsing fevers may be divided into two groups as follows:

I. The *Louse Group*, which is characterized by being carried by the louse. These are the European, the North African, the Indian, and the American types.

From the infective blood the spirochætes pass into the alimentary canal of the louse, and from thence into its cœlom, where they remain, and from there they find their way into the eggs, which are infective, as are their larvæ.

Infection of man is brought about by contaminative means— *i.e.*, the louse in biting causes irritation, the man scratches his skin, causing abrasions, and at the same time kills a louse, crushes it, and rubs it into the abrasions, which become infected. Nicolle and Blaizot believe that the organisms which are infective are granules just before they reappear as spirochætes. Sergent and Foley have stated that there were very small virulent forms in man during apyrexia.

In this life-cycle there is no definitive host, merely two hosts of equal value. Only the insect is the *preservative host* and the vertebrate the *intermediary host*.

I. THE LOUSE GROUP OF RELAPSING FEVERS.

Parasites.	*Preservative Host.*	*Preservative Reservoir.*	*Infection.*	*Intermediate Host.*	*Transmission.*
S. recurrentis, *S. berbera*, *S. carteri*, *S. novyi*.	Pediculus corporis	Lice by hereditary transmission	Small forms in body cavity. Contaminative	Man.	Small blood forms. — Ingestive.

Spirochætal Epidemic Jaundice. This is caused by *Spiroschaudinnia icterohæmorrhagiæ*, which may have its reservoir in rats, from which it probably escapes in the urine, and after living in water enters via the alimentary canal or the skin. It is believed to have been caused, but very rarely, as the result of a rat-bite. It is introduced here as a convenient place, though not known to be due to lice.

Parasite.	*Host.*	*Reservoir.*	*Method of Infection.*
Spiroschaudinnia icterohæmorrhagiæ.	Man.	Rats (?).	Contaminated water (?).

II. The *Tick Group*, which is characterized by being spread by the genus *Ornithodorus*. The known forms are the African (perhaps a separate East African), the Persian, the Colombian, with the Panamanian.

This group differs from the louse group in the pre-eminence of the *infective granule*, which, according to many authorities, is in itself doubtful.

Spirochætes enter the tick with the infective feed, bore their way into the cells of various organs, and break up into coccoid bodies, the infective granules. These granules pass into the second generation, and so the tick is a *preservative reservoir*. They also pass into the Malpighian tubules, from which they escape when the thick white Malpighian excrement is passed, which only takes place towards the end of a feed. The spirochætes now enter the new host via the hole made in the skin by the tick for its meal of blood.

II. THE TICK GROUP OF RELAPSING FEVERS.

Parasite	*Preservative Host.*	*Preservative Reservoir.*	*Infection.*	*Intermediate Host.*	*Transmission.*
Forms allied to *S. duttoni* and found in Africa, East Africa, Colombia, Panama, and perhaps in Persia	Species of *Ornithodorus*— e.g., *O. moubata*, *O. turicata*, *O. talaje*, and perhaps *O. savignyi*.	The ticks by hereditary transmission	The infective granules(?) — Contaminative.	Man	Blood spirochætes. — Ingestive

We have followed Balfour's suggestion that the Persian relapsing fever is not caused by *Argas persicus*, but by a species of Ornithodorus, probably *O. savignyi*. It must be admitted that many authorities disbelieve in the infective granule.

4. PHLEBOTOMUS FLIES.

Verruga Peruviana. It has been suggested that the carrier of this disease may be *Phlebotomus verrucarum* Townsend, 1913, but this appears to be very doubtful.

E. DISEASES OF UNKNOWN CAUSATION.

The evidence in favour of pellagra being an insect-borne disease has not increased, and many authorities believe it to be a deficiency disorder. The insects which were accused were species of Simulium and some Chironomid biting flies. There are suggestions that Rocky Mountain fever and tsutsugamushi disease are bacterial infections, and Noguchi has found a spirochæte in yellow fever.

Disease.	*Host.*	*Reservoir*	*Transmission.*	*Carrier.*	*Infection.*
Pappataci fever.	Man		Blood sucking. -- Ingestive.	Species of phlebotomus.	Bites. -- Inoculative.
Dengue fever	Man		Blood-sucking. - - Ingestive.	*Stegomyia culex* (?)	Bites. — Inoculative.
Yellow fever.	Man.	Man in mild attacks. — Monkeys (?).	Blood-sucking. — Ingestive	*Stegomyia calopus*	Bites — Inoculative.
Rocky Mountain fever.	Man		Blood sucking - - Ingestive.	*Dermacentor venustus* - *D. andersoni.*	Bites. - (?)
Tsutsugamushi disease.	Man	*Arvicola hatanezumi* (?)	Blood-sucking. — Ingestive	*Microtrombidium akamushi.*	Bites. -- (?)
Trench fever spirochæte (?).	Man.	—	Blood-sucking. - - Ingestive.	Lice.	Bites. - - Contaminative.
Typhus	Man	--	Blood-sucking. - Ingestive.	Lice.	Bites. - (?)
Acute anterior poliomyelitis	Man.	-	Blood-sucking. — Ingestive.	*Stomoxys calcitrans*	Bites. - Inoculative.

F. CHANCE TRANSMISSION.

Numerous blood-sucking and non-blood-sucking insects may by chance obtain an organism and carry it in their proboscis, and directly infect an open sore—*e.g.*, flies and yaws, which, according to Castellani's observations and experiments, is far from a rare occurrence.

G. IMPERFECT CARRIAGE OF PARASITES.

Parasites may develop up to a certain point in the alimentary canal of insects in which they are unable to complete their life-cycle—*e.g.*, the malarial germ in many anophelines only proceeds as far as the zygote.

H. TERMS.

TERMS FOR ANIMAL PARASITES.

Definitive host	Host with sexual life of parasites.
Intermediate host	Host with asexual life of parasites.
Intermediary host	No development of parasite. Merely carriage.
Definitive reservoir	Natural supply of infection of intermediate host.
Intermediate reservoir	Natural supply of infection for definitive host.
Transmission	Passage from intermediate to definitive host.
Infection	Passage from definitive to intermediate host.
Contaminative	Abrasions or bites contaminated by fæces, etc.
Inoculative	Parasites injected by insect during biting.
Ingestive	Parasites taken into alimentary canal *per os*.

TERMS FOR BACTERIA.

Infected host	Vertebrate infected by bacterium.
Infected reservoir	Vertebrate carrier.
Protective host	Arthropod carrier without germ increasing in number.
Propagative host	Arthropod carrier with germ increasing in number.
Transmission *Infection*	As in animal parasites.

SECTION II

VEGETAL PARASITES

CHAPTER XXXVI

SCHIZOMYCETES

Preliminary—Thallophyta—Schizomycetaceæ—Eubacteriales—Coccaceæ—Bacillaceæ—Spirillaceæ—Mycobacteriaceæ—References.

PRELIMINARY.

In our previous editions we drew attention to the numerous text-books and easily available works on bacteriology, which we decided not to consider, and we hold to that view still; but we notice that the works on this subject, as supplied to the student of medicine, are perhaps somewhat lacking in systematic classification.

To meet this need we have written the present chapter, which merely considers those bacteria which are of importance from the point of view of tropical medicine; and instead of giving descriptions of their characters, these are merely indicated by tables. Hence it should be used in conjunction with a good textbook on bacteriology, in which the details with reference to the species can be found.

It is well known that the nomenclature of the bacteria is in hopeless confusion, but an International Botanical Congress was to have been held in London in 1915, at which the medically important nomenclature of the schizomycetes would have been considered, and probably some such congress will take place after the war.

In the meanwhile the reader can find the existing rules in 'Règles Internationales de la Nomenclature Botanique,' published in Jena in 1912, and we may perhaps be permitted to remind him that names of orders should end in *-ales*, or suborders in *-ineæ*, and of families in *-aceæ*, while names of genera must be in the singular number and *written with a capital letter*, and those of subgenera and sections should resemble that of the genus.

With regard to species, it is designated by a *binomial name*, the first portion of which is the *generic name*, while the second portion is the *specific name*, and is usually begun with a small and not a capital letter, and is, further, of the nature of an adjective as a rule.

It is difficult to say what should be taken as the standard for bacterial nomenclature and classification, but it appears to us that it is useless to go further back than Migula; in any case the reader will realize that in no instance can a species be designated by more than two words—viz., the generic and the specific.

With regard to the value of bacterial species based upon biological and not upon morphological differences, the remarks which we wrote on this subject in regard to the Protozoa hold good here, and need not be repeated, while we would refer the reader again to the section on evolution in Chapter V., p. 112.

The *Regnum Vegetabile*, or vegetal kingdom, is usually divided into four great phyla or groups—viz., the Thallophyta, the Briophyta, the Pteridophyta, and the Phanerogamæ, but of all these only the first need concern us.

The Thallophyta include a great variety of plants whose vegetative body may consist of one or many cells, forming a more or less branched structure.

These plants may be defined and classified as follows:—

PHYLUM THALLOPHYTA.

Definition.—Vegetabiles with a cellular structure, which is generally little differentiated, and reproducing asexually by division and by spore formation or sexually, after conjugation, by oöspores.

Classification.—The Thallophyta may be divided into:—

- A. Thallophyta with chromatophores and often with chlorophyll—Class I., *Algæ* Roth, 1707.
- B. Thallophyta without chromatophores or chlorophyll—Class II., *Fungaceæ* Linnæus, 1737.

There can be no doubt that the Fungaceæ are descendants of the Algæ, which, because of a saprophytic or parasitic environment, have altered their food habits and have adapted themselves to new methods of nutrition, and hence no longer require chromatophores or chlorophyll, as they no longer manufacture their food with the aid of sunlight, but subsist on decaying animal or vegetal material rich in organic substances.

They may be parasitic or saprophytic, or a form which is usually parasitic may at times become a saprophyte, or *vice versa*.

With regard to their origin, the three great divisions probably differed in their evolution; thus the Schizomycetes are probably derived from the Cyanophyceæ, or Blue Green Algæ, while the Phycomycetes and the Eumycetes stand in closer relationship with the Chlorophyceæ, or Green Algæ; and it is because of this great difference in origin that the Schizomycetes are kept apart from the Fungaceæ, and are classified with the Algæ, although they are often included in the loosely used term *Fungi* (auctores).

Another less usual classification is to divide the Thallophyta into two great groups, of which the first includes the Cyanophyceæ and the Schizomycetes, while the second embraces the Myxomycetes, the Peridineæ, the Conjugatæ, the Diatomenæ, the Heterocontæ, the Chlorophyceæ, the Characeæ, the Phycomycetes, the Phæophyceæ, the Rhodophyceæ, the Eumycetes.

We will now turn to consider the Schizomycetes.

SCHIZOMYCETACEA Naegeli, 1857.

Definition.—Thallophyta without chlorophyll and as a rule without chromatophores, with the vegetative body consisting of a single cell, in which the nucleus is not present in the form typical for other thallophytes. Reproduction by fission or spore formation.

Classification.—The Schizomycetes may be divided into orders as follows:—

A. **Cells without sulphur or bacterio-purpurein—Order I., *Eubacteriales.***
B. **Cells containing sulphur—Order II., *Thiobacteriales.***
C. **Motile rods in pseudoplasmodial masses embedded in a gelatinous matrix and forming highly developed cysts—Order III., *Myxobacteriales.***

Only the first order contains forms of importance in tropical medicine.

ORDER I. EUBACTERIALES.

Definition.—Schizomycetes which contain neither sulphur nor bacterio-purpurein.

Classification.—The Eubacteriales may be divided into families as follows:—

A. Cells, in free condition, usually globular, in division somewhat elliptical—Family 1, *Coccaceæ* Zopf, 1885, *emendavit* Migula, 1900.
B. Cells, long or short, cylindrical, straight; division one direction—Family 2, *Bacillaceæ* Fischer, 1894.
C. Cells, spirally curved or representing part of a spiral; division in one direction—Family 3, *Spirillaceæ* Migula, 1900.
D. Cells, surrounded by a sheath and arranged in elongated filaments—Family 4, *Chlamydobacteriaceæ* Migula, 1900.
E. Cells short or long cylindrical or filamentous, often clavate, cuneate, or irregular, with enclosed granules. Filaments without a sheath—Family 5, *Mycobacteriaceæ* Chester, 1901.

The Chlamydobacteriaceæ do not concern us, but the other families require some consideration.

FAMILY COCCACEÆ Zopf, 1885, *emendavit* Migula, 1900.

Definition.—Eubacteriales in which the free cells are usually globular, though in division they become somewhat elliptical.

Type Genus.—*Micrococcus* Hallier, 1866, *emendavit* Cohn, 1872, and Winslow and Rogers, 1905.

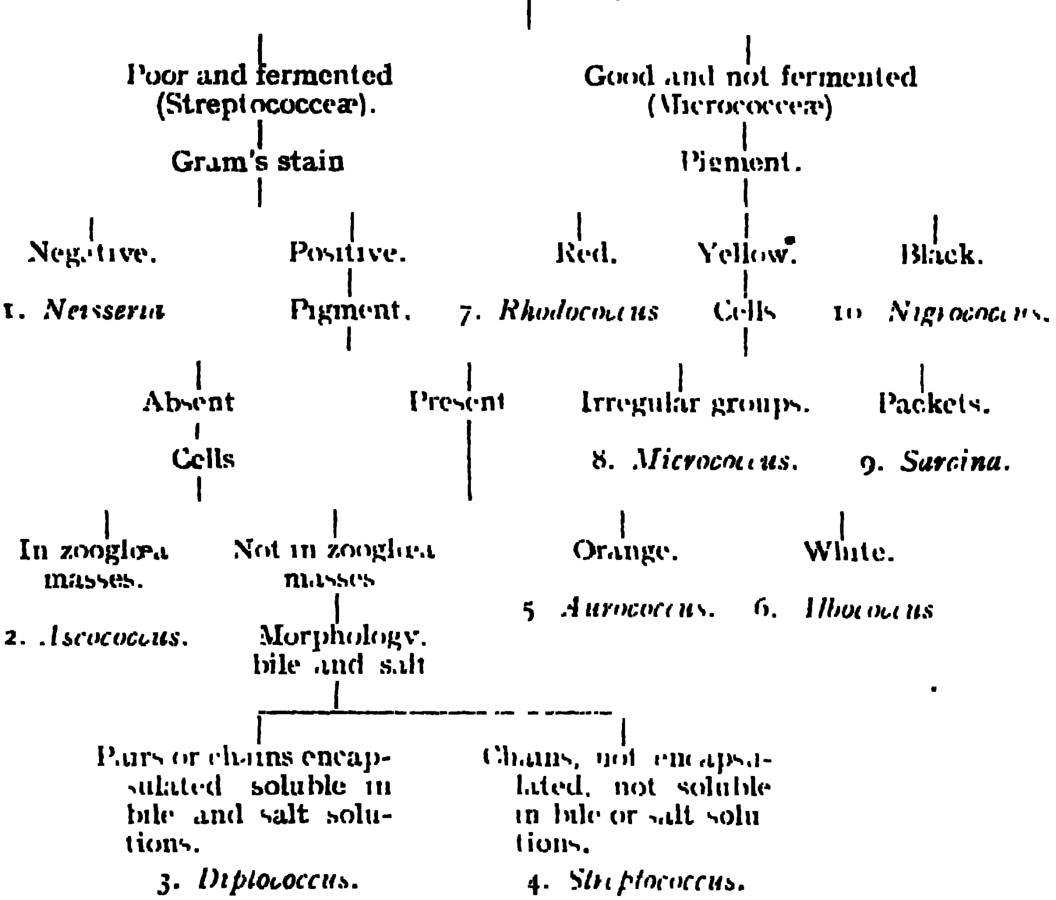
Classification.—This family, which contains forms of importance to us, may be divided into two tribes as follows:—

A. **Parasitic on plants and animals, often growing best anaerobically but frequently with difficulty and in small amount, or even not at all, on artificial media; in pairs or chains, generally but not always staining by Gram, and often producing acidity in glucose and lactose media, and when pigmented generally white or orange—Tribe I., *Streptococceæ* Trevisan, 1889, *emendavit* Winslow and Rogers, 1905.**
B. **Facultative parasites or saprophytes growing best under aerobic conditions and well on artificial media; in cell groups, packets or zoogloea masses and often Gram-negative, and when pigmented usually yellow or red—Tribe II., *Micrococceæ* Trevisan, 1889, *emendavit* Winslow and Rogers, 1905**

The two tribes may be divided into genera as set forth in the following table:—

DIAGNOSTIC TABLE OF THE FAMILY COCCACEÆ ZOPF, 1885.

Growth and Carbohydrates.



We are, however, only concerned with certain genera of the Streptococceæ, which are Neisseria, Diplococcus, Streptococcus, Aurococcus and one genus of the Micrococceæ—viz., Nigrococcus. As ***Micrococcus melitensis*** is often elongated (coccobacillus), we propose to place it under a separate heading, '*Incertæ Sedis*.'

TRIBE I. STREPTOCOCCEÆ TREVISAN, 1889, *emendavit* WINSLOW AND ROGERS, 1905.

Genus Neisseria Trevisan, 1885.

Synonyms.—*Micrococcus* Hallier, 1866, *pro parte*; *Diplococcus* Weichselbaum, 1887, *pro parte*.

Definition.—Streptococceæ growing best, and often only, aerobically, with or without pigment formation, usually present in pairs without a true capsule, and in exudates usually intracellular, and readily decolourized by Gram's method of staining.

Primary cultures grow poorly on usual laboratory media, but best on media containing glucose or blood serum. No lysis with bile. Ferment carbohydrates usually with but slight acid production.

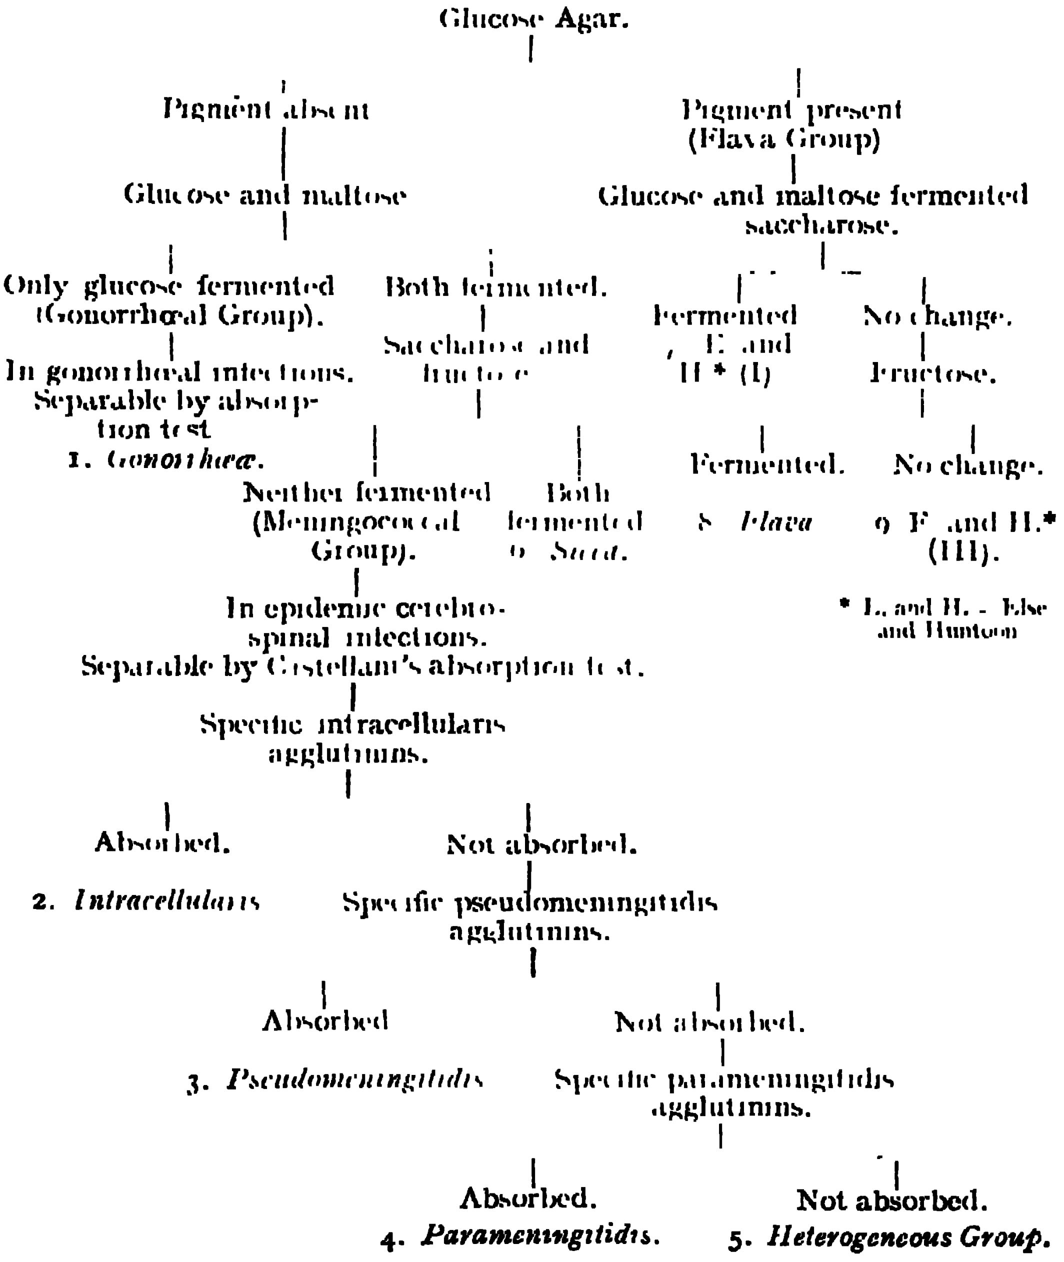
Type Species.—*Neisseria gonorrhϾ* (Bumm, 1885).

Classification.—The genus Neisseria includes the following species:

1. *N. gonorrhœæ* (Bumm, 1885), which is the cause of gonorrhœa.
2. *N. intracellularis* (Weichselbaum, 1887), which is one of the organisms causing epidemic cerebro-spinal meningitis.
3. *N. sicca* (von Lingelsheim, 1906).
4. *N. flava* (von Lingelsheim, 1906).
5. *N. pseudomeningitidis* (Elser and Huntoon, 1909).
6. *N. parameningitidis* (Dopter, 1909).
7. *A number of heterogeneous strains*, separable by the agglutination and absorption tests of specific immune sera.

These various strains and groups can be differentiated from one another by the tests set forth in the following diagnostic table:—

Diagnostic Table of the Genus Neisseria Trevisan, 1885



Glucose Agar.
Pigment absent
Glucose and maltose
Only glucose fermented (Gonorrhœal Group).
In gonorrhœal infections. Separable by absorption test
1. *Gonorrhœæ.*
Both fermented.
Saccharose and fructose
Neither fermented (Meningococcal Group).
In epidemic cerebro-spinal infections. Separable by Castellani's absorption test.
Specific intracellularis agglutinins.
Absorbed.
2. *Intracellularis*
Not absorbed.
Specific pseudomeningitidis agglutinins.
Absorbed
3. *Pseudomeningitidis*
Not absorbed.
Specific parameningitidis agglutinins.
Absorbed.
4. *Parameningitidis.*
Not absorbed.
5. *Heterogeneous Group.*
Both fermented
6. *Sicca.*
Pigment present (Flava Group)
Glucose and maltose fermented saccharose.
Fermented
7. E. and H.* (I)
No change.
Fructose.
Fermented.
8. *Flava*
No change.
9. E. and H.* (III).
* E. and H. - Elser and Huntoon

Genus Diplococcus Weichselbaum, 1886, *emendavit* Winslow and Rogers, 1905.

Definition.—Streptococceæ usually in encapsulated pairs, forming acid in glucose, lactose, saccharose, and inulin. Hæmolysis usually absent. Characteristic group serum reactions. Soluble in bile salts. Undergo autolysis in cultures and in emulsions of physiological saline.

Type Species. *Diplococcus pneumoniæ* Weichselbaum, 1886.

Remarks.—The genus contains the organisms associated with pneumonia, of which there are many strains separable by serum reactions. The genus requires further study before a definite classification can be given.

Two groups are recognized viz., those which exhibit a diplococcal form and are usually oval or lanceolate in shape (Pneumonia group), and those which are in chains and rounded in form (Mucosus group). These groups can be further differentiated by serological tests and by complement fixation.

Genus Streptococcus Rosenbach, 1884, *emendavit* Winslow and Rogers, 1905.

Definition. Streptococceæ parasitic in short or long chains or pairs, forming a large quantity of acid in fermented sugars. Hæmolysis present or absent. Without characteristic group serum reactions.

Type Species. *Streptococcus erysipelatos* Fehleisen, 1883.

Remarks.—Streptococci are frequently found in disease in the tropics, as primary agents causing the pathological changes, and as secondary or terminal infections in the course of illnesses due to other causes.

They are responsible for several types of puerperal fever, of abscesses, of septicæmias and of skin diseases.

Natural Habitat. Most streptococci are found as parasites (or saprophytes) of the nose, nasopharynx, and alimentary canal of vertebrate animals, but they can also be found in the alimentary tract of the invertebrata, and apparently also, but to a less extent, living on or in plants.

From these natural homes they may pass to air, soil, milk, or water, and so may be conveyed from one animal to another, as they are extremely resistant against heat and drought.

Thus *S. salivarius* Andrewes and Horder, 1906, lives in normal human saliva; *S. bovinus* Broadhurst, 1915, in bovine fæces, and is found in the cow-dung plastered on walls and floors of native huts; while *S. versatilis* Broadhurst, 1915, is found in equine and bovine fæces.

Researches with regard to certain human passages have shown how quickly these become infected with streptococci after birth.

It would appear that man quickly obtained his normal streptococcal flora from the animals by which he is surrounded, and that so long as they abide in their natural habitats they do no harm, but if they depart therefrom they become pathogenic.

Classification.—This is difficult, and perhaps should not be carried further than groups which may be recognized as follows:—

DIAGNOSTIC TABLE OF STREPTOCOCCAL GROUPS.

A. *Parasitic on plants.* Grow in broth but not on agar or gelatine—*I. Sphagni group.*

B. *Parasitic in animals.* Grow in broth and on agar and usually on gelatine:—

  I. Obligatory anaerobes—*II. Fœtidus group.*

  II. Aerobes, facultative anaerobes:—

    (*a*) *Pigment present—III. Sanguineus group.*

    (*b*) *Pigment absent*:—

      1. Gelatine actively liquefied—*IV. Gracilis group.*

      2. Gelatine usually not or rarely slightly liquefied, inulin usually not fermented:—

        (A) *Gas produced V. Gasogenous group.*

        (B) *Gas not produced*:—

      NON-FERMENTERS:—

        (*a*) Glucose and other sugar media not fermented—*VI. Non-fermenting group.*

      MONOSACCHARIDE FERMENTERS—*Equine Fæcal Type*:—

        (*b*) Glucose usually and other sugar media generally fermented.

        1. Glucose alone or with saccharose and salicin, but not with lactose, fermented—*VII. Equine group.*

      DISACCHARIDE FERMENTERS—*Human Fæcal Type*.—

        2. Lactose, glucose, saccharose, and salicin, but not mannitol fermented *VIII. Erysipelatos group.*

        3. Lactose, glucose, saccharose, salicin, mannitol, and sometimes raffinose fermented—*IX. Fæcalis group.*

      TRISACCHARIDE FERMENTERS—*Bovine Fæcal Type*.—

        4. Raffinose, lactose, saccharose, usually glucose sometimes salicin and rarely inulin, but not mannitol fermented—*X. Salivarius group.*

If desired the investigation can be extended, but in our experience only Groups II., VII., VIII., IX., and X. are of tropical importance, and therefore we shall limit our remarks to them:—

II. FŒTIDUS GROUP.

Definition.—Streptococcus parasitic in animals, obligatory anaerobes growing well at 37° C., and poorly or not at all at 20° C.:—

I. Fœtid gas produced; milk usually acidified and slowly clotted—*S. fœtidus.*

II. Fœtid gas not produced; milk unchanged—*S. anaerobius.*

Both these organisms have been known to cause puerperal fever.

VII. EQUINE GROUP.

Definition.—Streptococcus parasitic in animals, aerobe facultative anaerobe, without pigment, not liquefying gelatine nor producing gas, and being a monosaccharide fermenter. Glucose, salicin, and usually saccharose, are fermented, but not lactose, and with feeble or no growth at 20° C. Milk not clotted.

Classification.—By the action upon raffinose and inulin the group may be divided into two subgroups—*i.e.*, a typical, in which these are not fermented, and an atypical, in which one or both are fermented.

A. Raffinose and inulin not fermented and neutral red not reduced—*Typical subgroup.*
  I. Saccharose fermented—*S. equinus.*
  II. Saccharose not fermented—Andrewes and Horder, Winslow and Palmer, Broadhurst (A), Fuller and Armstrong.

B. Raffinose or inulin fermented or neutral red reduced—*Atypical subgroup.*

We have found *S. equinus* Andrewes and Horder, 1906, in a case of septicæmia in the tropics.

VIII. Erysipelatos Group.

Definition.—Streptococcus parasitic in animals, aerobe facultative anaerobe, without pigment; does not liquefy gelatine or produce gas; ferments lactose, glucose, saccharose, and salicin, but not mannitol or raffinose.

Classification.—The group may be differentiated into strains as follows:—

A. Colonies on agar large, white, and opaque, at the end of forty-eight hours resembling those of an albococcus; milk clotted. Hæmolytic action unknown—*S. puerperalis.*

B. Colonies on agar small, translucent, not resembling, at the end of forty-eight hours, those of an albococcus:—
  I. Hæmolysis present:—
    (*a*) Milk clotted:—
      1. Some kind of a capsule present, colonies on agar typical—*S. epidemicus.*
      2. Capsule absent, growth on agar may be absent or in the form of very fine or at times watery colonies, but typical on ascitic agar—*S. equi.*
    (*b*) Milk not clotted—
      Capsule absent, colonies on agar typical:—
      1. Found in cases of erysipelas—*S. erysipelatos.*
      2. Found in dermatitis cupoliformis—*S. tropicalis.*
  II. Hæmolysis absent:—
    (*a*) Milk clotted—*S. mitior.*
    (*b*) Milk not clotted—*S. mitis.*

S. puerperalis Furneaux-Jordan and Mackay, 1912, was found in twenty-one cases of puerperal fever in England.

S. equi Schutz, 1888, is the same as *S. coryzæ contagiosæ equorum* Eisenberg, and as *S. equi* Capelletti-Vivaldi, 1899, and *S. capellettii* Chester, 1901, and causes strangles, etc., or adenitis in horses.

S. erysipelatos Fehleisen, 1883, is the type species of the genus Streptococcus. It is the same as *S. pyogenes* Rosenbach, 1884, and *S. puerperalis* Arloing, 1884, and it may be the same as *S. puerperalis* Furneaux-Jordan and Mackay, though there are differences.

S. tropicalis Castellani, 1914, is the cause of *Dermatitis cupoliformis*, which is a type of tropical ecthyma (see p. 2034).

It may be that *S. mitior* Schottmüller, 1903, is the same as *S. mitis* Andrewes and Horder, 1906. It has been found in cases of puerperal fever.

IX. FÆCALIS GROUP.

Definition.—Streptococcus parasitic in man, facultative anaerobe, growing in broth and upon agar and blood serum without the formation of pigment, and well upon gelatine at 22° C., without producing liquefaction; fermenting glucose, saccharose, lactose, mannitol, and salicin; sometimes raffinose, but typically not inulin, and generally, but not always, clotting milk; variable as regards neutral red reduction and sulphuretted hydrogen formation, and usually producing relatively large amount of acidity in glucose media tested quantitatively.

Remarks. This is an important pathogenic group in the tropics, being found in all sorts of conditions. Its various strains may be differentiated as follows:

A. Glucose, saccharose, lactose, salicin, and mannitol fermented—Typical subgroup
  I. Raffinose not fermented *S. fæcalis* Andrewes and Horder, 1906.
  II Raffinose fermented *S. versatilis* Broadhurst, 1915.
B Suppression of one of the characters of the typical subgroup or with the addition of the fermentation of inulin Atypical subgroup.
  I Raffinose not fermented -Variants of *S. fæcalis*
  II. Raffinose fermented Variants of *S. versatilis*.

X. SALIVARIUS GROUP.

Definition. Streptococcus parasitic in animals, facultative anaerobe, growing in broth and on agar without pigment or gas formation; with slight or no growth at 22° C. in gelatine which is not liquefied, and capable of fermenting glucose, saccharose, lactose, and raffinose; may ferment inulin, but not mannitol, and generally capable of clotting milk. Habitat, human saliva, human fæces, bovine and equine fæces.

Classification. This group can be divided into a typical subgroup, and an atypical subgroup containing varieties of the typical group, in which there is suppression of some important character, which is not inulin fermentation.

TYPICAL SUBGROUP.- Glucose, saccharose, lactose, and raffinose, and at times inulin fermented.

A. Salicin not fermented: -
  I. Hæmolysis marked- -*S. anginosus*.
  II. Hæmolysis absent- *S. salivarius*.
B. Salicin fermented.
  I. Hæmolysis marked *S. actuosus*.
  II. Hæmolysis absent - *S. bovinus*.

ATYPICAL SUBGROUP.- Contains varieties of *S. anginosus*, *S. salivarius*, *S. actuosus*, and *S. bovinus*, in which there is suppression of some character but as these suppressions are generally only temporary it is not necessary to specially characterize them.

Remarks.—These streptococci are frequently found in sore throat and other infections in the tropics.

Shottmüller's Classification of the Genus Streptococcus.—This is very simple, and is based on the characters of colonies on blood-agar plates.

1. Colonies surrounded by a clear zone of hæmolysis—*S. hæmolyticus* (=*S. pyogenes* = *S. erysipelatos* = *S. erysipelatosus*).
2. Colonies not surrounded by a clear zone of hæmolysis; of a peculiar greenish colour—*S. viridans* (= *S. mitior*).
3. Colonies whitish, slimy, somewhat adherent to the medium (cocci capsulated)—*S. mucosus*.

Genus Aurococcus Winslow and Rogers, 1905.

Definition.—Streptococceæ parasitic, producing pigment, and in irregular groups or in non-capsulated groups of four, or in pairs, but never in zooglœa masses. Growth good. Sugars fermented with formation of a moderate amount of acid, but no gas. May or may not reduce nitrates and liquefy gelatine.

Type Species.—*Aurococcus aureus* (Rosenbach, 1884).

Classification.—Winslow and Rogers, after a long discussion of synonyms, have recognized only three types, which may be differentiated as follows:—

A. Nitrates not reduced:—
   (1) Gelatine strongly liquefied—*Aurococcus aureus* (Rosenbach, 1884).
   (2) Gelatine not liquefied—*Aurococcus aurantiacus* (Cohn, 1872).
B. Nitrates reduced:—
   (3) Gelatine may or may not be liquefied—*Aurococcus mollis* (Dyar 1895).

Remarks.—This group is of great interest in the tropics; as its members are the cause of boils and pyosis in various parts—*e.g.*, *Aurococcus mollis* causes Nile boils and pyosis Corletti.

With regard to 'pyosis Mansoni,' Castellani in Ceylon showed it to be caused by a species of aurococcus, which Clegg and Wherry in 1906 called *Micrococcus pemphigicontagiosi*, which seems to be the same as that named *Micrococcus pemphigineonatorum* by Almquist in 1901, and both may be *Aurococcus mollis*. *Aurococcus tropicus* Chalmers and O'Farrell, 1913, found in Castellani's 'pyosis tropica,' appears to be different, as its vaccine was without effect on a case of Nile Boils, but, unfortunately, it was not possible to test it on nitrates and gelatine.

TRIBE II. MICROCOCCEÆ Trevisan, 1880, *emendavit* Winslow and Rogers, 1905.

Genus Rhodococcus Winslow and Rogers, 1905.

Definition.—Micrococceæ, usually saprophytes, rarely parasites, with cells in groups or regular packets. Generally more or less decolourized by Gram. Growth on agar abundant, with the formation of red pigment. Very slight fermentative action. Gelatine rarely liquefied. Generally reduce nitrates to nitrites.

Type.—*Rhodococcus roseus* (Flügge, 1886), *emendavit* Dyar, 1895.

Remarks.—Winslow and Rogers recognize, in addition to the type, *R. fulvus* Cohn, 1875, and they leave the rest in groups to await further investigation.

We add *Rhodococcus castellanii*, discovered by Castellani and which Chalmers and O'Farrell in 1913 named and more fully described. It is found in *Trichomycosis rubra*, and we differentiate the three species as follows:—

A. Does not ferment glucose—*Castellanii*.
B. Produces slight acidity in glucose:—
  I. Nitrates reduced to nitrite.—*Roseus*.
  II. Nitrates not reduced—*Fulvus*.

Genus Nigrococcus Castellani and Chalmers, 1918.

Definition.—Micrococceæ saprophytic, rarely parasitic, producing black or bluish-black pigment.

Type.—*Nigrococcus nigrescens* (Castellani, 1911).

Classification.—The type is found in *Trichomycosis nigra*, along with *Cohnistreptothrix tenuis* Castellani; other forms are *N. fuscus* Adametz (1888), in water; *N. cyaneus* Schroeter, 1870, in air and water; and they may be differentiated as follows:—

A. Gelatine liquefied—*Fuscus*
B. Gelatine not liquefied:—
  I. Pigment indigo blue—*Cyaneus*.
  II. Pigment black—*Nigrescens*.

INCERTÆ SEDIS.

The so-called *Micrococcus melitensis* Bruce, 1886, which is the causal agent in Mediterranean, Malta, or undulant fever, is difficult to classify, because elongated forms are seen at times in cultures, and because it seems to have no affinity with the Gram-negative cocci; but, on the other hand, is very like the typhoid-colon group of organisms in certain respects. It does not ferment sugars, nor produce indol; does not liquefy gelatine, nor show polar-staining; while milk becomes alkaline.

FAMILY BACILLACEÆ Fischer, 1894.

Definition.—Eubacteriales with cells long or short, flagellate or non-flagellate, sporogenous or non sporogenous, but always cylindrical and straight. They divide in one direction only.

Type Genus.—*Bacillus* Cohn, 1872.

Remarks.—The enormous numbers of species and varieties gathered together under the names *Bacterium* and *Bacillus* form such an unwieldy mass, that we have endeavoured to simplify matters by formulating a number of tribes with genera.

Classification.—The family 'Bacillaceæ' may be classified into tribes as follows:—

Growth in ordinary laboratory media:—
A. Entirely or almost entirely absent—Tribe 1, *Nitrobactereæ*.
B. Poor, Gram-negative, grow best on blood media—Tribe 2, *Hæmophileæ*.
C. Extremely slow and scanty growth on ordinary and blood media—Tribe 3, *Graciloideæ*.
D. Growth good:—
  I. Endospores present—Tribe 4, *Bacilleæ*.
  II. Endospores absent:—

- (*a*) Fluorescent or chromogenic—Tribe 5, *Bacteridieæ*.
- (*b*) Neither fluorescent nor chromogenic:—
  - 1. Obligatory anaerobes—Tribe 6, *Bacteroideæ*.
  - 2. Aerobes often facultative anaerobes:—
    - (1) Gelatine liquefiers—Tribe 7, *Proteæ*.
    - (2) Gelatine non-liquefiers:—
      - (i.) Without capsules:—
        - (A) With polar staining—Tribe 8, *Pasteurelleæ*
        - (B) Without polar staining—Tribe 9, *Eberthieæ*
      - (ii.) With capsules—Tribe 10, *Encapsulateæ*.

THE TRIBES.

This is obviously not the place to enter into a prolonged discussion with regard to these tribes, but in order that there may be no doubt as to our meaning, we give the following table showing the type genus and type species which we propose for each tribe:—

Tribe.	*Type Genus.*	*Type Species.*	*Original Name of Type Species.*
Nitrobacterieæ.	*Nitrobacterium* Castellani and Chalmers, 1918.	*Nitrobacterium nitrobacter* (Winogradsky, 1892).	*Nitrobacter* Winogradsky, 1892.
Hæmophileæ.	*Hæmophilus* Castellani and Chalmers, 1918.	*Hæmophilus influenzæ* (Pfeiffer, 1892).	Bacillus of influenza, Pfeiffer, 1892.
Graciloideæ.	*Graciloides* Castellani.	*Graciloides albofaciens.*	*Bacillus albofaciens* Castellani 1904.
Bacilleæ.	*Bacillus* Cohn, 1872, *pro parte.*	*Bacillus subtilis* (Ehrenberg, 1833).	*Vibrio subtilis* Ehrenberg, 1833.
Bacteridieæ.	*Bacteridium* Schroeter, 1872.	*Bacteridium prodigiosum* (Ehrenberg, 1838).	*Monas prodigiosa* Ehrenberg, 1838.
Bacteroideæ.	*Bacteroides* Castellani and Chalmers, 1918.	*Bacteroides fragilis* Veillon and Zuber.	*Bacillus fragilis* Veillon and Zuber.
Proteæ.	*Proteus* Hauser, 1885.	*Proteus vulgaris* Hauser, 1885.	*Proteus vulgaris* Hauser, 1885.
Pasteurelleæ.	*Pasteurella* Toni and Trevisan, 1889.	*Pasteurella gallinæ* Toni and Trevisan, 1889.	Microbe du choléra des Poles, Pasteur, 1880.
Ebertheæ.	*Eberthus* Castellani and Chalmers, 1918.	*Eberthus typhosus* Zopf, 1885.	Bacillus of Eberth auctores.
Encapsulateæ.	*Encapsulatus* Castellani and Chalmers, 1918.	*Encapsulatus pneumoniæ* (Friedlaender, 1883).	Pneumococcus. The micrococcus of pneumonia. Friedlaender, 1883.

Of all these, the most important from our present point of view is *Eberthea*, which contains many intestinal organisms.

TRIBE ENCAPSULATEÆ CASTELLANI AND CHALMERS, 1918.

Definition.—Bacillaceæ growing well on ordinary laboratory media, without endospores; neither fluorescent nor chromogenic aerobes, not liquefying gelatine, possessing capsules in animal tissues.

Type Genus.—*Encapsulatus* Castellani and Chalmers, 1918.

Genus Encapsulatus Castellani and Chalmers, 1918.

Definition.—Encapsulateæ with the tribal characters.

Type Species.—*Encapsulatus pneumoniæ* (Friedlaender, 1883).

Remarks.—This genus is the only one at present in the tribe, and it includes the old group of encapsulated bacilli which have been reviewed by Fricke in 1896, Clairmont in 1902, Perkins in 1904, Abel and Hallwachs in 1912, and Fitzgerald in 1914.

The species are mostly short, non-motile, Gram-negative, encapsulated pleomorphic organisms, which ferment glucose and lactose; but as regards the latter sugar, they may give rise to acid only, though more usually they form acid and gas.

Classification.—The various species of this genus may be recognized as follows:—

A. Glucose completely fermented with the formation of acid and gas; lactose fermented partially with the formation of acid, but no gas. Milk clotted—*Pneumoniæ*.

B. Glucose and lactose completely fermented with the formation of acid and gas. Milk clotted:—

  I. Inosite not fermented—*Acidi lactici*.

  II. Inosite fermented with the formation of acid and gas—*Lactis aerogenes*.

TRIBE EBERTHEÆ CASTELLANI AND CHALMERS, 1918.

Definition.—Bacillaceæ growing well on ordinary laboratory media; not forming endospores, aerobes, and often facultative anaerobes; without fluorescence, pigment formation, or gelatine liquefaction; without polar staining; Gram-negative, without a capsule.

Type Genus.—*Eberthus* Castellani and Chalmers, 1918.

Classification.—The tribe may be divided into genera, which may be recognized as follows:—

A. Glucose and lactose either not at all or only partially fermented with the production of acid, but no gas:—

  I. Milk not clotted.

    (*a*) Glucose and lactose not fermented—Genus 1, *Alcaligenes* Castellani and Chalmers, 1918.

    (*b*) Glucose partially fermented with the production of acid and no gas, lactose not fermented:—

      1. Motile—Genus 2, *Eberthus* Castellani and Chalmers, 1918.

      2. Non-motile—Genus 3, *Shigella* Castellani and Chalmers, 1918.

    (*c*) Lactose and glucose partially fermented with the production of acid, but no gas—Genus 4, *Dysenteroides* Castellani and Chalmers, 1918.

II. **Milk clotted :—**

Glucose partially fermented with the production of acid, but no gas; lactose not fermented (no gas in any sugar)—Genus 5. *Lankoides* Castellani and Chalmers, 1918.

B. Glucose completely fermented with the production of acid and gas; lactose not fermented:—

I. Milk not clotted—Genus 6, *Salmonella* Lignières, *emendavit* Castellani and Chalmers, 1918.

II. Milk clotted—Genus 7, *Balkanella* Castellani and Chalmers, 1918.

C. Glucose completely fermented with the production of acid and gas; lactose partially fermented with the production of acid and no gas:—

I. Milk not clotted—Genus 8, *Wesenbergus* Castellani and Chalmers, 1918.

D. Glucose and lactose completely fermented with the production of acid and gas:—

I. Milk not clotted—Genus 9, *Enteroides* Castellani and Chalmers, 1918.

II. Milk clotted—Genus 10, *Escherichia* Castellani and Chalmers, 1918.

In order to be quite definite, we give the following table showing the type species for each genus:—

Genus.	*Type Species.*	*Original Name of the Type Species.*
Alcaligenes.	*Alcaligenes faecalis* (Petruschky, 1896).	*Bacillus faecalis alkaligenes* Petruschky, 1896.
Eberthus.	*Eberthus typhosus* (Zopf, 1885).	Bacillus of Eberth auctores.
Shigella.	*Shigella dysenteriae* (Kruse, 1899).	*Bacillus dysenteriae* Kruse, 1899.
Lankoides.	*Lankoides pyogenes* (Passet, 1902).	*Bacillus pyogenes foetidus* Passet, 1902.
Dysenteroides.	*Dysenteroides metadysentericus* (Castellani, 1917).	*Bacillus metadysentericus* Castellani, 1904.
Salmonella.	*Salmonella paratyphi* (Schottmuller, 1902).	*Bacillus paratyphosus A* Schottmuller, 1902.
Balkanella.	*Balkanella coagulans* (Castellani, 1916).	*Bacillus coagulans* Castellani, 1916.
Wesenbergus.	*Wesenbergus wesenbergi* (Castellani, 1913).	*Bacillus wesenberg* Castellani, 1913.
Enteroides.	*Enteroides entericus* (Castellani, 1907).	*Bacillus entericus* Castellani, 1907.
Escherichia.	*Escherichia coli* (Escherich, 1886).	*Bacterium coli commune* Escherich, 1886.

Genus Alcaligenes Castellani and Chalmers, 1918.

Definition.—Ebertheæ which do not ferment glucose or lactose, and are characterized by their general lack of fermentative power and by actually increasing the alkalinity of the media. Milk is not clotted, and is rendered alkaline.

Type.—*Alcaligenes fæcalis* (Petruschky, 1896), *emendavit* Castellani and Chalmers, 1918.

Here also comes *Alcaligenes vivax* (Archibald, 1918), which was obtained from the blood of a case of enteroidea in the Anglo-Egyptian Sudan, produced acidity in galactose and mannitol and was characterized by its marked motility.

Classification.—These various organisms can be differentiated as follows:—

A. Non-motile—*Metalkaligenes.*
B. Motile:—
  I. No acidity in any sugar—*Fæcalis.*
  II. Acidity in mannitol—*Vivax*

Genus Eberthus Castellani and Chalmers, 1918.

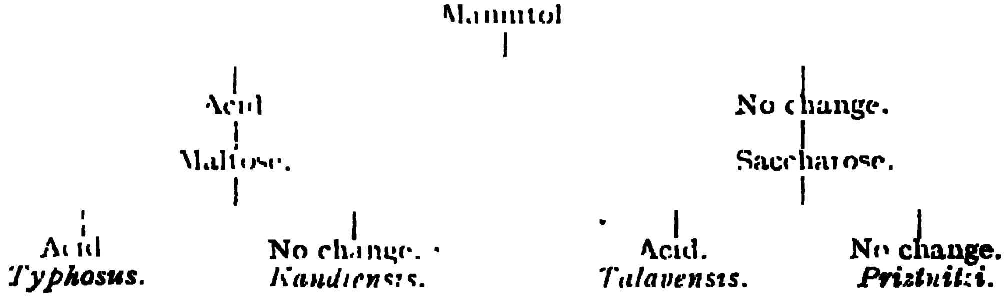
Definition.—Bacillaceæ motile, partially fermenting glucose with the production of acid and no gas. Lactose not fermented. Milk not clotted.

Type Species.—*Eberthus typhosus* (Zopf, 1885).

Remarks.—This genus has as its type species the organism which causes that variety of enteric fever which is called typhoid fever, as well as a number of species which are the causal agents of forms of enteroidea.

Classification.—The genus contains the following species, in addition to the type: *E. kandiensis* Castellani, *E. talavensis* Castellani, *E. priztnitzi* Castellani.

They may be differentiated biochemically as follows, though they can be distinguished in addition, by their serological reactions:—



Genus Shigella Castellani and Chalmers, 1918.

Definition.—Ebertheæ non-motile, partially fermenting glucose with the production of acid, but no gas; lactose not fermented. Milk not clotted.

Types.—*Shigella dysenteriæ* (Kruse, 1899).

Remarks.—This genus includes a number of forms which are associated with bacillary dysentery, but in going through those which have been described, we have rejected all with very imperfect descriptions which will never permit of their recognition.

Classification.—The species belonging to this genus may be divided for purposes of recognition into:—

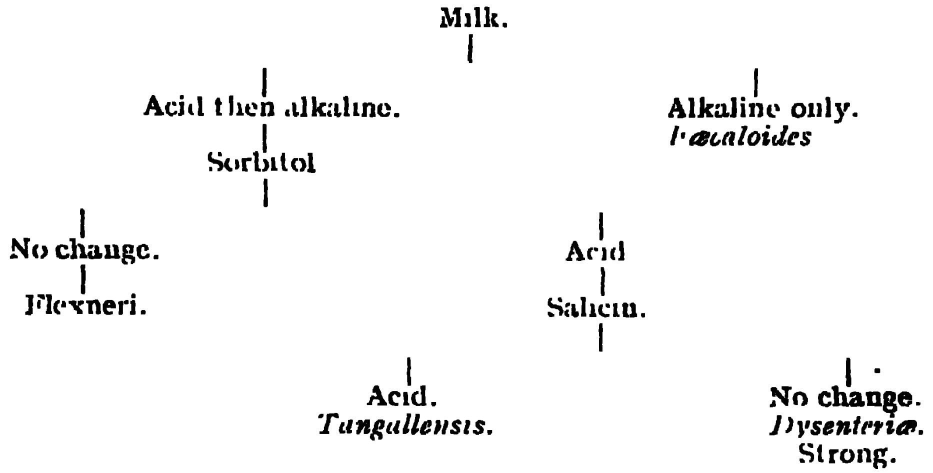
A. *Mannitol fermented*—Subgenus *Flexnerella* (Flexner group *sensu lato*).
  I. Maltose fermented—*Flexner group*.
  II. Maltose not fermented—*Pseudodysentery group*.
B. *Mannitol not fermented*—Subgenus *Shigella*

The forms belonging to these divisions and sections may be recognized by the following tables:—

Subgenus Flexnerella Castellani and Chalmers, 1918.

(Mannitol Partial Fermenters.)

Flexner Group: Maltose Partial Fermenters.

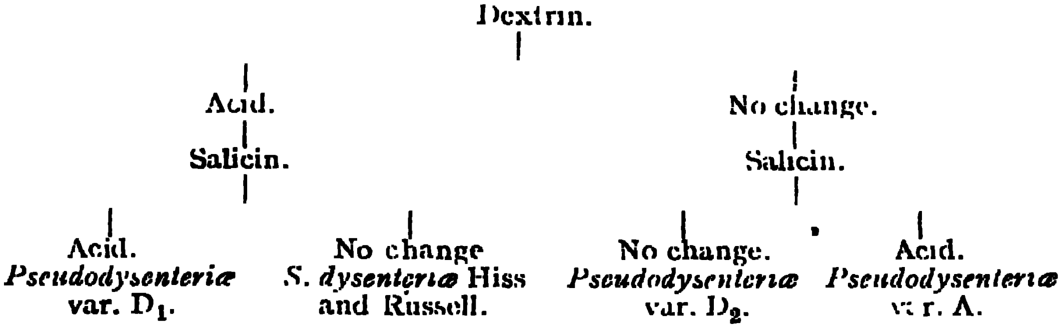


- Milk.
  - Acid then alkaline.
    - Sorbitol
      - No change.
        - Flexneri.
      - Acid
        - Salicin.
          - Acid. *Tangallensis.*
          - No change. *Dysenteriæ.* Strong.
  - Alkaline only. *Fæcaloides*

Subgenus Flexnerella Castellani and Chalmers, 1918.

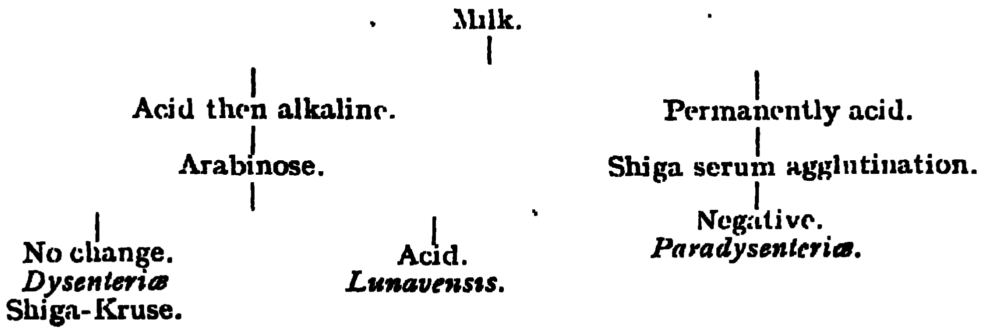
(Mannitol Partial Fermenters.)

Pseudodysentery Group: Maltose Non-Fermenters.



- Dextrin.
  - Acid.
    - Salicin.
      - Acid. *Pseudodysenteriæ* var. D_1.
      - No change *S. dysenteriæ* Hiss and Russell.
  - No change.
    - Salicin.
      - No change. *Pseudodysenteriæ* var. D_2.
      - Acid. *Pseudodysenteriæ* var. A.

Shiga-Kruse Division: Mannitol not Fermented.



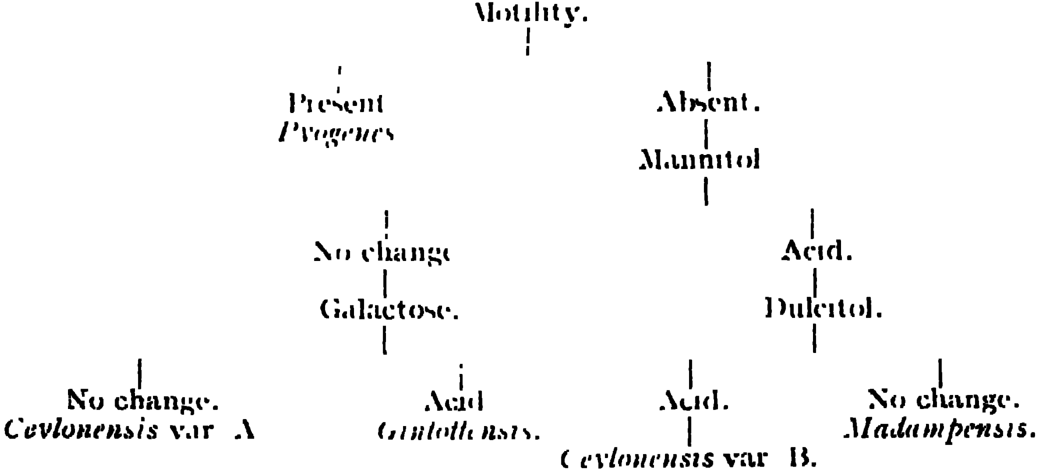
- Milk.
  - Acid then alkaline.
    - Arabinose.
      - No change. *Dysenteriæ* Shiga-Kruse.
      - Acid. *Lunavensis.*
  - Permanently acid.
    - Shiga serum agglutination.
      - Negative. *Paradysenteriæ.*

Genus Lankoides Castellani and Chalmers, 1918.

Definition.—Ebertheæ fermenting glucose partially with the production of acid, but no gas; lactose not fermented or only partially, without gas production. Milk clotted.

Type Species.—*Lankoides pyogenes* (Passet, 1902).

Classification.—The species classified in this genus may be recognized as follows:—

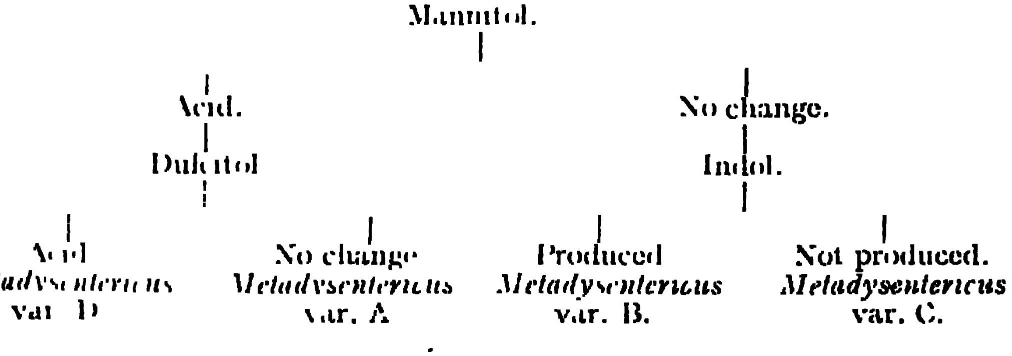


Genus Dysenteroides Castellani and Chalmers, 1918.

Definition.—Ebertheæ fermenting glucose and lactose partially, with the production of acid, but no gas. Milk not clotted.

Type Species.—*Dysenteroides metadysentericus* (Castellani, 1917).

Remarks.—This genus contains the organisms of the Metadysenteric group, which may be differentiated as follows:—



Genus Salmonella Lignières, *emendavit* Castellani and Chalmers, 1918.

Definition.—Ebertheæ which completely ferment glucose, but do not ferment lactose, and partially or completely ferment mannitol, in addition to other carbohydrates. Milk not clotted.

Type Species.—*Salmonella paratyphi* (Schottmüller, 1902).

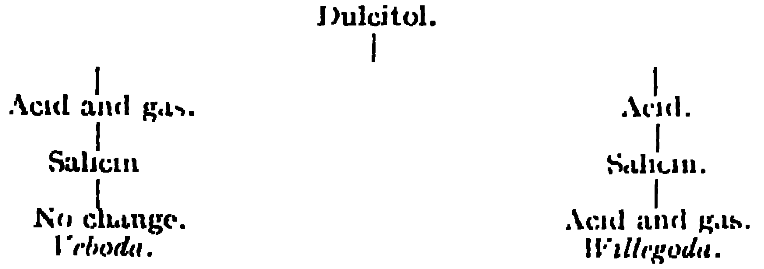
Remarks.—This genus contains a large number of species, which may be divided into groups as follows:—

A. Mannitol not fermented—*Morgan group*.
B. Mannitol partially fermented with the production of acid, but no gas —*Veboda group*.
C. Mannitol completely fermented with the production of acid and gas—*Paratyphoid-Asiaticus group*.

The Morgan group only contains *Salmonella morgani*, which is the same as Morgan I. of older nomenclature.

VEBODA GROUP.

This group contains two organisms viz., *Salmonella veboda* Castellani, 1909, and *S. willegoda* Castellani, 1911. They may be distinguished as follows:—



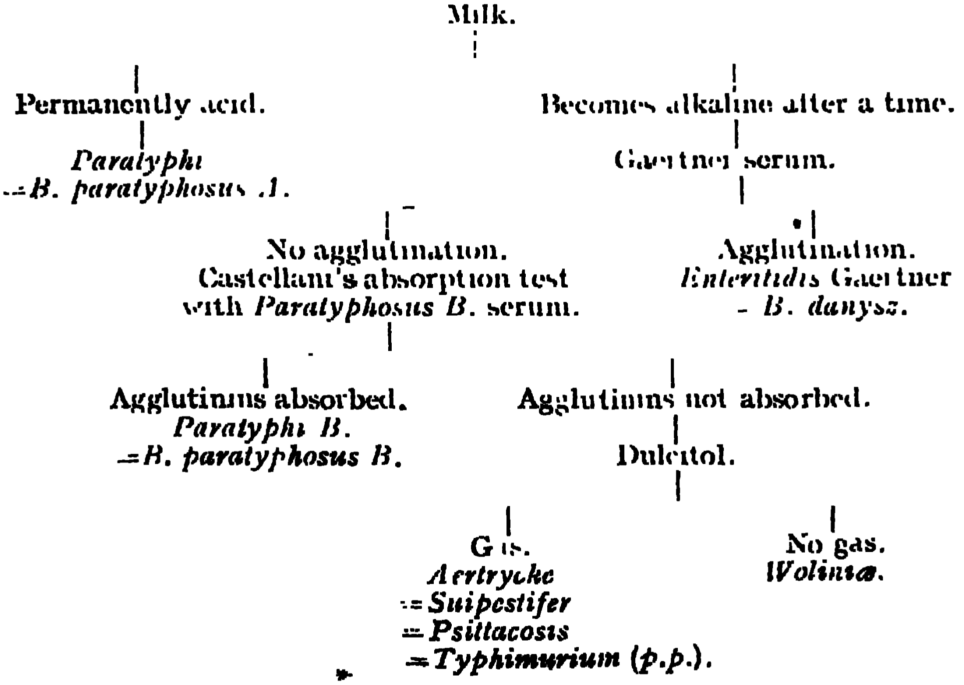
PARATYPHOID-ASIATICUS GROUP.

This group contains a number of forms, some of which are of tropical importance. It may be classified as follows:—

A. Indol not produced -*Paratyphoid division*.
B. Indol produced *Asiaticus division*.

The first subgroup contains *S. paratyphi A*, *S. paratyphi B*, *S. aertrycke*, *S. wolinia*. The term *S. paratyphi C* has been applied by various authors to indicate different germs, one of which is identical serologically with *S. enteritidis*.

PARATYPHOID DIVISION: INDOL NON-PRODUCERS.



ASIATICUS DIVISION: INDOL FORMERS.

Saccharose.
- No change.
  - Voges-Proskauer.
    - Positive. *Archibaldi* Castellani and Chalmers.
    - Negative
      - *Carolina* Castellani
- Acid and gas.
  - Salicin.
    - Acid and gas. *Pseudo-asiatica* Castellani.
    - No change.
      - Motility.
        - Present. *Asiatica* var. *mobilis* Castellani.
        - Absent. *Asiatica* Castellani.

Genus Balkanella Castellani and Chalmers, 1918.

Definition.—Eberthcæ which ferment glucose completely with the production of acid and gas; lactose not fermented. Milk clotted.

Type Species. *Balkanella coagulans* Castellani, 1916.

Remarks.—There are two species—viz., the type and *B. carolinoides* Castellani—which may be separated as follows:—

Saccharose.
- No change. *Coagulans.*
- Acid and gas. *Carolinoides*

Genus Wesenbergus Castellani and Chalmers, 1918.

Definition.—Eberthcæ which ferment glucose completely and lactose partially, producing acid, but no gas. Milk not clotted

Type Species.—*Wesenbergus wesenbergi* Castellani, 1913.

Remarks.—The type described by Castellani is motile, and produces acidity in litmus milk. It forms acid and gas in glucose and saccharose, but only acid in lactose, mannitol, and dulcitol. It is an indol producer.

To the same group belongs *Wesenbergus giumai* Castellani, which is non motile.

Archibald in the Anglo-Egyptian Sudan obtained an organism of this type from the blood of a case of enteroidea in Khartoum on the fifth day of the illness. It was motile, formed acid and gas in glucose, galactose, and rhamnose (iso-dulcite), dextrin, starch, mannitol, and sorbitol, but only acid in lactose, levulose, maltose, and dulcitol, while it failed to ferment saccharose, raffinose, inulin, salicin, glycerol, erythrol, or adonitol. It did not produce indol, gave a negative Voges-Proskauer reaction, but reduced nitrates and neutral red. Specific serum reactions separated it from *Eberthus typhosus, Salmonella paratyphi, S. paratyphosa*, and *S. gaertneri*, and it was well agglutinated by the patient's serum during convalescence. We name it *Wesenbergus fermentosus*.

Readers interested in this group will find some strains described by Alexander in 1914 in the supplement to the Annual Report of the Local Government Board, which may well be classified here.

The named species may be separated as follows:—

A. *Indol produced* :—
  I. Dulcitol fermented—*Wesenbergi.*
  II. Dulcitol not fermented—*Giumai.*
B. *Indol not produced—Fermentosus.*

Genus **Enteroides** Castellani and Chalmers, 1918.

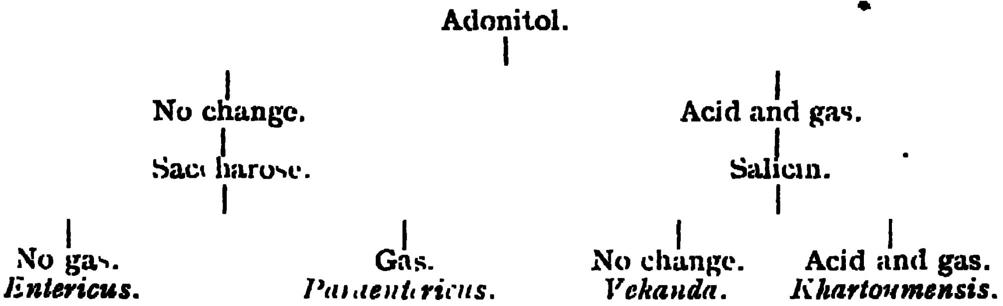
Definition.—Eberthеæ which ferment glucose and lactose completely with the production of acid and gas. Milk not clotted.

Type Species.—*Enteroides entericus* (Castellani, 1907).

Remarks.—Castellani isolated two organisms from cases of enteroidea and appendicitis in Ceylon—viz., the type and *E. paraentericus*—and later found another, *E. vekanda*, in the Balkans.

Chalmers and Macdonald obtained *E. khartoumensis* from cases of enteroidea in the Anglo-Egyptian Sudan.

Classification.—The various species of the genus may be recognized as follows:—



Genus **Escherichia** Castellani and Chalmers, 1918.

Definition.—Eberthеæ which ferment glucose and lactose completely; milk clotted.

Type Species.—*Escherichia coli* (Escherich, 1886).

Classification.—The number of species gathered together under this genus, even after the rejection of those so imperfectly described that they cannot be classified, is so large that they require to be divided into groups and sections as follows:—

A. Indol produced—*Smith's indol division.*
  I. Saccharolytic—*Communior section.*
  II. Non-saccharolytic—*Communis section.*
B. Indol not produced—*Smith's non-indol division.*

We recognize the mistake which has been made with regard to the organism called *Coscoroba*, which, as originally described, belongs to the genus *Pasteurella*—*i.e.*, among the hæmorrhagic septicæmias, being a cause of disease and death in swans. By some mistake, years ago quite a different organism belonging to the Colon group received this name. In order to prevent confusion, we propose to call the Colon type of Coscoroba by the name *Escherichia pseudocoscoroba* Castellani and Chalmers, 1918. The species may be recognized as follows:—

SMITH'S INDOL-PRODUCING DIVISION.

Durham's Saccharolytic Communior Section.

Dulcitol.

- Acid and gas.
  - Adonitol.
    - Acid and gas
      - Motility.
        - Absent. *Oxytocus.*
        - Present *Metacoli*
    - No change.
      - Motility.
        - Present
          - Pseudocoli serum
            - Agglutination. *Pseudocoli*
            - Non-agglutination (late fermentation of saccharose). *Coliformis.*
        - Absent
          - *Neapolitanus.*
- No change.
  - Motility.
    - Present.
      - Inosite.
        - Acid and gas. *Pseudocoloidella*
        - No change. *Pseudocoloides.*
    - Absent. *Pseudocoscoroba.*

SMITH'S INDOL-PRODUCING DIVISION.

Durham's Non Saccharolytic Communis Section.

Dulcitol.

- Acid and gas
  - Salicin.
    - Acid. *Cavicida.*
    - Acid and gas
      - Motility.
        - Absent.
          - Inosite.
            - No change. *Coloidella.*
            - Acid and gas. *Coloides.*
        - Present. *Coli.*
    - No change. *Metacoloides.*
- No change
  - Motility.
    - Absent
      - Maltose.
        - Acid and gas. *Colitropicalis.*
        - No change. *Vesiculosus*
    - Present.
      - Maltose.
        - Acid and gas. *Paragrünthali.*
        - No change. *Grünthali.*

SMITH'S NON-INDOL-PRODUCING DIVISION.

This division contains only one organism, *Escherichia coli mutabilis* Massini, insufficiently described.

TRIBE PASTEURELLEÆ CASTELLANI AND CHALMERS, 1918.

Definition.—Bacillaceæ with good growth on ordinary media, without endospores, aerobic, without fluorescence or pigment formation, unable to liquefy gelatine, and Gram-negative, but with polar staining.

Type Genus.—*Pasteurella* Toni and Trevisan, 1889.

Genus Pasteurella Toni and Trevisan, 1889.

Definition.—Pasteurelleæ with the tribal characters.

Type Species.—*Pasteurella cholerægallinarum* (Zopf, 1885).

Remarks.—This genus was formed by Toni and Trevisan, and includes all the organisms of the hæmorrhagic septicæmic group, and especially plague. It is to be noted that *Pasteurella coscoroba* (Trétrop, 1900) belongs to this genus, as well as *Pasteurella pestis* Kitasato and Yersin, 1894. The two great divisions, the animal and the human diseases, may be separated as follows:—

A. No growth on MacConkey's medium containing glucose, levulose galactose, or mannitol—*Animal group*.
B. Growth on MacConkey's medium containing the above-mentioned sugars—*Plague*.

This test must, however, be confirmed by animal inoculations.

TRIBE PROTEÆ CASTELLANI AND CHALMERS, 1918.

Definition.—Bacillaceæ growing well on ordinary laboratory media, not forming endospores, aerobic, without fluorescence or pigment formation, but liquefying gelatine.

Type Species.—*Proteus vulgaris* Hauser, 1885.

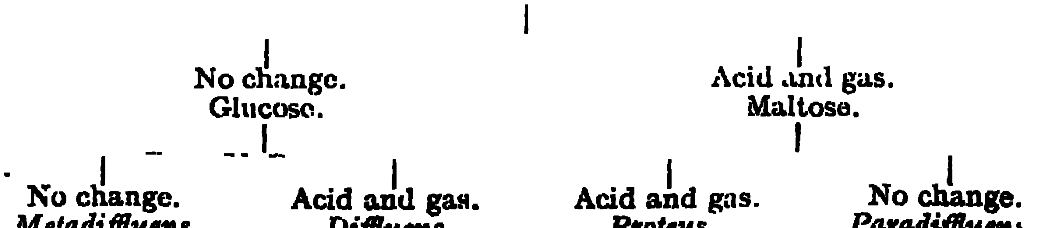
Classification.—The tribe may be divided into genera as follows:—

A. Rapid gelatine liquefiers; do not ferment lactose, mostly Gram-positive—*Proteus*.
B. Slow gelatine liquefiers; ferment lactose; Gram-negative—*Cloaca*.

Genus Proteus Hauser, 1885, *em.* Castellani and Chalmers, 1918.

Type Species.—*Proteus vulgaris* Hauser, 1885.

Remarks.—These organisms are of difficult classification, as the serological reactions are not always in accord with the biochemical characters. To this group belongs Proteus X_{19} (see page 1336). Some species may be separated as follows:—



Bacteria.	*Motility.*	*Gram.*	*Gelatine.*	*Serum.*	*Litmus Milk.*	*Lactose.*	*Saccharose.*	*Dulcite.*	*Mannite.*	*Glucose.*	*Maltose.*	*Dextrin.*	*Raffinose.*	*Arabinose.*	*Adonite.*

Genus Cloaca Castellani and Chalmers, 1918.

Type Species.—*Cloaca cloacæ* Jordan, 1890.

Remarks.—Two species are known, *C. cloacæ* Jordan and *C. levans* Wolffin, but they are not important in tropical medicine. They may be recognized as follows:—

Saccharose.

Acid and Gas.	No change.
Cloacæ.	*Levans.*

TRIBE BACTERIDIEÆ CASTELLANI AND CHALMERS.

Definition.—Bacillaceæ growing well on ordinary laboratory media, without endospores, and either fluorescent or chromogenic.

Type Genus. *Bacteridium* Schroeter, 1872.

Remarks.—Two distinct groups belong to this tribe—viz., the fluorescent and the chromogenic—but we are only concerned with the latter, to which the type genus belongs.

Genus Bacteridium Schroeter, 1872.

Definition.—Bacteridieæ which are chromogenic.

Type Species. *Bacteridium prodigiosum* (Ehrenberg, 1838).

Remarks.—Although we are not particularly concerned with this genus as a whole in the tropics, still there is one species—*Bacteridium pyocyaneum* Gessard, 1882, synonym *Bacterium æruginosum* Schroeter, 1872—which is the organism of bluish-green pus.

It is a common intestinal parasite in the tropics, and is moderately common in pus in Ceylon, India, and the Anglo-Egyptian Sudan.

It is a small motile rod, which becomes pleomorphic if grown on media containing carbolic or boric acids. It only produces its bluish-green pigment when grown aerobically.

It produces acid, but no gas, in glucose, and no change in maltose, dulcitol, or salicin. Litmus milk is rendered alkaline and not clotted.

TRIBE GRACILOIDEÆ CASTELLANI AND CHALMERS 1918.

Definition.—Bacillaceæ growing very slowly and scantily on ordinary and blood media, without endospores or capsules, neither fluorescent nor chromogenic.

Type Genus.—*Graciloides* Castellani.

Genus Graciloides Castellani, 1917.

Definition.—*Graciloideæ* with the tribal characters.

Type Species.—*Graciloides albofaciens* Castellani, 1904.

Classification.—Two species have been so far described, which may be recognized as follows:—

A. Litmus milk rendered acid and clotted—*Albofaciens.*
B. Litmus milk decolorized or peptonized—*Tardus.*

TRIBE BACTEROIDEÆ CASTELLANI AND CHALMERS.

Definition.—Bacillaceæ with good growth on ordinary laboratory media, without endospores, fluorescence, or pigment formation, and obligatory anaerobes.

Type Genus.—*Bacteroides* Castellani and Chalmers, 1918.

Genus Bacteroides Castellani and Chalmers, 1918.

Definition.—Bacteroideæ with the tribal characters.

Type Species.—*Bacteroides fragilis* Veillon and Zuber.

The type is found in abscesses from various parts of the body. Another species is the well-known *Bacteroides fusiformis* of Le Dantec and Vincent, found in hospital gangrene, and in Vincent's angina and many other conditions, as well as in the mouths of healthy persons and in the tartar on teeth.

Some of the intestinal forms are given on p. 960.

TRIBE BACILLEÆ CASTELLANI AND CHALMERS, 1918.

Definition.—Bacillaceæ growing well on ordinary laboratory media and possessing endospores.

Type Genus.—*Bacillus* Cohn, 1872, *parte*.

Genus Bacillus Cohn, 1872.

Definition.—Bacilleæ with the tribal characters.

Type Species.—*Bacillus subtilis* (Ehrenberg, 1833).

Classification.—The genus may be divided into two groups as follows:—

A. Aerobes—*Subtilis group*.
B. Obligatory anaerobes—*Tetanus group*.

Only the latter concerns us at present.

TETANUS GROUP.

The group may be divided into subgroups as follows:—

A. Gelatine liquefied:
  I. Inspissated blood serum not liquefied:—
    (*a*) Little or no gas in milk; white of egg not sensibly affected. Usually motile—*Subgroup Quarter Evil*.
    (*b*) Much gas in milk; white of egg slightly affected. Usually non-motile—*Subgroup Saccharolytic*.
  II. Inspissated blood serum liquefied:—
    White of egg digested—*Subgroup Proteolytic*.
B. Gelatine not liquefied:—
  Inspissated blood serum not liquefied. White of egg not digested—*Subgroup Non-liquefactive*.

SUBGROUP QUARTER EVIL.

Synonym.—Rauschbrand group.

Definition.—Tetanus group usually motile, liquefying gelatine, non-proteolytic, and do not liquefy inspissated blood serum. Clotting milk without much shrinkage. Citron and bladder forms occur. Spores usually central.

Classification.—The organisms of this group may be recognized as follows:—

A. Long threads present—*Vibrion septique*.
B. Long threads absent:—
  I. Saccharose fermented—*Feseri*.
  II. Saccharose not fermented:—
    (*a*) Spores rare in animals—*Novyi*.
    (*b*) Oval end spores present—*End-sporing types*.

Bacteroides.	*Motility.*	*Litmus Milk.*	*Lactose.*	*Saccharose.*	*Glucose.*	*Starch.*	*Indol.*	*Gelatine.*	*Egg Albumen.*	*Broth.*	*Gram.*	*Spores.*	*Appearance of Growth in Deep Glucose Agar.*	*Formation of Gas in Agar.*	*Remarks.*

B. pseudo-ramosus Distaso	O	C	S+	S+	S+	O	+	O	O	T	–	O	Round; non-transparent.	O	—
B. anaerobicus Distaso	+	O	O	O	S+	O	O	O	O	T	+	O	Almost invisible.	O	—
B. cornutus Distaso	O	O	O	O	S+	O	O	O	O	T	+	O	Almost invisible.	O	—
B. bullosus Distaso	+	O	O	O	S+	O	O	O	O	T	O	O	Minute colonies, pin-head sized.	O	—
B. tethaiotaomicron Distaso	+	C	+	O	+	O	+	O	O	T	O	O	Transparent, medium-sized.	S+	—
B. variegatus Distaso	+	C	S+	O	S	O	+	O	O	T	+	O	Minute colonies, pin-prick sized.	O	—
B. bifidus Tissier	O	C	+	+	+	O	O	O	O	T	+	O	Pleomorphic colonies; mainly round or crenated.	O	— —

Abbreviations used in the Table.—O=negative result; + =positive result; C=clotted; T=turbidity; S+ =slight positive.

Remarks.—*Bacillus feseri* [Trevisan, 1885, the causal organism of quarter-evil, is the same as *B. chauvœi* Arloing, Cornevin, and Thomas, 1887; *B. carbonis* Migula, 1900; *B. anthracis symptomatici* Kruse, 1896; and the *Bacillus of Rauschbrand auctores.*

The Vibrion septique of Pasteur is the same as the bacillus of Ghon and Sachs, and has been found in gas gangrene; it really covers a group of strains which agree in morphology and in cultural characters, as well as in pathogenicity, but their agglutinative reactions are different.

SUBGROUP SACCHAROLYTIC.

Synonyms.—*Welchii subgroup : Perfringens subgroup.*

Definition.—Tetanus group, liquefying gelatine, usually causing stormy fermentation in milk, in which spores are not formed. Do not blacken meat or liquefy blood serum.

Classification.—The following organisms belong to this group:—

1. *B. welchii* Migula, 1900. (*Synonyms* :—*B. perfringens* Veillon and Zuber, 1898; *B. aerogenes capsulatus* Welch and Nuttall, 1892; *B. phlegmonis emphysematosi* Fraenkel, 1902; *B. saccharobutyricus immobilis* Schattenfroh and Grassberger, 1900; *B. enteritidis sporogenes* Klein, 1915, *pro parte.* This organism is merely a mixture of *B. welchii* and *B. sporogenes*, Achalme's bacillus.)
2. *B. fallax* Weinberg, 1915.
3. *B. œdematiens* Weinberg and Sequin, 1915.
4. *B. aerofetidus* Weinberg, 1916.

They may be differentiated as follows: -

- A. *Non-motile* :—
  - Saccharose and lactose fermented, but salicin not fermented—*Welchii.*
- B. *Feebly motile in cultures, more motile in tissues* :—
  - I. Saccharose and salicin fermented, but lactose not fermented—*Fallax.*
  - II. Saccharose not fermented, but lactose and salicin fermented -*Aerofetidus.*
  - III. Saccharose, lactose, and salicin not fermented —*Œdematiens.*

SUBGROUP PROTEOLYTIC.

Definition.—Tetanus group liquefying gelatine and inspissated blood serum. Meat media blackened. Milk usually digested without forming a clot. Colonies grow out in long tangled filaments.

Classification.—The following organisms belong to this subgroup:—

1. *B. tetani* Flügge, 1886.
2. *B. sporogenes* Metchnikoff, 1908. (*Synonyms* :- -*B. cadaveris sporogenes* Klein, 1901; *B. œdematis maligni* Koch, 1881; *B enteritidis sporogenes* Klein, 1895, *pro parte* *B. putrificus coli* Bienstock, 1906)
3. *B. botulinus* van Ermengem, 1898.
4. *B. histolyticus* Weinberg and Sequin, 1916.

They may be differentiated as follows: -

- A. *Dense white balls in four to five days in meat media :*
  - Very few large subterminal spores in culture. Pathogenic for laboratory animals—*Histolyticus.*
- B. *No formation of white balls in meat media* :-
  - I. Non-pathogenic for laboratory animals:
    - Central, subterminal, or terminal spores a marked feature in cultures—*Sporogenes.*
  - II. Pathogenic for laboratory animals:—
    - (*a*) Spores oval, central, or terminal—*Botulinus.*
    - (*b*) Spores round and terminal—*Tetani.*

Subgroup Non-Liquefactive.

Definition.—Tetanus group, motile, not liquefying gelatine or inspissated blood serum, and do not blacken meat media.

Remarks.—This group includes:—

1. *B. tertius* Henry, 1917, found in gas gangrene. (*Synonyms:— B. Y. Fleming*, 1915; *B. von Hibler* IX.; *B. rodella* III.)
2. *B. von Hibler* VII.
3. *B. amylobacter* Gruber, 1887.

Classification.—These organisms may be recognized as follows:—

A. Attack milk slowly, forming a soft clot after a long period:—
  I. Spores usually central—*Von Hibler* VII.
  II. Spores typically terminal—*B. tertius*.
B. Attack milk, forming tough clot, broken by gas—*Amylobacter*.

FAMILY 8: SPIRILLACEÆ Migula, 1900.

Definition.—Eubacteriales with cells spirally curved or representing part of a spiral; division in one direction.

Type Genus.—*Spirillum* Ehrenberg, 1838.

Classification.—The family may be divided into the following genera:—

A. Non-motile, comma-shaped, or spirally curved filaments, rigid, without flagella—Genus 1, *Spirosoma* Migula, 1900.

B. Motile, short, slightly curved, rigid, comma-like, sometimes in chains, with one, rarely more, flagella at one end, seldom at both ends—Genus 2, *Vibrio* O. F. Muller, 1773, *emendavit* Loeffler.

C. Motile, long, spirally curved, usually with a bunch of polar flagella composed of long and short forms—Genus 3, *Spirillum* Ehrenberg, 1838, *emendavit* Loeffler.

Remarks.—We are only concerned with the genus Vibrio, which contains the cholera and paracholera organisms.

If the spirochætes were to be considered to be bacteria, they would be classified here under the name Spironema

Genus Vibrio O. F. Müller, 1773.

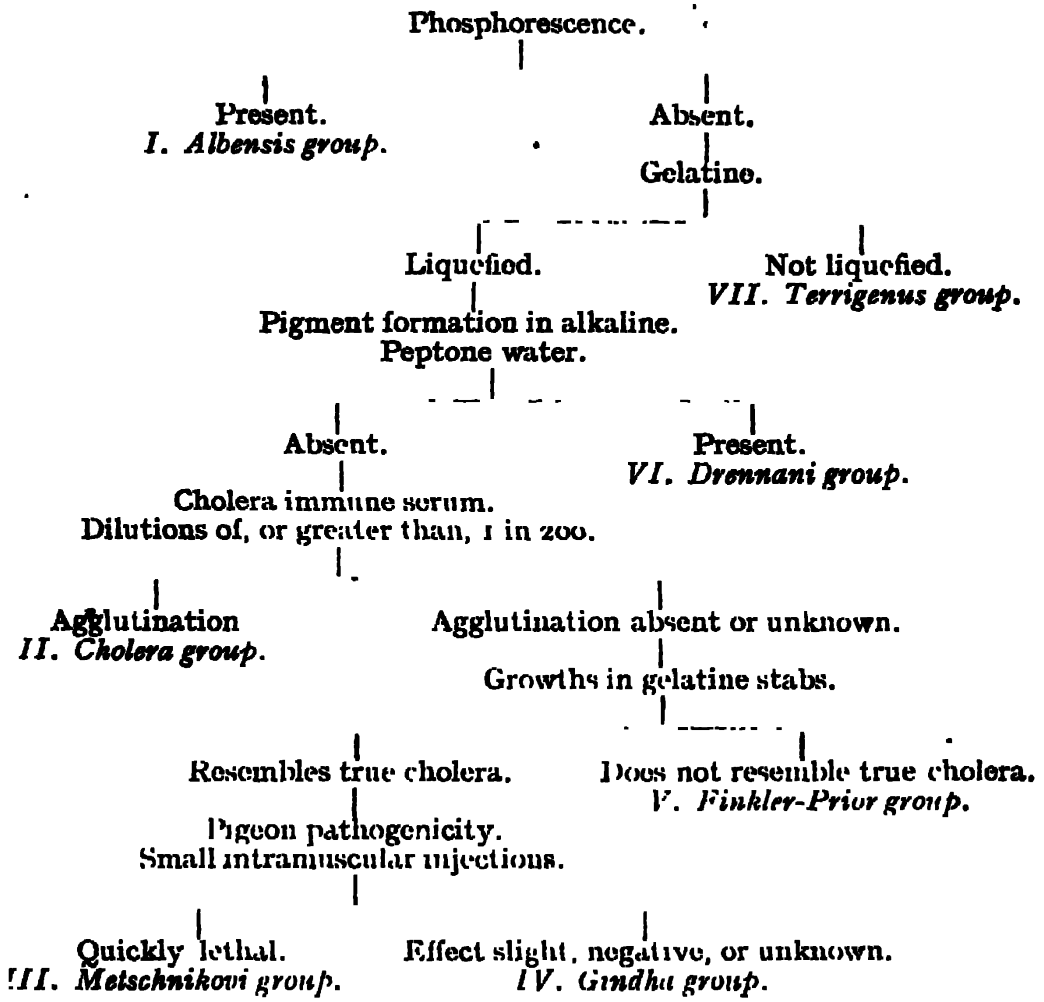
Definition.—Spirillaceæ motile, with short comma-like cells, possessing one, rarely more, flagellum at one, rarely at both ends.

Type.—It is difficult to decide which is the type of this genus so defined.

Remarks.—The important species is the *Vibrio comma* Koch, 1884, which is the cause of Asiatic cholera, but there are many other which cause paracholera—*e.g.*, *V. gindha*, Pfeiffer, 1896; *V. kegallensis* Castellani, 1913; *V. insolitus* Castellani, 1913, etc.

Classification.—The genus may be divided into aerobic groups as follows:—

The Aerobic Groups of the Genus Vibrio O. F. Müller, emendavit Loeffler.



nly the cholera and the gindha groups concern us.

CHOLERA GROUP.

Ruffer classifies the strains of the cholera group as follows:—

Series I.—A. Cholera immune serum.

1. Agglutination positive.
2. Castellani's saturation positive.
3. Pfeiffer's reaction positive.
4. Complement fixation positive.

B. *Hæmolysis negative.*

Series II., El tor vibrios.—A. Cholera immune serum.

1. Agglutination positive.
2. Castellani's saturation positive.
3. Pfeiffer's reaction positive.
4. *Complement fixation negative.*

B. Hæmolysis strongly marked.

Series III.—**A. Cholera immune serum.**

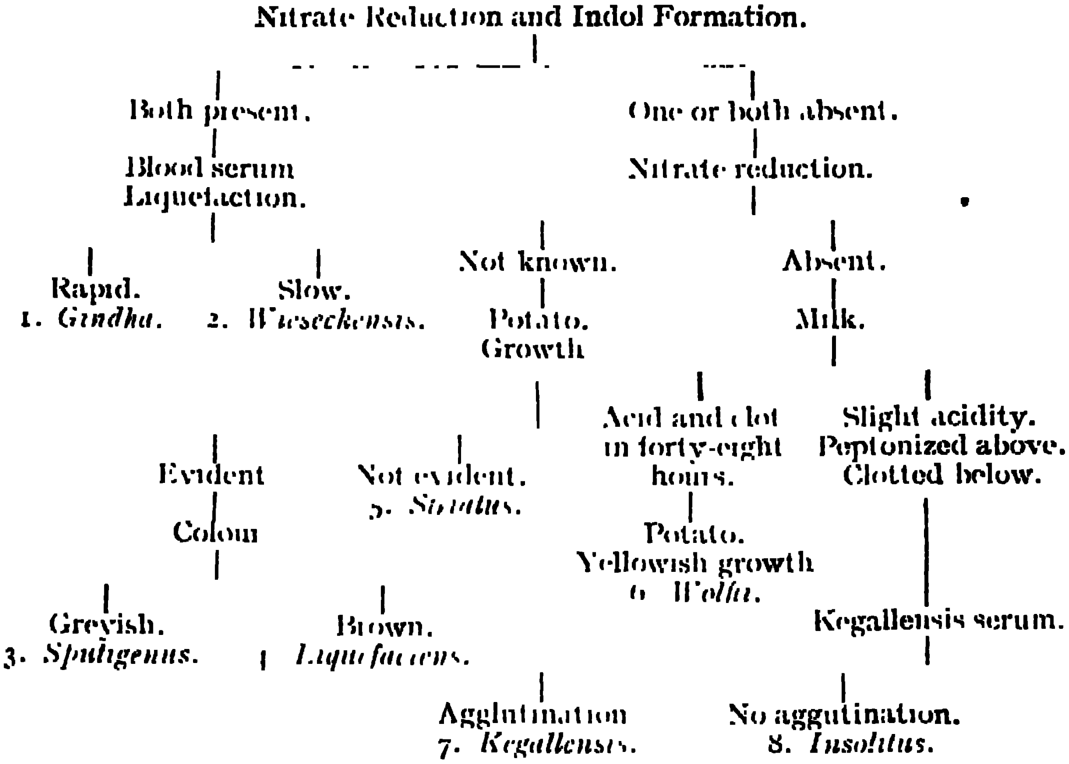
1. **Agglutination positive.**
2. ***Castellani's saturation negative.***
3. ***Pfeiffer's reaction negative.***
4. **Complement fixation positive.**

B. Hæmolysis feeble and late.

The bacteriological characters of the usual vibrio are to be found in every textbook on bacteriology.

GINDHA GROUP.

This group may be divided into species as follows:—



The names of the eight species so differentiated are:—

1. *V. gindha* (Pfeiffer, 1896).
2. *V. liquefaciens* (Migula, 1900).
3. *V. wiesseckensis* (Migula, 1900).
4. *V. striatus* (Migula, 1900).
5. *V. wolfii* (Migula, 1900).
6. *V. sputigenus* (Migula, 1900).
7. *V. kegallensis* vel *paracholeræ* (Castellani, 1913).
8. *V. insolitus* (Castellani, 1913).

Of these, the first and the last two have been associated with paracholera, to the exclusion of other organisms.

FAMILY MYCOBACTERIACEÆ Chester, 1901.

Definition.—Eubacteriales with short or long cells, cylindrical or filamentous, without a sheath, but often clavate, cuneate, or irregular, and often with enclosed granules.

Type Genus.—*Mycobacterium* Lehmann and Neumann, 1896.

Remarks.—Chester created this family to hold such forms as the diphtheria germ, the tubercle bacillus, and the nocardias.

The latter we classify with the Fungi Imperfecti, and probably the other organisms, especially the tubercle bacillus, should join them; nevertheless, for the time being, we keep them in Chester's family.

Mycobacterium becomes the only genus of the family, as Chester included with it the Corynebacterium of Lehmann and Neumann.

Genus Mycobacterium Lehmann and Neumann, 1896.

Definition. Mycobacteriaceæ with the characters of the family.

Type Species. - *Mycobacterium lepræ* (Hansen, 1874).

Remarks.- -From our point of view there are two divisions of the genus which are of importance viz:

A. Acid-fast when stained by Ziehl-Neelsen's method.
B. Not acid-fast when stained by Ziehl-Neelsen's method.

The former include the tubercle and the leprosy bacilli, which may be distinguished by the latter being present in very large numbers in the leprotic nodules, and being very resistant to decolourization, while the former are but few in a cell and relatively easier to decolourize. Moreover, the leprosy bacillus can be readily stained by Gram, while the tubercle is difficult to stain properly.

The tubercle bacillus can be cultivated, but so far there is a doubt as to the leprosy bacillus ever having been cultivated.

The other group contains the diphtheria bacillus. The names of these three organisms are: *M. lepræ* (Hansen, 1874); *M. diphtheriæ* (Klebs, 1883); and *M. tuberculosis* (Koch, 1882).

In addition the *Mycobacterium mallei* (Loeffler, 1886), the cause of glanders, may be mentioned, as Whitmore has described a fever in Rangoon characterized by broncho-pneumonic symptoms and often multiple abscesses, which is due to a closely allied organism introduced into the body while injecting morphine subcutaneously.

REFERENCES.

The current literature may be found in the *Bull. for Trop. Diseases*, and in the *Bulletin de l'Institut Pasteur*. A very valuable general account of anaerobe bacteria is given by Weinberg and Seguin in their recent monograph: "Gangrène Gazeuse" (Masson and Co., Paris).

CHAPTER XXXVII

FUNGACEÆ—PHYCOMYCETES

Preliminary—Fungaceæ—Phycomycetes—Zygomycetes—Mucorales—References.

PRELIMINARY.

THE study of fungi, or *mycology*, as it is often called, includes macroscopic and microscopic forms. The microfungi are those which principally cause disease, which, for this reason, is termed a *mycosis*. Thus 'otomycosis' means a mycosis of the ear, and 'mucormycosis' a disease caused by a mucor, which is a fungus known to Malpighi in 1686.

The study of the microfungi began in the days of Charles II., when Hooke in 1677, made a lens with which he examined the blighted or yellow specks on the leaves of the damask rose, and made excellent drawings of the microfungi which he saw. His book contains a chapter devoted to the 'Blue Mold and the First Principles of Vegetation arising from Putrefaction.'

Malpighi, in 1686, has a chapter devoted to 'Plantis quæ in alliis vegetant,' in which he refers to mucedo.

Ray, in 1706, in his 'Historia Plantarum,' describes *Pilobolus crystallinus*, one of the Mucoraceæ, which has beautiful crystalline sporangia on yellowish sporangiophores, and of which Plukenet in 1720 gave the first illustration.

Micheli, in 1729, named and gave a scientific account of the genus *Mucor*, as well as of *Aspergillus* and many other fungi.

Linnæus, in 1753, in his 'Species Plantarum,' made a résumé of knowledge up to that date; and Hudson, in 1762, described mucors in his 'Flora Anglica'; while Lightfoot in his 'Scottish Flora,' published in 1777, mentioned the ascomycete-sphæria. Pelham (1785), Withering (1795), Dickson (1785-1801), and Hill (1796), all contributed to the knowledge of microfungi, which was slowly growing, as did Batsch, in 1783, in Germany, and Bulliard, in 1791, in France.

This slow but sure progress now became very rapid, and the only way in which we can trace its evolution is by mentioning the great systematic works which are of use for reference.

They are Persoon (1801), 'Synopsis Methodica Fungorum'; Link (1824), 'Caroli Linné Species Plantarum,' Editio Quarto, tomus vi., p. 1; Fries (1821-1829), 'Systema Mycologicum'; Nees von Esenbeck and Henry (1837), 'Das System der Pilze; Kützing (1849), 'Species Algarum'; Charles Robin (1853), 'Végétaux Parasites'; Küchenmeister (1857), 'Animal and Vegetal Parasites of Man'; Fuckel (1869-1870), 'Symbolæ Mycologiæ'; Eidam (1872), 'Mycologie'; Naegeli (1877), 'Die Niederen Pilze.'

In 1881 Winter, Rehm, Fischer, and Lindau's 'Die Pilze Deutschlands,' etc., began to appear, and in 1886 Saccardo's great work of reference, the 'Sylloge Fungorum,' began. Both have continued down to the present period. In 1890 Zopf's oft-quoted work, 'Die Pilze,' was published, and in 1900 Engler and Prantl's 'Pflanzenfamilien.' In 1907 Vuillemin started his new classification in his paper, 'Les Bases actuelles de la Systematique en Mycologie.'

Leaving now the systematic study, we turn to the discovery of forms parasitic in man, beginning with the ringworm discoveries of Remak (1837), Schönlein (1837), Gruby (1842), and Malmsten (1845), and passing through the days of Carter and Manson to those of Sabouraud, Brumpt, De Beurmann, and Gougerot, down to the last, and by no means least, Pinoy, whose valuable researches are of such use in tropical medicine.

The above rather dry account will enable the reader of this and the two following chapters to realize the references and the names of the genera and species. Nomenclature is, however, very confused, and an author, before he gives a fungus a name, should read 'Règles Internationales de la Nomenclature Botanique,' published in 1912. Unfortunately, it has been decided that the nomenclature of the Fungi Imperfecti, which are so important in tropical medicine, should commence with Fries' work, while we are in accord with Vuillemin, who says that Saccardo's 'Sylloge' should be the basis for all fungi.

With this brief history we will pass on to consider the *Fungaceæ* Linnæus, 1737, which, as we have already seen, belongs to the Regnum Vegetabile, division Thallophyta.

SUBDIVISION FUNGACEÆ Linnæus, 1737.

Synonym.—*Fungi auctores.*

Definition.—Thallophyta thread-like, with apical growth producing cells (hyphæ) or rows of cells (hyphæ), which collectively are termed a mycelium, and reproducing by freely escaping spores, which are formed either acrogenously at the end of hyphæ or endogenously in special cells (sporangia), situate either at the apex of a free hypha, or are formed by sexual cells, which may be enclosed in a fruit or perithecium, formed by the interlacing of mycelial threads without chromatophores or chlorophyl.

Morphology.—Fungi are Thallophytes without chlorophyl, and do not contain starch or chromatophores. Their vegetative body, or thallus, consists generally of a mass of filaments or threads termed the 'mycelium.' The threads or filaments forming the mycelium are called 'hyphæ.' The mycelial threads or hyphæ may be *septate* or *non-septate*. Their walls do not consist of ordinary cellulose, but of a substance known as *fungus-cellulose*, which does not stain blue by iodine and sulphuric acid.

Nutrition.—The fungi, being unprovided with chlorophyl, cannot make use of the carbon dioxide of the air, and therefore derive their carbonaceous food material from complex organic compounds, as, for instance, decaying organic substances.

Mode of Life.—Fungi live as parasites or as saprophytes. They may live one way or the other, according to circumstances. Fungi are parasites of man, of the lower animals, and of plants.

Biological Characters.—Recent researches have shown the great biological analogies between fungi and bacteria as regards production of toxins, agglutination, and immunization phenomena, etc. Charrin and Ostrowsky, Concetti, Roger, and others, have obtained a soluble toxin from *Monilia albicans*. Auclair and Verliac have isolated from *Nocardia bovis* a toxic product soluble in ether, which they call 'actinomycetine.' They state that the injection of this substance produces the same lesions as the fungus. Ceni, Besta, Otto, and others, have obtained various toxins from fungi of the genus *Aspergillus*.

Macfadyen, by vaccinating animals with cultures of a saccharomyces, and G. H. Rogers and Concetti, using *Monilia candidans* Robin, have noticed a production of specific agglutinins and immune bodies. Similar results have been obtained by Quarelli using *Monilia balcanica* Castellani.

Plato, Bloch, Truffi, and others have prepared trichophyton vaccines by killing with heat, and triturating cultures of these fungi. By injecting these vaccines into patients suffering from trichophytoses, they have observed a general reaction, with fever, similar to the reaction obtained in tubercular patients by injecting tuberculin. De Beurmann has described a cuti-reaction in patients affected with sporotrichosis.

Widal and Abrami have introduced a general diagnostic method, 'sporo-agglutination,' based on the fact that the blood of patients suffering from diseases due to fungi contain specific agglutinins for the spores of such fungi. Non-specific coagglutinins may, however, be present in large amount.

Other biological reactions—complement fixation, etc.—have been described.

Reproduction.—The seeds of the Phanerogamia may be said to be represented in the fungi by the roundish or oval-shaped bodies called 'spores.' The spores multiply by budding, producing daughter spores, identical with the parent spores. Under certain conditions the spore, by a process of germination, gives rise to a true mycelial filament, which ramifies, producing mycelial hyphæ. Some of the terminal hyphæ are shorter and structurally different from the other hyphæ, and they become organs of fructification, which produce spores. The formation of spores upon these hyphæ takes place in various modes, of which five different types may be distinguished.

1. *Conidia or Exospores.*—These are non-sexual spores, which take origin by a process of budding or septation from the extremity of a germinal mycelial hypha or *sporophora*. The spores may all be of the same size, or, at other times, some are much larger, *macroconidia*, others smaller, *microconidia*. The conidia are at first always unicellular, but later they may divide and become multicellular.

2. *Chlamydospores or Endoconidia.*—These are asexual globular spores of great size, and provided with a thick membrane. Chlamydospores are terminal or intramycelial.

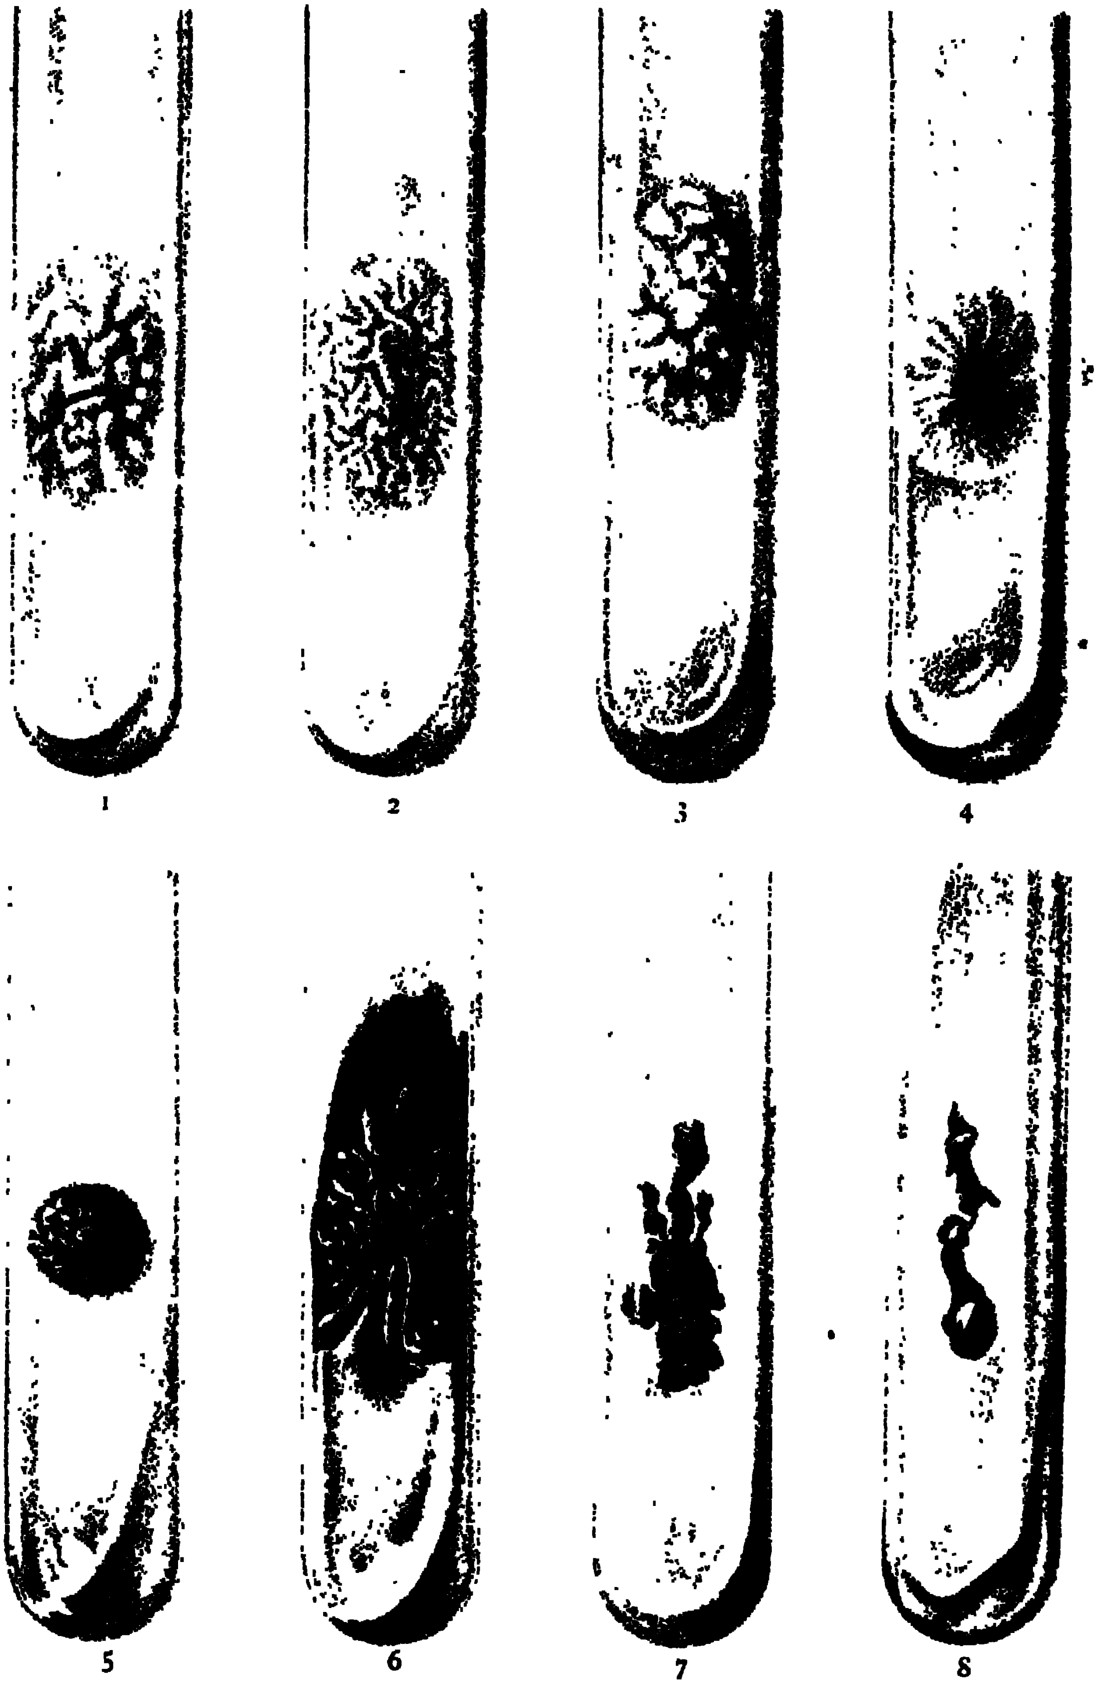
3. *Endospores or Gonidia.*—These spores take origin inside a special spore-case structure, or *sporangium*, which is often terminal and aerial. Endospores which are free and provided with organs of locomotion (cilia or flagella) are called *zoöspores*, and the sporangium is known under the name of *zoösporangium*.

PLATE V.

CULTURES OF SOME TROPICAL FUNGI.

1. ENDODERMOPHYTON CONCENTRICUM Blanchard, 1901, *emendavit* Castellani, 1911.
   Typical culture on glucose agar three weeks old.
2. ENDODERMOPHYTON TROPICALE Castellani, 1914.
   Old culture on glucose agar.
3. ENDODERMOPHYTON INDICUM Castellani, 1911.
   Fairly old culture on glucose agar.
4. ENDODERMOPHYTON INDICUM Castellani, 1911.
   Young culture on glucose agar.
5. EPIDERMOPHYTON RUBRUM Castellani, 1909
   Culture on glucose agar.
6. TRICHOPHYTON VIOLACEUM Bodin, 1902; VAR. DECALVANS Castellani, 1911.
   Culture on Sabouraud's agar.
7. CLADOSPORIUM MANSONI Castellani, 1905.
   Culture on Sabouraud's agar.
8. NIGROCOCCUS NIGRESCENS Castellani, 1910.
   Culture on Sabouraud's agar.

PLATE V.



CULTURES OF SOME TROPICAL FUNGI.

Geo. Waterston & Sons, Ltd. Edin.

To face page 970

***Ascus Fructifications*, or *Asci*, are special sporangia, containing four or eight or a multiple of eight spores arranged in a single line. These spores are called *ascospores*. Each ascospore presents two membranes, *one internal, one external*. The external membrane frequently shows a pore, which is called the *germinating pore*.**

***Basidia Fructifications*.**—Basidia are large elongated cells, each of which supports at its apex two or four slender processes (sterigmata), each terminating in a small roundish conidium or basidio-spore.

4. *Zygospores*.—These are the product of a process of conjugation or modified sexual act between two special hyphæ. These hyphæ give rise to small club-shaped branches, which come into contact and fuse together, forming a new large cell, which presents a very resistant double wall. The special branches (*gametes*) which come into contact and unite to produce the *zygospore* do not show any apparent sexual differentiation.

5. *Oöspores*.—These are formed by a complete sexual act or fertilization, and can therefore be compared with a fertilized ovum.

The female element (*oösporangium, oögonium*) contains one or more roundish protoplasmatic masses (macrogametes or *oöspheres, female gametes*), and presents a thick wall pierced by several *pores*. The male gamete (*antheridium*), which originates on a delicate special hypha, comes into contact with the oösporangium, sending a protoplasmatic process through it. In other cases the *antheridium* divides into several motile bodies called *microgametes, antherozoids*, or *spermatozoids*, which come into contact with the oösporangium, and fertilization takes place. In some rare cases the transformation of the oösporangium into an oöspore is in reality a process of parthenogenesis.

Classification.—The Fungaceæ may be arranged in two divisions, viz.:—

A. Vegetative body a multinucleate naked plasmodium—*Myxomycetes*.
B. Vegetative body usually filamentous—*Eumycetes* Schroeter, 1892.

We are only concerned with the Eumycetes.

Eumycetes Schroeter, 1892.

The Eumycetes may be classified as follows:—

A. Mycelium continuous in the vegetative stage—Class I., *Phycomycetes* De Bary, 1856.
B. Mycelium septate:—
    I. Spores in asci—Class II., *Ascomycetes* Berkeley.
    II. Spores in basidia—Class III., *Basidiomycetes* De Bary, 1856.
    III. Spores not in asci or basidia, but on conidiophores, naked or in pycnidia or unknown—Class IV., *Fungi Imperfecti* Fuckel, 1869.

The fungi parasitic in man are practically all found among the Phycomycetes, the Ascomycetes, and the Fungi Imperfecti. Only one species of importance is found among the Basidiomycetes, and none among the Myxomycetes.

CLASS I. PHYCOMYCETES DE BARY, 1856.

Definition.—Eumycetes with mycelium continuous in the vegetative stage.

Type Genus.—*Mucor* Micheli, 1729.

Classification.—The Phycomycetes may be divided into subclasses as follows:—

A. Sexual spores when present isogamous (similar gametes)—Subclass 1, *Zygomycetes*.
B. Sexual spores when present heterogamous (dissimilar gametes)—Subclass 2, *Oomycetes*.

ZYGOMYCETES.

Definition.—Phycomycetes with similar gametes.

Classification.—The Zygomycetes may be divided into two orders:—

A. Several asexual spores in sporangia—Order 1, *Mucorales*.
B. Solitary asexual spore, a true conidium, on conidiophore—Order 2, *Entomophthorales*.

Only the first order is of interest to us.

ORDER MUCORALES.

Definition.—Zygomycetes with several asexual spores in a sporangium, which in some genera are conidia like bodies.

Type Genus.—*Mucor* Micheli, 1729.

Classification.—The Mucorales may be divided into the following families:—

A. Asexual spores in typical sporangia, in some genera few spored.
   I. Columella present, zygospores naked and thinly covered—Family 1, *Mucoraceæ*.
   II. Columella absent, zygospores closely covered by hyphæ—Family 2, *Mortierellaceæ*.
B. Asexual spores not in typical sporangia—Families *Choanephoraceæ*, *Chætocladiaceæ*, *Piptocladiaceæ*.

Only the Mucoraceæ are of importance to us.

FAMILY MUCORACEÆ.

These organisms have a ramified thallus, branches taking origin laterally or by dichotomy. Some species are provided with *rhizoids*, root-like hairs by which they are attached to the surface on which they grow. From the surface of the mycelium some aerial branches called 'gonidiophores' take origin, each of which supports on its distal extremity a pear-shaped, globular, or claviform sporangium called *gonidangium*. The *sporangium* is at first separated from the gonidiophore by a septum, which later protrudes into the lower portion of the sporangium to form a variously shaped structure termed the *columella*.

Inside the sporangium or gonidangium *endospores* or *gonidia* develop by free cell-formation.

The sporangial protoplasm not used in the formation of endospores gives rise to a peculiar mucilaginous substance, which at a later period, by absorption of water, causes the bursting of the sporangium. Each endospore or gonidium, when it has become free, gives rise to a mycelial tube by germination. This mycelial tube ramifies, and a new mycelium is formed.

In some species, under certain conditions, a sexual reproduction may take place. This consists in the conjugation of undifferentiated non-motile gametes, which leads to the formation of zygospores.

Many species, when vegetating in unfavourable media, reproduce only by formation of conidia and chlamydospores.

The Mucoraceæ are extremely common as parasites or saprophytes of plants and animals. A mycosis due to these parasites is often termed 'mucormycosis.'

Mucoraceæ can be easily grown on sugar culture media—for instance, Sabouraud's maltose agar—or even on ordinary agar. The optimum temperature for their growth is between 35° and 40° C. The Mucoraceæ require plenty of oxygen, and therefore the media tubes must never be closed with rubber caps. When there is not enough oxygen, the Mucoraceæ lose their characteristics, and give rise to monilia-like or yeast-like forms.

Classification.—Four genera of Mucoraceæ are found to contain species parasitic on man:—

Family Mucoraceæ	Mycelium ramified, no rhizoids—*Mucor*. Mycelium non-ramified, with or without rhizoids; the peduncle supporting the sporangium terminates in a special formation encircling the base of the columella—*Lichtheimia*. Mycelium with rhizoids, columella ovoid—*Rhizomucor*. Mycelium with rhizoids; columella hemispheric, shaped like a mushroom—*Rhizopus*.

Genus Mucor Micheli, 1729.

Ramified mycelium; absence of rhizoids.

Mucor mucedo Linnæus, 1761.

Synonyms.—*Mucor vulgaris* Micheli, 1729; *M. sphærocephalus* Bulliard, 1791

The hyphæ carrying sporangia (sporangiophores) are long and erect; the sporangium is globular, 100 to 200 μ in diameter; its colour brownish; its surface covered by fine, minute crystals of oxalate of calcium. The spores (gonidia) are elliptical, with a smooth surface. The columella is ovoid-shaped, and generally yellowish. Occasionally very large zygospores may be observed.

M. mucedo L. is very common, living in organic substances in decomposition—for instance, horse-dung. It is the cause of a deadly disease in bees—the so-called 'mucorine,' or May's disease—but is seldom found in man. Fürbringer has observed it twice in cases of pulmonary infarcts. A case of broncho-pulmonary mucormycosis has been observed by Castellani in the Balcanic Zone.

Mucor pusillus Lindt, 1886.

Mycelium at first white, then yellowish. The hyphæ carrying sporangia are much shorter than in the preceding species. The sporangium is globular, at first pale greyish, then dark greyish. Its diameter varies between 50 and 80 μ. The columella is claviform, ovoid or spherical, yellowish or brownish. The spores are smooth, spherical, 3 to 3·5 μ in diameter.

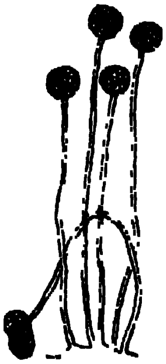


FIG. 479.—*Mucor mucedo* LINNÆUS.

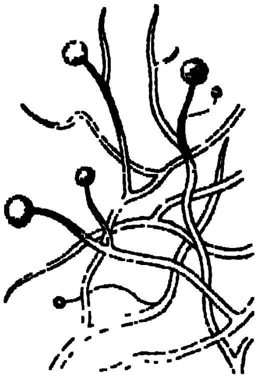

FIG. 480.—*Mucor pusillus* LINDT. (After Lindt.)

M. pusillus is often found in bread which has been soaked in water. It is very pathogenic to rabbits: it has once been found in man in a case of otomycosis by Jakowski.

Genus Lichtheimia Vuillemin, 1904.

Non-ramified mycelium; rhizoids may be present or not; peduncle supporting sporangium terminates in a formation encircling the base of the columella.

Lichtheimia corymbifera Cohn, 1884.

Synonym.—*Mucor corymbifer* Cohn, 1884.

Mycelium at first white, then yellowish. The sporangia are pear-shaped, 10 to 70 μ in diameter: columella conical, dark greyish or brownish: spores elliptical, 2 to 3 μ. The hyphæ carrying sporangia are ramified in corymbiform formation. This parasite has been observed several times in man, giving rise to a mycosis of the ear (Hückel, Siebenmann, Graham), of the nose (Siebenmann), of the lungs (Podack). A case of generalized infection has been recorded by Paltauf (see p. 977).

Lichtheimia ramosa Lindt, 1886.

Synonyms.—*Mucor ramosus* Lindt, 1886; *Lichtheimia ramosa* Vuillemin, 1904.

Closely resembles *L. corymbifera*, but rhizoids are often present. The spores are larger, ovoidal, 4 to 7 μ in length. The columella is always smooth.

This species has been observed in man by Jakowski in a case of otomycosis. According to Vuillemin, it is frequently found in the nasal mucosa of horses.

Genus Rhizomucor Lucet and Costantin, 1900.

Rhizoids generally present, columella of ovoid shape.

Rhizomucor parasiticus Lucet and Costantin, 1900.

Mycelium at first greyish, later brownish. Sporangium globular, 35 to 80 μ. Hyphæ carrying sporangia are often ramified, and are between 1 and 2 centimetres in length. They are often provided at their basal portion with rhizoids.

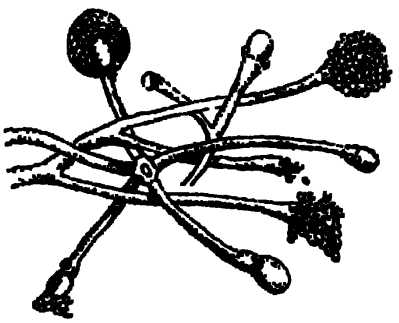

FIG. 481.—*Lichtheimia corymbifera* VUILLEMIN. (After Lichtheim.)

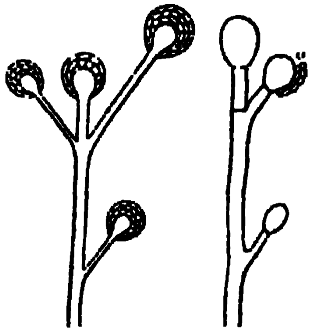

FIG. 482.—*Rhizomucor parasiticus* LUCET AND COSTANTIN. (After Lucet and Costantin.)

The columella is ovoid or pyriform; dark brownish; spores ovoid; longitudinal diameter, 4 μ, transverse diameter, 2·5 μ.

R. parasiticus is pathogenic for guinea-pigs and rabbits. It was found in the expectoration of a woman by Lucet, Costantin, and Lambry. The patient had been considered at first to be suffering from tuberculosis. She recovered under a potassium iodide and arsenical treatment.

Rhizomucor septatus von Bezold, 1889.

Synonyms.—*Mucor septatus* von Bezold; *Rhizomucor septatus* Lucet and Costantin, 1889.

Rhizoids present; sporangia of a brownish-greyish colour, spherical, with a smooth, or occasionally slightly moriform surface; diameter about 30 to 35 μ columella spherical, brownish; spores roundish or slightly oval, from 2·5 to 4 μ.

The spores are of a yellowish or brownish colour; spherical or ovoid, with a smooth surface.

This species was found by Siebenmann in a case of otomycosis.

Genus Rhizopus Ehrenberg, 1820.

Rhizoids present; columella hemispheric; mushroom-like.

This genus contains only one species.

Rhizopus niger Ciaglinski and Hewelke, 1893.

Synonym.—*Mucor niger* Ciaglinski and Hewelke, 1893

The mycelial filaments are provided with abundant rhizoids forming a snow-white mass. Sporangia globular, of black colour when ripe. Spores ovoid, smooth. Columella is at first globular, but later takes a cylindrical shape, and when the spores have become detached, shows a peculiar mushroom-like appearance.

FIG. 483.—*Rhizomucor septatus* VON BEZOLD. (After Siebenmann.)

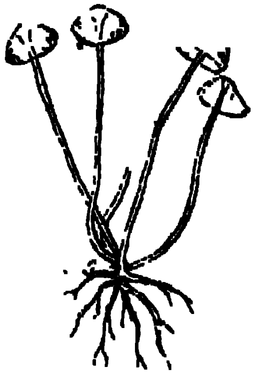

FIG. 484.—*Rhizopus niger* CIAGLINSKI AND HEWELKE. (After Ciaglinski.)

This species was discovered by Ciaglinski and Hewelke in a case of black mycosis of the tongue.

General Remarks on Mycoses due to Species of the Family Mucoraceæ.

These mycoses are generally called mucormycoses. They have been recorded several times in man.

MUCORMYCOSIS OF THE NOSE.—Several cases are on record in which species of Mucoraceæ (generally *Lichtheimia corymbifera*) were found in various affections of the nose. Their pathogenic rôle in such affections has not been demonstrated with certainty.

MUCORMYCOSIS OF THE TONGUE.—Ciaglinski and Hewelke, and later Seniyiak, have described cases of so-called 'black tongue,' due to *Rhizopus niger*.

MUCORMYCOSIS OF THE EAR—OTOMUCORMYCOSIS.—Several cases are found in the literature (Siebenmann, Böke, Hückel, etc.). Almost always *Lichtheimia corymbifera* was present. In the tropics we have observed two cases in which *L. ramosa* occurred. When the fungus is in great quantity, the patient complains of tinnitus aurium and deafness—the same symptoms as those produced by a plug of cerumen in the external auditory meatus.

MUCORMYCOSIS OF THE LUNGS.—This condition is rare. Fürbringer has described two cases in which *L. corymbifera* was found at the autopsy in some hæmorrhagic foci in the lungs. Lucet, Costantin, and Lambry described a case of bronchitis in a woman due to *Rhizomucor parasiticus*. The expectoration was rather scanty and mucopurulent, but without blood. Mycelial threads and spore-like bodies were present. Cultures were made, and the fungus grown. The condition lasted several months. Potassium iodide was given, and later, owing to the symptoms of iodism, various arsenical preparations. Castellani has recorded a case of bronchomucormycosis due to *Mucor mucedo*, in the Balcanic Zone.

General Mucormycosis.—One case only is on record—that of Paltauf. The patient during life presented fever, slight jaundice, enlargement of the spleen and liver, with signs of diffuse bronchitis and obscure nervous symptoms. At the post-mortem the brain presented several foci of a friable, yellowish substance; the other internal organs showed nodules of various size, some rather hard; others had undergone a purulent change. In all these formations mycelial threads were found; in the lung-nodules fructifications (sporangia) were also present, which enabled Paltauf to determine the fungus as *Lichtheimia corymbifera*. According to him, the infection must have originated from the intestine, which showed several ulcerative lesions containing the same fungus.

REFERENCES.

Current Literature.

This is very scattered, but references can usually be found in the *Bulletin de l'Institut Pasteur*, while original papers may be found in the *Archives de Parasitologie*, edited by R. Blanchard; in the *Centralblatt f. Bakteriologie*, in the principal journals of dermatology, such as the *British Journal of Dermatology*, the *Archiv für Dermatologie und Syphilis*, the *Annales de Dermatologie*, *Il Giornale Italiano delle Malattie della Pelle*, and *Lo Sperimentale*.

CHAPTER XXXVIII

ASCOMYCETES AND BASIDIOMYCETES

Preliminary—Classification—Protoascomycetes—Saccharomycetales—Saccharomycetaceæ—Endomycetaceæ—Euascomycetes—Gymnoascaceæ—Aspergillaceæ—Pyrenomycetes—Basidiomycetes—References.

PRELIMINARY.

THIS chapter includes an account of the fungi parasitic on man which belong to the Ascomycetes. These fungi are characterized by their mode of reproduction—viz., by spores originating inside special cells called *asci*. The spores (ascospores, endospores, gonidia) inside the asci are generally four or eight or a multiple of eight. While these fungi live a parasitic life, no asci are found, and reproduction takes place by germination and conidia. The fungi belonging to this order are often pleomorphic, their morphological characters changing according to the medium on which they live.

Classification.—The Ascomycetes are divided into subclasses as follows:—

- A. Asci with varying number of spores, usually numerous—*Hemiascomycetes*.
- B. Asci with a definite number of spores:—
  - I. Asci separate or scattered—*Protoascomycetes*.
  - II. Asci approximate, usually forming a hymenium—*Euascomycetes*.

SUBCLASS PROTOASCOMYCETES.

This subclass contains a single order, the Saccharomycetales.

ORDER SACCHAROMYCETALES.

This order is divided into two families as follows:—

- A. Vegetative cells single or loosely attached in irregular colonies—*Saccharomycetaceæ*.
- B. Vegetative cells forming a mycelium—*Endomycetaceæ*.

FAMILY SACCHAROMYCETACEÆ REES, 1870.

Definition.—Protoascomycetes with vegetative cells single or loosely attached in irregular colonies; mycelium not usually developed; asci isolated, not differentiated from vegetative cells.

Remarks.—These organisms are generally round or ovoid cells, presenting a cell wall of single or double contour; the internal protoplasmatic mass often shows granules and vacuoles. During active vegetation as parasites they reproduce by a ***budding process***, hence the name of ***budding fungi***; when living on artificial media, under unfavourable nutritive conditions, or in the absence of oxygen, they multiply also by formation of endospores or ascospores. Each cellular element may become an ascus containing 1-4, sometimes more, up to 12 spores (ascospores).

The organisms are, as a rule, unicellular plants, but at times the cells elongate, and a rudimentary mycelium may be formed. This occurs, for instance, when the organisms are cultivated in certain fluid culture media—for example, fluid beer-wort. In such cases side-buds, which separate into conidia-like bodies, may also develop on the hyphæ.

Classification.—The family contains thirteen genera, of which only two—*Saccharomyces* Meyen, 1837, and *Willia* Hansen, 1904—contain species parasitic on man; while, in regard to *Schizosaccharomyces* Beyerinck, 1893, it appears doubtful to us whether this really should be placed in this family, as it reproduces by division instead of by budding. The various genera may be recognized as follows:—

- A^1. Vegetative cells globose, ovoid, or pyriform, without lemon-shaped extremities:—
  - B^1. *Vegetative cells increase by budding*:—
    - C^1. Vegetative cells without large fat globule; asci 3-4 spored:—
      - D^1. *Ascospores globose or ovoid*:—
        - E^1. On germination spores form typical yeast cells:—
          - F^1. *Ascus formation not preceded by zygosis*:—
            - G^1. Spore membrane single:—
              - H^1. Spore membrane verrucose—*Debaryomyces* Klöcher.
              - H^2. Spore membrane verrucose and possessing a superficial elevated linear process, dividing the surface into two unequal portions—*Schiönniomyces* Klöcher.
              - H^3. Spore membrane without verrucosities or crest—*Saccharomyces* Meyen, 1838.
            - G^2. Spore membrane double—an inner, *endosporium*, and an outer, *exosporium*—*Saccharomycopsis* Schiönning.
          - F^2. Ascus formation preceded by zygosis:—
            Ascospores have a smooth membrane—*Zygosaccharomyces* Barker, 1901.
        - E^2. On germination spores form a poorly developed promycelium, multiplication by a process intermediate between budding and transverse division—*Saccharomycodes* Hansen, 1904.
      - D^2. Ascospores pileiform or limoniform; costate with bowler-hat shape. No alcoholic formation, but ethers produced, with pleasant fruity odour, in sugar media—*Willia* Hansen, 1904.
      - D^3. Ascospores spherical, hemispherical, or irregularly shaped. Thick pellicle with air-bubbles on sugar liquid media—*Pichia* Hansen, 1904.
    - C^2. Vegetative cells large, spherical, each containing a large fat globule as in torula. D. Asci 8-spored—*Torulaspora* Linder.
  - B^2. *Vegetative cells increase by fission*:—Asci 8-spored—*Schizosaccharomyce* Beyerinck, 1893.
- A^2. Vegetative cells oval, with one or both extremities lemon-shaped. Asci 1-spored—*Hansenia* Linder.
- A^3. Vegetative cells elongate, cylindrical, spores filiform.
  Asci 1-spored—*Monospora* Metchnikoff.
  Asci 8-spored; ascospores flagellate—*Nematospora* Peglion.

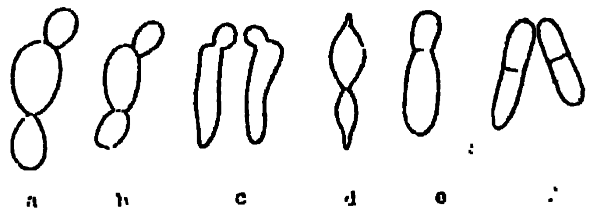

FIG. 485.—TYPES OF YEASTS.
a, Saccharomyces cerevisiæ; *b*, S. ellipsoideus; *c*, S. pastorianus; *d*, S. apiculatus; *e*, Saccharomycodes; *f*, Schizosaccharomyces.
(After Lindner.)

(After Guilliermond.)

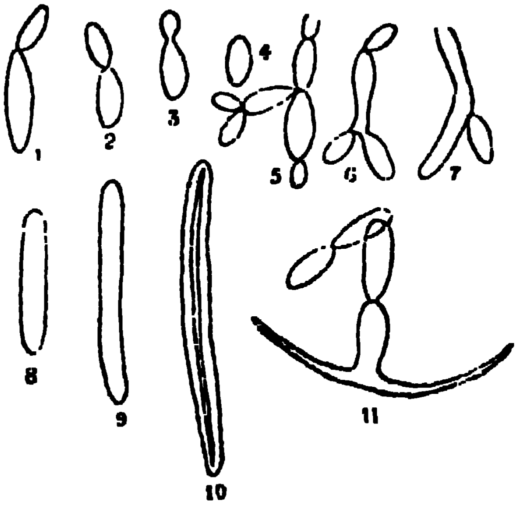

FIG. 489.—*Monospora cuspidata.*
1-7, Budding cells; 8-9, Ascus formation; 10, Ascospore germinating.
(After Metchnikoff and Guilliermond.)

Genus Saccharomyces Meyen, 1838.

Definition.—No proper thallus. Reproduction by budding and ascospores; fermentation of glucose and saccharose, and often of other carbohydrates. Ascospores with one membrane. No trace of any copulative process. Occasionally rudimentary mycelial tubes present, with transverse septation.

Remarks.—As already stated, the fungi of this genus, as well as of the genera *Cryptococcus*, *Monilia*, *Oidium*, and *Coccidioides*, are usually called Blastomycetes, and the diseases induced by them blastomycoses.

The fungi of the genera *Saccharomyces*, *Cryptococcus*, and *Coccidioides* have a great importance in dermatology, as they give rise to peculiar ulcerative affections of the skin, often resembling a syphilide or a tuberculide. The first cases of blastomycosis were observed in America by Posadas, Wernike, and others, who at first believed them to be a protozoal infection. Later Gilchrist, Ricketts, and others recognized the true nature of the parasites. By some authors (Sanfelice, Roncali, etc.), cancer has been considered to be of blastomycetic origin.

Fungi of the genus Saccharomyces are very important from an industrial and agricultural standpoint, being the cause of alcoholic fermentation. The best-known yeast is the brewer's yeast, *S. cerevisiæ*, which is slightly ovoid, 8 to 9 μ in diameter.

Saccharomyces blanchardi Guiart, 1906.

Found at an operation by Blanchard, Schwartz, and J. Binot, on a patient who had been considered to be suffering from tubercular peritonitis. The fungus had produced in the peritoneum a large, whitish, gelatiniform mass, weighing about 1 kilogramme. The fungus grew well on all sugar media.

On maltose agar it produced crateriform colonies of a snow-white colour. Presence of asci with eight spores. On gelatine mucoid-like, of greyish colour. Slow liquefaction of the medium. On potato mucoid growth, whitish, darkening after a long time. On carrot growth viscid, abundant; pathogenic to rabbits, in which it induced a general mycosis, terminating fatally.

Saccharomyces granulatus Vuillemin and Legrain, 1900.

Observed by Vuillemin and Legrain in a tumour of the submaxillary bone. Cells ovoid, 4 to 5 μ in length, and 3 to 4 μ in breadth. Cultures pinkish or pinkish-red; ascospores and chlamydospores present. Gelatine not liquefied. Sugar reactions not given.

Saccharomyces tumefaciens Curtis, 1896.

Synonym.—*Saccharomyces subcutaneus tumefaciens* Curtis, 1896.

Found by Curtis in a myxomatous tumour. It appeared in the tissues in the shape of spherical bodies 16 to 20 μ in diameter, each surrounded by a zone of amorphous substance. Grows well on all sugar media; in very old cultures asci are seen, with 1–4 spores.

Gelatine with surface growth whitish; no liquefaction. Said to ferment saccharose, but not maltose or lactose. Its action on glucose is not mentioned. Pathogenic to rats and dogs.

Saccharomyces samboni Castellani, 1907.

Cells roundish 6 to 8 μ in diameter—easily grown on various media, producing white colonies, which rapidly coalesce. Found by Castellani in Ceylon in a few cases of intertriginous dermatitis of the cruro-scrotal region. A similar or identical organism has been observed by Whitfield in England in a case of the same dermatitis. Ferments glucose, levulose, and maltose. Gelatine is not liquefied. In very old cultures asci present.

Saccharomyces ellipsoides Rees, 1870.

Found by Maggiora and Gradenigo in two cases of chronic otitis media. The cells are elliptical, about 6 μ in maximum diameter; presence of asci. Maggiora and Gradenigo do not consider this fungus to be pathogenic. The yeast is found on ripe grapes, and has been carefully described by Hansen, *Asci ellipsoide* containing 1-4 spores each. The fungus often produces a pellicle in sugar fluid media. Ferments glucose, maltose, and saccharose.

Saccharomyces hominis Klein and Gordon, 1903.

Isolated in some cases of tonsillitis clinically resembling diphtheria. Roundish or oval cells, 5 to 7 μ in diameter. Pathogenic to guinea-pigs and rabbits. Sugar reactions unknown.

Saccharomyces anginæ Achalme and Troisier, 1895.

Found by Achalme and Troisier in a case of tonsillitis showing white patches; *in situ* cells ovoid, 8-15 × 5-6 microns. In cultures asci, 4-spored, present. On gelatine surface growth white. Ferments saccharose, but other reactions not given.

Saccharomyces balzeri Balzer, Burnier, and Gougerot, 1911.

Synonym.—*Parendomyces balzeri* Balzer, Burnier, and Gougerot, 1911.

Grows on culture media under the type of oval or roundish yeast-like cells, proliferating by budding. Isolated by Balzer, Burnier, and Gougerot from a gummatous affection. Sugar reactions unknown.

FIG. 490.—CRATERIFORM COLONIES *Saccharomyces blanchardi* GUIART. (After Blanchard, Schwartz, and Binot, from Brumpt.)

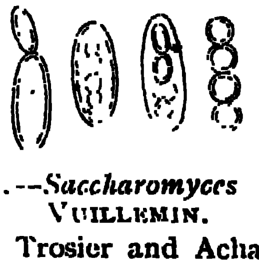

FIG. 491.—*Saccharomyces anginæ* VUILLEMIN. (After Trosier and Achalme.)

Saccharomyces roseus Maggiora and Gradenigo, 1890.

Found by Maggiora and Gradenigo in the Eustachian tube, and considered by them to be non-pathogenic. Cultures of pink colour. Sugar reactions unknown.

Genus Willia Hansen, 1904.

Definition.—Saccharomycetaceæ with ascospores lemon-shaped or hat-shaped (see Fig. 492). As a rule do not produce alcoholic fermentation, but produce various ethers. Cultures present a pleasant fruity odour.

Species in Man.—*Willia anomala* Hansen, 1904.

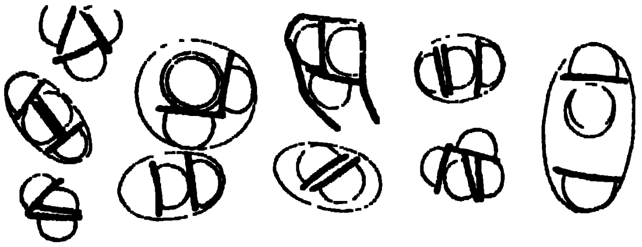

FIG. 492.—ASCOSPORES OF *Willia anomala* HANSEN. (After Guilliermond.)

Willia anomala Hansen, 1904.

Rather small oval cells. In sugar liquid media it forms a well-marked membrane, containing air-bubbles. Asci with 2-4 spores of the so-called hat-like type. Glucose fermented, but not saccharose or maltose. Ferments beer-wort, with production of ethers. Found by Beauverie and Lesieur in the sputum of a tubercular patient.

FAMILY ENDOMYCETACEÆ.

Definition.—Mycelium usually well developed, multiseptate; asci 4-8 spored; spores one-celled.

- A. Mycelium poorly developed—*Podocapsa.*
- B. Mycelium well developed:—
  - I. Asci formed after zygosis—*Eremascus.*
  - II. Asci formed asexually:—
    - (*a*) Asci 4-spored—*Endomyces.*
    - (*b*) Asci 8-spored—*Oleina.*
    - (*c*) Asci with a large number of spores—*Coccidioides.*

Only Endomyces and Coccidioides concern us.

Genus Endomyces Rees, 1870.

Definition.—Endomycetaceæ with mycelium abundant, ramified or not, simple or septate. Presence of budding and asci with four spores. Reproduction by external spores, ascospores, and spores situated inside the mycelial tubes.

Remarks.—Vuillemin believed at one time that the thrush fungus belonged to this genus. Researches carried out by Castellani have demonstrated that the condition known as *thrush* may be caused by various fungi. These fungi, as a rule, do not reproduce by ascospores, and, as justly remarked by Pinoy and Vuillemin himself, belong to the genus *Monilia* (see p. 1079). For the fungus isolated once by Vuillemin, which has all the characteristics of the genus *Endomyces*, Landrieu has suggested the term *Endomyces vuillemini.*

Endomyces vuillemini Landrieu, 1912.

Synonym.—*Endomyces albicans* Vuillemin, 1898.

Found by Vuillemin in 1898 in thrush patches.

Parasitic Life.—This fungus forms white patches on the tongue and buccal mucosa. The patches are easily detached. A particle examined under the microscope shows septate mycelial threads, simple or ramified, the articles of which are straight or somewhat bent. Each article or cell is about 20 μ in length, and 3 to 5 μ in breadth. At the terminal portion of each mycelial thread three or four shorter ovoid elements are found which reproduce by budding. Some similar ovoid or roundish globular refringent cells can be observed, originating laterally at the septations of the mycelium. These globular elements, which were at first considered to be spores, become detached, and reproduce by germination.

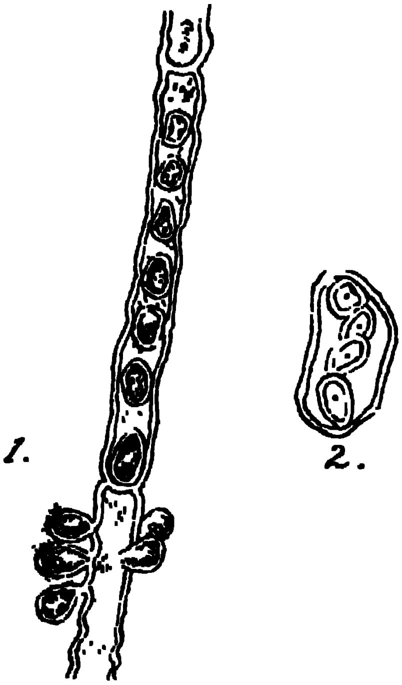

FIG. 493.—*Endomyces vuillemini* LANDRIEU.

(From a culture. After Vuillemin.)

1, Mycelial threads, with endospores and conidia; 2, ascus fructification.

Saprophytic Life--Culture Characters. - The fungus grows well on slightly acid, Sabouraud's, and other media; does not grow abundantly in alkaline media; does not ferment lactose and is Gram-positive.

In cultures the fungus appears under two forms: (1) A filamentous form, showing the mycelial threads simple or ramified. (2) A globular form, morphologically similar to a typical yeast, and reproducing by budding. Both forms may be found in the same culture.

The fungus in cultures reproduces by:—

1. Chlamydospores or external spores; large globular cells 10 to 20 μ in diameter, with thick resistant walls. The chlamydospores are situate at the terminal extremity of some mycelial hyphæ, and represent modified mycelial articles.
2. Asci containing four ascospores.
3. Internal spores. These are oval cells with membrane, protoplasm, and nucleus similar to the external spores. The internal spores are arranged in a single string inside some mycelial tubes.

Pathogenicity.—The fungus was found by Vuillemin in a case of *thrush*, a condition generally due to fungi of the genus *Monilia* (see p. 1079).

Genus Coccidioides Rixford and Gilchrist, 1896.

Definition.—Endomycetaceæ with mycelium well developed and asci containing a large number of spores, with intermediate characters between *Saccharomyces* and *Monilia*. One species only: *Coccidioides immitis* Rixford and Gilchrist, 1896.

Coccidioides immitis Rixford and Gilchrist, 1896.

Synonyms.—*Coccidioides pyogenes* Rixford and Gilchrist, 1896; *Oidium coccidioides* Ophüls, 1905; *O. protozoides* Ophüls, 1905; *Posadasia esferiformis* Cantón, 1898; *Oidium immite* Verdun, 1907.

Definition.—Coccidioides with a large number of spores in the asci.

Discovered by Wernicke in 1882 in America in a patient with patches resembling a tuberculide, and gummata. In the lesions roundish bodies are seen of various sizes, 3 to 80 μ in diameter, with a well-defined thick membrane. Inside some of the bodies numerous spores may be seen. This genus is not well defined.

Cultures.—The fungus grows under two types: (1) a saccharomyces-like type, reproducing by budding; (2) a filamentous type. The colonies are roundish, slightly elevated, but deepening into the medium. They are grey or white, but when old often become brownish. In old cultures chlamydospores may be present. The biochemical properties of the fungus are not known.

Pathogenicity.—The fungus induces in man a type of blastomycosis (see p. 2084). It is pathogenic to monkeys, mice, guinea-pigs, and rabbits. It probably lives saprophytic in nature.

SUBCLASS EUASCOMYCETES.

Definition.—Ascomycetes with asci not separate or scattered, but approximate, usually forming a hymenium, and with a definite number of spores in an ascus.

Classification.—According to Stevens, the following orders may be recognized:—

- A. Asci approximate, no definite ascoma, but an indefinite hymenium—*Protodiscales*.
- B. Asci grouped in a definite ascoma:—
  - I. Asci not in a cylindrical or globose perithecium—*Helvellales*, *Pezizales*, *Phacidiales*, *Hysteriales*, *Tuberales*.
  - II. Asci in a cylindrical or globose perithecium:—
    - (*a*) Perithecium sessile:—
      - 1. Asci arising from a common level in the perithecium—*Perisporiales*, *Hypocriales*, *Dothidiales*, *Sphæriales*, *Pyrenomycetes*.
      - 2. Asci arising at different levels in the perithecium—*Aspergillales*.
    - (*b*) Perithecium on a short pedicle—*Laboulbeniales*.

Only the Aspergillales and the Pyrenomycetes interest us. The latter differ from the former by having their asci arranged in a hymenium within the closed ascocarp.

ORDER ASPERGILLALES.

Definition.—Euascomycetes with asci gathered into definite cylindrical or globose perithecia.

Type Family.- Aspergillaceæ.

Classification.- The order contains a number of families, which may be recognized as follows:—

A. Peridium of loose floccose hyphæ— *Gymnoascaceæ* Baranetsky, 1872.
B. Peridium compact:—
  I. Perithecia small:—
    (*a*) Perithecia mostly sessile:—
      1. Peridia closed—*Aspergillaceæ*.
      2. Peridia open—*Trichocomaceæ*.
    (*b*) Perithecia mostly stalked—*Oxygenaceæ*.
  II. Perithecia large—*Elaphomycetaceæ* and other families

Only the Gymnoascaceæ and the Aspergillaceæ concern us.

FAMILY GYMNOASCACEÆ BARANETZKY, 1872.

Definition.—Aspergillales with the peridium composed of loose hyphæ, at the extremities of which the asci are situate, or without perithecial or ascal formation, and reproducing (as far as is known), as a rule, by mycelial or conidial spores.

Type Genus.- *Gymnoascus* Baranetzky, 1872.

Classification.- From the definition given above, it is obvious that the family is capable of being divided into two tribes, as follows:—

A. *Ascomycetes type* :—
  With perithecia and asci—Tribe 1, *Gymnoasceæ* Castellani and Chalmers, 1918.
B. *Fungi Imperfecti type* :—
  Without perithecia or asci. Reproduction asexual by mycelial and conidial spores—Tribe 2, *Trichophytoneæ* Castellani and Chalmers, 1918.

The first tribe includes the genera *Myxotrichum* Künze, 1823; *Gymnoascus* Baranetzky, 1872; *Ctenomyces* Eidam, 1880; ***Amauroascus*** Schroeter, 1893; *Arachniotus* Schroeter, 1893; and ***Eidamella*** Matruchot and Dassonville, 1901; but these are not directly concerned with tropical medicine, and will only receive a passing notice as required in the following pages.

The second tribe is, however, of considerable importance, and must be considered in some detail; but we must first inquire why the genus Trichophyton and its allies, which are included in this tribe, should be classified here.

It must be pointed out that Vuillemin would classify all these genera as follows:—***Class***, Fungi Imperfecti; ***Order***, Thallosporales; ***Suborder*** 1, Blastosporineæ; ***Family***, Oösporaceæ; ***Genus***, Achorion; ***Suborder*** 2, Arthrosporineæ; ***Genera***, Microsporum, Trichophyton, etc.

We, however, classify them as given above, and our reasons for so doing may be set forth in a short historical statement.

Historical.—In 1844 Gruby discovered the parasite of ringworm, and this was verified in 1845 by Malmsten, who proposed two generic names for the new fungus—*i.e.*, 'Trichophyton' or 'Trychomyces'—and one specific name, 'Tonsurans.' The first generic name has become established, and the genus, the systemic position of which we are about to review, is now known as *Trichophyton* Malmsten, 1845; very often the date given is 1848, which is that of the publication of the German translation, and not the date of the original Swedish work, the name being derived from *θρίξ*, 'hair,' and *φυτόν*, 'a plant.'

Malmsten believed the genus *Trichophyton* to be closely related to the genus *Torula* Persoon, 1801, and especially to the species *T. olivacea* Corda, 1837, and *T. abbreviata* Corda, 1837.

This relationship was adopted by Charles Robin in his celebrated work 'Histoire Naturelle des Végétaux Parasites,' published in 1853. His classification is as follows: Fungi: Division *Arthrosporei*; Tribe, *Torulacei*; Genus, *Trichophyton* Malmsten.

In 1886 Hallier regarded the relationship to be closely allied to the genus *Penicillium* Link, 1809.

In 1875 Grawitz made a new assertion, claiming that the relationship was with *Oospora* Wallroth, 1833 a view which was adopted by Baumgarten in his 'Pathologischen Mykologie' in 1890.

Later researches by Duclaux in 1886, by Verujsky in 1887, and still later by Sabouraud, indicated that some of the species should be classified near to *Sporotrichum* Link, 1809, which suggestion has been adopted by Saccardo in his 'Sylloge Fungorum,' though he goes further, making Trichophyton merely a synonym of *Sporotrichum*.

Bodin (1899-1902) brought forward views tending to show that the relationship is complex, some of the species being allied to *Endoconidium* Prillieux and Delacroix, 1891 (a genus which lately disappeared, having become *Stromatinia* Prillieux, 1897), while other species were held to be more closely related to *Acladium* Link, 1809, and to *Haplaria* Link, 1809. These views are based upon a study of the sporulation, and indicate that *Trichophyton* is a genus belonging to Fuckel's class *Fungi Imperfecti*, and, adopting the older methods of classification, to the subclass *Hyphomyceteæ* Martius, 1817, the family *Mucedinaceæ* Link, 1809, subfamily *Amerosporeæ* Saccardo, 1886, tribe *Macronemeæ* Saccardo, 1886, and subtribe *Botrytideæ* Saccardo, 1886

In June, 1899, Matruchot and Dassonville published a paper entitled 'Sur la Position systématique des Trichophytons,' and followed it later in the same year by another paper entitled 'Sur le *Ctenomyces serratus* (Eidam) comparé aux Champignons des teignes.' Briefly stated, their view is that the genus *Trichophyton* Malmsten, 1845, belongs to the Ascomycetes of De Bary, if this is taken to include Hemiascomycetes of Brefeld. In either case, whether these classifications or Schroeter's more detailed arrangement of the Ascomycetes be adopted does not concern our present purpose, as both contain the family Gymnoascaceæ (often written Gymnoasceæ), in which Matruchot and Dassonville place the genus *Trichophyton*.

Their reasons for this classification are:—

1. *Ctenomyces serratus* Eidam, 1880, is a fungus found on the feathers of birds, which, when cultivated on Sabouraud's proof media, produces growths strikingly analogous to those of species of Trichophyton.

2. *Ctenomyces serratus*, when inoculated into animals, gives rise to lesions, resembling a *Trichophyton* eruption, in which it appears in a filamentous form.

3. A fungus closely resembling a ctenomyces, which they found in a ringworm in a dog, when cultivated gave rise to perithecia. For this fungus they created a new genus, *Eidamella* Matruchot and Dassonville, 1901, calling the given species *Eidamella spinosa* Matruchot and Dassonville, 1901.

Against this view Sabouraud has pointed out that in the cultures of this fungus they found intercalary chlamydospores but neither fusiform bodies nor the conidia usually seen in Trichophyton cultures, and therefore he considers their demonstration to be still incomplete.

Chalmers and Marshall in 1914 pointed out that they had found oval perithecia in very old cultures of *Trichophyton currii*. The peridium was at first loose, but hardened later, and contained a number of asci situate at different levels, but these were degenerate and did not contain ascospores. The perithecia were judged to belong to the Trichophyton, because there was no sign at any time of any other organism in or on the growth, macroscopically or microscopically, and the perithecia appeared at the same time all through the culture. When very old the peridium became compact and like that of the Aspergillaceæ, but at that stage they consisted of the outer wall only, the contents having all disappeared. They therefore considered that their observation supported the views of Matruchot and Dassonville.

We therefore classify the genus Trichophyton in the Gymnoascaceæ, but the very large number of species included in that genus exhibit such different characters that they can easily be arranged in groups, which appear to us to be of generic value, especially as we know that Malmsten meant only the form we now call 'endothrix' to be designated by his name Trichophyton, because he states:—'The mould formation appears in the root of the hair, and it occurs *only* inside of the hair, between its fibres, so that the epithelial layer is uninfected: besides, there is no mould formation to be found among the epidermal cells, so that one can say with good reason that the disease absolutely belongs to the hair.'

We have therefore distinguished the other groups by the generic names *Ectotrichophyton*, *Neotrichophyton*, and *Atrichophyton*, given below.

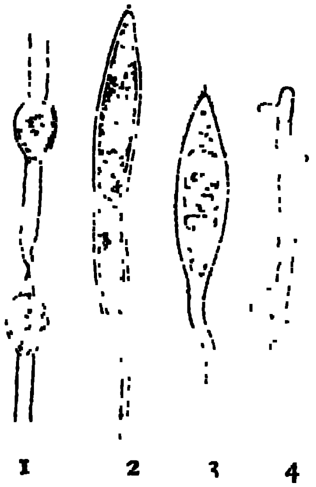

FIG. 494. -- *Microsporum audouini* GRUBY.

(After Bodin.)

1, Chlamydospores; 2, spindle; 3, pluri-septate spindle; 4, spore-bearing hypha; type Acladium.

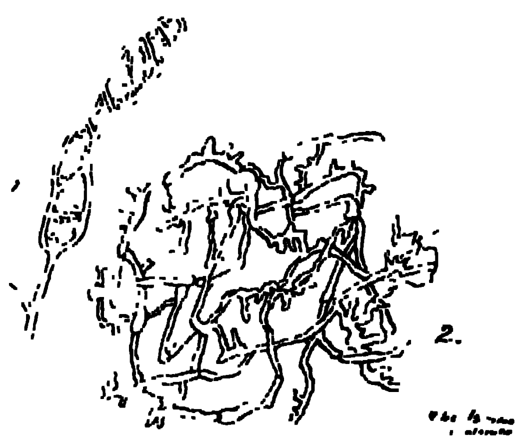

FIG. 495. — *Microsporum audouini* GRUBY.

(From cultures.)

1, Septate spindle body; 2, mycelium, with denticulated structures.

TRIBE TRICHOPHYTONEÆ Castellani and Chalmers, 1918.

Definition.—Gymnoascaceæ of the Fungi Imperfecti type.

Type Genus.—*Trichophyton* Malmsten, 1845.

Classification.—The various genera belonging to this tribe may be recognized as follows:—

A. *In lesions* only mycelial filaments and no spores present—Genus *Lophophyton* Matruchot and Dassonville, 1899.

B. *In lesions* mycelial filaments and spores present:—

I. In cultures no conidial-bearing hyphæ found. Do not attack hairs or hair follicles, but grow in the superficial or deep strata of the epidermis.

(*a*) Pluriseptate spindles present in cultures. Grow in the superficial strata of the epidermis, do not attack hairs. Cultures not faviform—Genus *Epidermophyton* Lang, 1879.

(*b*) Pluriseptate spindles unknown in cultures. Grow between the superficial and deep layers of the epidermis. Cultures faviform—Genus *Endodermophyton* Castellani, 1909.

II. In cultures conidial-bearing hyphæ present. May or may not attack hairs or hair follicles.

(*a*) Conidia only at the ends of hyphæ; large—Genus *Montoyella* Castellani, 1907.

(*b*) Conidia only at the sides of hyphæ; not large—Genus *Pinoyella* Castellani and Chalmers, 1918.

(*c*) Conidia at the ends and sides of hyphæ:—

1. In cultures fusiform bodies present as septate or non-septate spindles. Yellow favic scutula not present in lesions:—

(A) Conidia on short stalks:—

(1) Attack hairs or hair follicles:—

(i.) Grows in and on the surface of the hair. Is often pyogenic and of animal origin—Genus *Ectotrichophyton* Castellani and Chalmers, 1918.

(ii.) Grows mainly in the hair, but a few mycelial filaments and spores can be found outside the hair. Not pyogenic; of human origin—Genus *Neotrichophyton* Castellani and Chalmers, 1918.

(iii.) Grows entirely in the hair, and filaments and spores cannot be found outside it. Not pyogenic, except most rarely. Of human origin—Genus *Trichophyton* Malmsten, 1845.

(2) Do not attack hairs or hair follicles—Genus *Atrichophyton* Castellani and Chalmers, 1918.

(B) Conidia sessile—Genus *Microsporum* Gruby, 1843.

2. In cultures fusiform bodies present in the form of swollen claviform ends of filaments. Yellow favic scutula present in lesions—Genus *Achorion* Remak, 1845.

FIG. 496.—*Trichophyton currii*, CHALMERS AND MARSHALL, TO SHOW FUNGUS IN HAIR.

Genus Microsporum Gruby, 1843.

Definition.—Gymnoascaceæ with only Fungi Imperfecti forms known; producing in the lesions mycelial filaments and mycelial spores, which are small, roundish, and about 2-3 microns in diameter. In cultures hyphæ bearing sessile conidia may be seen and septate or non-septate fusiform bodies. The lesions in man do not produce yellow favic scutula.

Type Species.—*Microsporum audouini* Gruby, 1843.

Remarks.—The fungi belonging to this genus are generally parasitic in the hairs and hair follicles, but may attack glabrous parts. When parasitic in the hairs, they are characterized by the mycelial spores being roundish, small (2 to 3 μ), and irregularly arranged in a mosaic-like manner. They are easily cultivated on Sabouraud's and other sugar media (see Genus *Trichophyton*, p. 996). In cultures the microsporons proliferate by *sprouting* with branching of the mycelium: and also, often, by

1. *Spore-Bearing Hyphæ*—of type *Acladium*, the conidia being oval, 3 to 4 μ in length, and 2 to 3 μ in breadth. They are not supported by short sterigmata, as is the case in the genus *Trichophyton*.

2. *Terminal Septate or Non-Septate Spindles.*—These structures are found at the end of certain filaments, and may be considered to be modified terminal conidia. They are large fusiform structures, 30 to 60 μ in length, and 15 to 18 μ in breadth. They have granular contents, and may be septate or non-septate. The surface, especially at the apex, presents some peculiar hair-like formations which are not observed in the spindles of the fungi of the genus *Trichophyton*.

3. *Chlamydospores.*—Certain mycelial articles become expanse, ovoid, or ampulliform, 22 to 18 μ in length, and 6 to 8 μ in breadth. Their protoplasm may be granular, and the membrane may become much thicker and have a double contour. These elements are chlamydospores. They are generally found when the fungi vegetate under unfavourable conditions. Another structure often seen in fungi of the genus *Microsporum* are the so-called *denticulate* or *pectinate bodies*, which are mycelial segments, generally curved, showing on one side—the convex side as a rule—several small protruding processes. Bodin has demonstrated these processes to be mycelial tubes arrested in their development.

Pleomorphism.—After a time, and often rapidly, the cultures of microsporons lose their characteristics and become pleomorphic. This phenomenon is not very prominent, however, in the most important species—viz., *Microsporum audouini*—while it is very accentuated in some microsporons of animal origin, especially *M. minimum*, in which, according to the complete investigation carried out by Bodin, two types may be met with:—

1. THE DOWNY TYPE (*Acladium type*).
2. THE GLABROUS TYPE (*Endoconidium type*).

1. **The downy type** is found on the ordinary sugar media in which there is an abundant development of white duvet. Microscopically, fructifications of the type *Acladium* are seen, the spore-bearing hyphæ presenting numerous lateral sexile conidia. Subcultures will always give rise to the same downy type.

2. **The glabrous type** is observed on wort agar. The growth has a smooth surface, without duvet. Microscopically, short strings of hyaline, ovoid, or cylindrical conidia are seen inside the terminal segments of the fertile hyphæ. Lateral conidia are absent.

Mode of Infection.—Infection takes place from man to man in the case of microsporons of human origin; from the lower animals to man in the case of microsporons of animal origin. The human microsporons (*M. audouini*, *M. velveticum*, *M. umbonatum*, *M. tardum*) do not seem to be inoculable into the lower animals

Table showing Species of Microsporum Parasitic on Man.

Genus.		Species.
Microsporum Gruby, 1843	of human origin	M. audouini Gruby, 1843.
		M. velveticum Sabouraud, 1907.
		M. umbonatum Sabouraud, 1907.
		M. tardum Sabouraud, 1909.
	of animal origin	M. scorteum Priestley, 1914.
		M. minimum Le Calvé et Malherbe, 1898.
		M. lanosum Sabouraud, 1907.
		M. felineum C. Fox and Blaxall, 1896.
		M. fulvum Uriburu, 1907.
		M. pubescens Sabouraud, 1909.
		M. villosum Minne, 1907.
		M. tomentosum Pelagatti, 1909.
		M. iris Pasini, 1912.
		M. flavescens Horta, 1912.
		M. depauperatum Guéguen, 1912.

Some species (*M. audouini*, *M. velveticum*, *M. umbonatum*, *M. tardum*) seem to be parasitic on man only; others (*M. lanosum*, *M. felineum*, *M. minimum*, etc.) are parasitic on the lower animals, but occasionally infect man.

Microsporum audouini Gruby, 1843.

This parasite was described by Gruby in 1843, but his investigation was forgotten, till Sabouraud, in his classical researches on ringworm in 1892, demonstrated the plurality of species of the fungi found in this affection, and showed that a form of tinea capitis was due to the microsporon described by Gruby.

Parasitic Life.—Around the affected hairs the fungus forms by means of its mycelial spores a white opaque sheath, extending 2 or 3 millimetres above the opening of the hair follicle. The sheath is composed of a mosaic of small, roundish, or polyhedral spores, the diameter of which varies between 2 and 3 μ. In the interior of the hair a few mycelial filaments of the fungus may be observed. The fungus very seldom attacks glabrous parts of the body.

Saprophytic Life—Cultures.—*Microsporum audouini* grows well on Sabouraud's maltose agar and other media. The rate of growing is slow. In maltose agar the growth becomes evident about a week after inoculation under the appearance of a plaque of a so-called 'satiny aspect,' beneath the surface. In a few days more, aerial hyphæ develop, extending above the surface. When the development is complete—generally this takes about six to eight weeks—the growth is roundish, covered with short greyish duvet, and presents often a central knob, and some concentric rings of a whitish-greyish colour. The cultural characters, however, are variable, and pleomorphism occurs. The cultural characters have been thoroughly investigated by Sabouraud, Fox and Blaxall, Bodin, and others. The fungus very slowly liquefies gelatine; on potatoes it produces a brownish discoloration compared by Sabouraud to the colour of dried blood.

Reproduction.—This takes place—

1. By sprouts from the mycelial tubes.
2. By small terminal and lateral conidia, there being spore-bearing hyphæ of type Acladium (see Fig. 494).
3. By large unilocular or multilocular spindle conidia. These spindles are large structures 30 to 60 μ in length, and 15 to 18 μ in breadth. They may be septate or non-septate.
4. By formation of chlamydospores.

Pathogenicity.—*Microsporum audouini* causes the most obstinate form of tinea capitis. The patches affected are often large, scaly, and present stumps, provided with an opaque whitish sheath. It seldom attacks glabrous parts of the body. *M. audouini* is extremely common in England; but rare in the South of Europe (Italy), and extremely rare in the tropics. We have never seen cases of ringworm due to *M. audouini* in Equatorial Africa or Ceylon, but a few cases have been described in Brazil, in Madagascar, and in Senegal.

M. audouini seems to live only on the human subject, but closely allied species have been found by Fox in cats, by Bodin in dogs, and by Bodin, Fox, and others, in horses.

Microsporum velveticum Sabouraud, 1907.

Resembles closely *M. audouini*, but the cultures are more velvety, the duvet being white instead of greyish, and of closer growth. Not inoculable into guinea-pigs.. This species seems to be fairly common in North America.

Microsporum umbonatum Sabouraud, 1907.

Found by Sabouraud in two cases of microsporosis of the scalp contracted in Russia. The appearance of the growth when it has reached complete development (about twenty-five to thirty days after inoculation) has been compared by Sabouraud to the appearance of an ancient round shield, with a central conical formation representing the *umbo* of the shield. Not inoculable into guinea-pigs.

Microsporum tardum Sabouraud, 1909.

Found by Sabouraud in cases of microsporosis capitis clinically identical with the type caused by *M. audouini*. Differs from *M. audouini* by the growth being much slower and scantier, and the duvet being shorter.

Microsporum lanosum Sabouraud, 1907.

Synonym.—*Microsporon audouini* var. *canis* Bodin, 1897.

Commonly found in dogs. May affect man, causing a type of severe tinea capitis; may also produce forms of tinea barbæ and tinea corporis.

On Sabouraud's agar the growth is at first similar to *M. audouini*, only more abundant and more downy. Later—twenty-five to thirty days from inoculation—the central portion of the growth becomes umbilicated, the depression being surrounded by a ring of snow-white duvet, which in very old cultures may become yellowish. Pleomorphism is common.

Microsporum felineum C. Fox and Blaxall, 1896.

Common in the cat in England, North America, and Belgium; may infect man, attacking hairy and non-hairy regions of the body. On Sabouraud's agar the growth is rather abundant, discoid, with flattened surface, showing no furrows, and covered with a large amount of grey duvet. The fungus is easily inoculable into cats, dogs, and guinea-pigs.

Microsporum minimum Le Calvé and Malherbe, 1898.

Synonyms.—*Microsporon audouini* var. *equinum* Bodin, 1896; **Trichophyton minimum* Le Calvé and Malherbe, 1898.

Very common in foals; may infect man, giving rise to a mild type of tinea corporis, which gets cured spontaneously.

On Sabouraud's and glucose agar the growth is deeply furrowed, and, in contrast to all other microsporons, duvet is absent, or, when present, is very scanty, very short, and of a pinkish colour.

Microsporum fulvum Uriburú, 1907.

Found by Uriburú in cases of tinea capitis in the Argentine. It grows very rapidly on Sabouraud's agar, the growth presenting a central *umbo*, or projection, surrounded by a brownish powdery ring. The peripheral zone of the growth is covered with white duvet.

Microsporum pubescens Sabouraud, 1909.

Discovered by Sabouraud in a case of tinea capitis contracted in New York. It grows rapidly on Sabouraud's medium, the culture being characterized by the presence of abundant but very delicate silky duvet. At complete development—about thirty days from inoculation—the growth may have a flattened surface, or some furrows, radiating from the centre, may be present. The central portion, which is covered with rather long, white duvet, is encircled by a zone of powdery appearance; outside this there is the peripheral zone covered by the extremely delicate, characteristic, silky-like duvet.

Microsporum villosum Minne, 1907.

Found in Belgium by Minne in a child suffering from ringworm of the hair clinically identical with the type caused by *M. audouini*. On Sabouraud's agar the growth at complete development is about 6 centimetres in diameter; the central portion is flattened, with powdery, slightly brownish surface. This is surrounded by mammillary, downy formations, which decrease in size towards the periphery.

Microsporum tomentosum Pelagatti, 1909.

Found by Pelagatti in Sardinia in a case of microsporosis capitis, clinically identical with the usual type caused by *M. audouini*. It grows rapidly on Sabouraud's agar. The growth at complete development has a somewhat flattened appearance, but several furrows are present, originating from the central portion, which may be umbilicated. The whole surface is covered by thin white duvet.

Microsporum iris Pasini, 1911.

Discovered by Pasini in Italy in some cases of microsporosis capitis, clinically somewhat different from the usual type. The fungus grows well on Sabouraud's agar. At complete development -twenty-two to twenty-six days from inoculation- the growth presents a central knob covered with white duvet, and surrounded by white and brick-red rings, alternating.

The microsporosis capitis due to this microsporon is characterized by the hairs remaining nearly of normal length, and presenting a white-greenish discoloration.

Microsporum flavescens P. Horta, 1912.

Isolated by Horta from some circinate squamous patches situate on the neck of a child in Brazil. Grows rapidly on Sabouraud's agar: the growth is of a yellow colour; there is a depression at the centre, from which radiate four or five shallow furrows. Pleomorphic duvet appears quickly.

Microsporum depauperatum F. Guéguen, 1912.

Isolated by Guéguen from some circinate, dry, squamous patches. In cultures the membrane of some nuclear filaments presents peculiar thickenings. Spore-bearing hyphæ are not so well differentiated as in other species.

Microsporum scorteum Priestley, 1914.

This parasite resembles *M. fulvum* Uriburú, 1909, both morphologically and culturally, and may be identical therewith, as the descriptions given in Europe of Uriburú's parasite are scanty. It was found by Priestley in Townsville in Tropical Queensland; and occurred in two circular inflamed areas on the calf of a boy's leg. There was no scaliness, and the hairs were not visibly altered, though microscopically they contained mycelium and a few spores.

On Sabouraud's maltose agar it grew rapidly, producing a growth like a piece of chamois leather. It slowly digested milk, which it did not clot. Multiseptate spores were abundant, but lateral conidia were few, 3-4 × 2-3 microns in size, while chlamydospores were infrequent. Nodular bodies like those found by Sabouraud in *T. lacticolor* were found. Spirals were frequent and pectinate bodies rare. Duvet was formed.

Genus Trichophyton Malmsten, 1845.

Definition.—Trichophytoneæ with mycelial filaments and spores present in the lesions and conidial-bearing hyphæ in cultures, only attacking hairs and entirely of human origin. Almost never pyogenic.

Type Species.—*Trichophyton tonsurans* Malmsten, 1845.

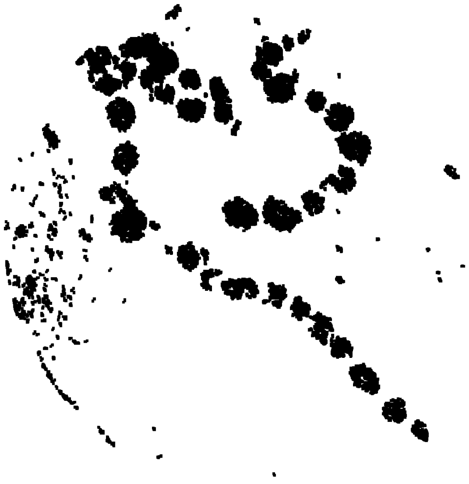

FIG. 497.—*Trichophyton currii*, TO SHOW MYCELIAL SPORES.

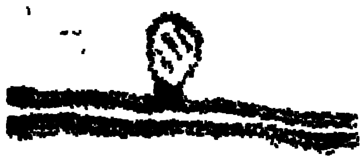

FIG. 498.—*Trichophyton currii*, TO SHOW CONIDIAL-BEARING HYPHA.

General Considerations.—During their parasitic life the species of the genus *Trichophyton* vegetate according to two types: (1) mycelial filaments; (2) mycelial spores.

The mycelial filaments consist of long cylindrical cells, separated by septa. The so-called mycelial spores are simply a modification of the mycelial filaments, due to the septa being much closer, so that the cells limited by them are almost as broad as they are long. The term 'mycelial spores' is incorrect, as they are not organs of reproduction, but only vegetative organs.

When the shape of these mycelial spores or sporulating mycelia is roundish or oval, the filament takes a moniliform appearance. Moreover, these cells are easily dissociated. Such a type is called 'fragile mycelium.' To this type belongs, for instance, *Trichophyton sabouraudi* R. Blanchard.

When the mycelial spores are square, the filament straight, and its articles long, the mycelium is called 'resistant.' This type is observed, for example, in *Trichophyton tonsurans* Malmsten.

Cultivation. Most *Trichophytons* can be cultivated, some cannot. The best medium is Sabouraud's maltose agar, the composition of which is the following:—

Maltose .. .	4 grammes.
Peptone Chassaing	1 gramme.
Agar .. .	1·50 grammes.
Distilled water .	100 c.c.

On this medium, however, pleomorphism is of frequent occurrence.

Pleomorphism. Cultures on maltose and other sugar agars of all *Trichophytons*, with the single exception of *T. sabouraudi*, becoming old, lose their characteristics and become covered with abundant white duvet. In these cultures, which can be considered degenerate, and are generally called 'pleomorphic,' organs of fructification are usually absent. By transplanting these cultures, the same pleomorphic, downy type of growth will be obtained: never again will the growth show the characteristics of the original *young* cultures directly obtained from the lesions. It is impossible to return to the original type, even by animal inoculations.

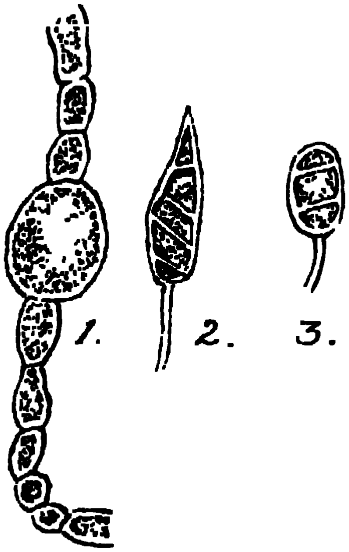

FIG. 499.—TRICHOPHYTON.

(Preparation from cultures, after Bodin.)

1, Chlamydospore; 2 and 3, septate spindle bodies.

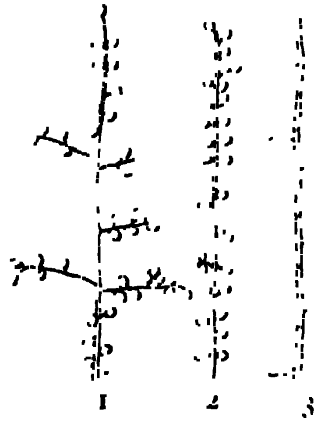

FIG. 500.—FRUCTIFICATIONS.

1, 2, Spore-bearing hyphæ (*Trichophyton*); 3, spore-bearing hypha (*Microsporum*).

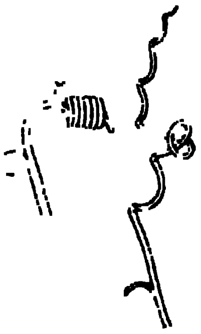

FIG. 501.—TRICHOPHYTON: SPIRAL BODIES.

To prevent pleomorphism, Sabouraud advises the following medium:—

Agar..	1·8 grammes.
Peptone Chassaing	3 to 5 grammes.
Water	100 c.c.

On this medium the growth of the various *Trichophytons* is much less abundant than on sugar media, but the cultures are fairly characteristic, and do not become pleomorphic.

Experimental Inoculations.—Certain *Trichophytons* can be easily inoculated experimentally into man and many of the laboratory animals—guinea-pigs, rabbits, etc. Sabouraud advises the inoculation of portions of the cultures to be made into a small flictena, artificially induced by burning, such as by applying to the skin a lighted match.

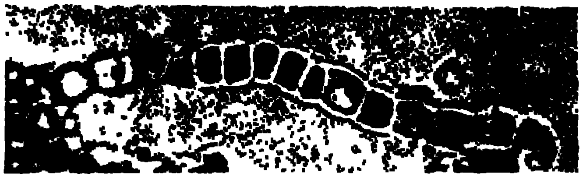

FIG. 502.—*Trichophyton currii*, TO SHOW LADDER-LIKE ROWS OF MYCELIAL SPORES.

The *intravenous* injection may induce generalized lesions of the internal organs.

The intraperitoneal injection as done by Citron may induce a type of peritoneal pseudo-tuberculosis.

Mode of Infection.—Infection may take place from man to man—this is generally the case with *Trichophytons* of the group *endothrix*—or from the lower animals to man. There is also little doubt that *Trichophytons* may live saprophytically in nature, this explaining sporadic cases of trichophytoses in man.

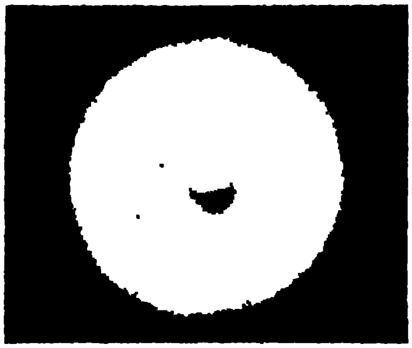

FIG. 503. — *Trichophyton currii*, FOUR DAYS' GROWTH ON SABOURAUD'S MALTOSE AGAR AT 34° C., TO SHOW WHITE GROWTH WITH KNOB-LIKE CENTRE.

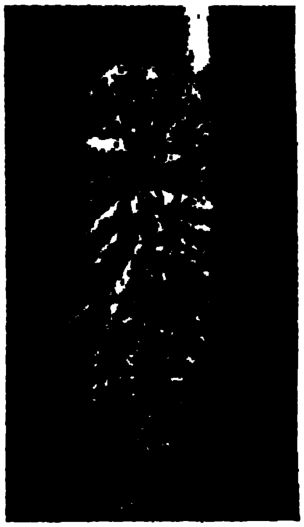

FIG. 504.—*Trichophyton violaceum* VAR. *khartoumense*.

(Note absence of acuminate centre and dark [violet] colour of the growth.)

Reproduction.—This takes place by—

1. Lateral and terminal conidia, supported by short sterigmata.
2. Chlamydospores; these are rare.
3. Large terminal septate and unseptate spindles.

Classification.—The principal species of the genus *Trichophyton* arranged chronologically are:—

1. *T. tonsurans* Malmsten, 1845.
2. *T. sabouraudi* R. Blanchard, 1895.
3. *T. violaceum* Bodin, 1902.
4. *T. sulphureum* C. Fox, 1908.
5. *T. glabrum* Sabouraud, 1909.
6. *T. fumatum* Sabouraud, 1909.
7. *T. effractum* Sabouraud, 1909.
8. *T. circonvolutum* Sabouraud, 1909.
9. *T. regulare* Sabouraud, 1909.
10. *T. umbilicatum* Sabouraud, 1909.
11. *T. exsiccatum* Uriburú, 1909.
12. *T. polygonum* Uriburú, 1909.
13. *T. soudanense* Joyeux, 1912.
14. *T. currii* Chalmers and Marshall, 1914.

These may be recognized as follows:—

A. Condition of mycelium in hair not definitely stated, but probably that of the Crateriform subdivision (see below)

(1) In cultures very convoluted—*Circonvolutum*

B. Condition of mycelium in hair definitely stated.

I. Mycelium in hair resistant to caustic potash, segments characteristically quadrangular in shape, with double contour, 4 to 6 μ in breadth, arranged in fairly straight ladder-like rows—*Crateriform subdivision*.

(*a*) *Cultures coloured and with craters: Tonsurans group*:—

(2) Yellow in centre white at periphery—*Tonsurans*.

(3) As 'tonsurans,' but, when old, cracked and dry—*Effractum*.

(4) Orange-red centre, remainder sulphur coloured—*Sulphureum*.

(5) Golden-yellow convoluted centre, becoming crateriform later—*Soudanense*.

(6) When old of a yellowish-brown colour—*Fumatum*.

(*b*) *Cultures white with craters: Umbilicatum group*:

(7) Deeply umbilicated with aureola—*Umbilicatum*.

(8) Slow growth, surface cracked with dry appearance—*Exsiccatum*.

(9) Growth at first roundish and then polygonal—*Polygonum*.

(*c*) *Cultures white with knob-like centre: Currii group*:

(10) Does not form duvet—*Currii*.

II. Mycelium in hair not resistant to caustic potash; segments rounded, 4·7 μ in diameter, not arranged as a rule in rows, but if a row is visible it resembles a string of beads and not a ladder—*Acuminate subdivision*.

(*a*) *Without acuminate centre: Violaceum group*:—

(11) Primary growth violet:—

(A) Most strains do not melt gelatine very rapidly:—

(i.) Ordinary amount of scaling on the head—*Violaceum*.

(ii.) Enormous numbers of scales, followed at times by permanent baldness—Var. *decalvans*.

(B) Melts strong gelatine very rapidly, beginning as soon as growth appears—Var. *khartoumense*.

(12) Primary growth white—*Glabrum*.

(*b*) *With acuminate centre: Sabouraudi group*:—

(13) Without duvet when old—*Sabouraudi*.

(14) With duvet when old—*Pilosum*.

Courmont's parasites cannot be easily classified.

Trichophyton tonsurans Malmsten, 1845.

Synonyms.—*Trichomyces tonsurans* Malmsten, 1845; *Oidium tonsurans* Zopf, 1890; *Trichophyton megalosporum endothrix* Sabouraud, 1894; *T. crateriforme* Bodin, 1902, which is the term in current use in dermatological literature.

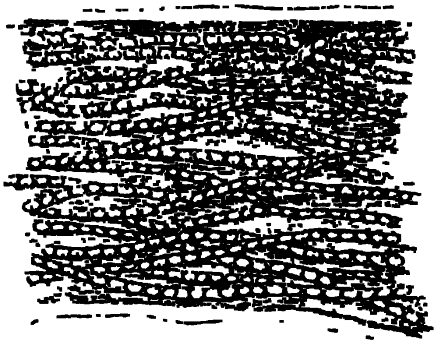

FIG. 505.—*Trichophyton tonsurans* MALMSTEN.

(Preparation of a hair in liquor potassæ, after Sabouraud.)

Causes a type of tinea capitis somewhat rare in England, but common on the Continent. The hairs are broken 2 to 4 millimetres from the scalp, and the stumps are variously bent. The diseased hairs have a powdery, greyish appearance, and on pulling them out the roots are not black, as in normal hairs. It belongs to the type Endothrix. The mycelial cells are large (4 to 5 μ), quadrangular (so-called resistant mycelium type). Grows well on maltose agar and other media; on maltose agar colonies are white or yellowish, often crateriform, and present a velvety surface at first, later powdery. In hanging-drop cultivations spore-bearing fructifications can be seen.

T. tonsurans, besides producing a type of tinea capitis, produces also a form of tinea corporis and a trichophytosis of the nails.

Trichophyton sabouraudi R. Blanchard, 1895.

Synonym.—*Trichophyton acuminatum* Bodin, 1902. This is the term commonly used in dermatological works.

This *Trichophyton* is of the type Endothrix. Mycelial threads have a moniliform appearance, and their articles become easily dissociated (so-called fragile mycelium). Grows well on maltose agar, giving rise to conical white colonies; often acuminate with central plumes, and occasionally may present yellowish or pinkish rings; older cultures may present a powdery surface of a dark pinkish colour. Pleomorphism always absent. In hanging-drop cultures aerial filaments with lateral conidia are seen.

T. sabouraudi causes a form of tinea capitis called by Sabouraud 'tondante peladoide,' and also a variety of tinea circinata.

The tinea capitis induced by this fungus is also known under the name of 'black-dotted ringworm.' The hairs get broken lower than in the type of ringworm caused by *T. tonsurans*. The stumps are on the same level as the surface of the scalp, and appear as black dots.

Trichophyton pilosum Sabouraud, 1909.

Very similar to *T. sabouraudi*, from which it differs only by the cultures being covered, when old, by a dense, short, white duvet.

Trichophyton soudanense C. Joyeux, 1912.

Endothrix: very similar to *T. tonsurans*. In the hairs the mycelial spores are generally rectangular, arranged in long strings. On Sabouraud's agar the growth appears three to four days after inoculation as a small yellow nodule; later, the peripheral portion of the growth appears white. It has been found by C. Joyeux in cases of tinea capitis in the Sudan.

Trichophyton violaceum Bodin, 1902.

Discovered by Sabouraud in cases of tinea barbæ; type Endothrix. The growth on maltose agar is of a light brownish or greyish colour, with moist surface, and later becomes violet.

This species is common in Italy and North Africa. In Ceylon a variety of this fungus produces a type of very common ringworm of the scalp in children, with white patches covered by enormous numbers of pityriasic squamæ. The patches often remain permanently bald. The Ceylon fungus is endo-ectothrix, and although culturally is hardly distinguishable from *T. violaceum*, is probably a different variety (var. *decalvans* Castellani, 1913), as it produces lesions generally different from those induced by *T. violaceum*. In the Sudan it apparently liquefies gelatine more rapidly (var. *khartoumense* Chalmers and Macdonald, 1915).

Trichophyton glabrum Sabouraud, 1909.

Closely allied to *T. violaceum*, but shows a more rapid growth, and no violet pigmentation develops. Surface smooth and moist.

Trichophyton sulphureum C. Fox, 1908.

Described by Colcott Fox in some cases of tinea capitis in England. Endothrix type. On Sabouraud's agar the growth is characterized by a central reddish nodule, which later becomes crateriform, assuming a speckled appearance. The rest of the culture has a delicate but distinct primrose or sulphur colour.

Trichophyton plicatile Sabouraud, 1909.

Colonies closely resemble those of *T. tonsurans*, but have a creased appearance. Found by Sabouraud in cases of sycosis. Sequeira has observed it in a case of trichophytic granuloma. We have placed the fungus in the genus Neotrichophyton (p. 1001).

Trichophyton circonvolutum Sabouraud, 1909.

Endothrix; somewhat similar to *T. plicatile*; the growth has a convoluted surface. Found by Sabouraud in cases of trichophytosis contracted in the Sudan and Dahomy.

Trichophyton exsiccatum Uriburú, 1909.

Found in Argentina by Uriburú. Endothrix; very slow growth; crateriform colonies, with surface finely cracked, and of a dry aspect

Trichophyton polygonum Uriburú, 1909.

Endothrix. The growth is at first roundish, then takes a characteristic polygonal outline. The central part is crateriform.

Trichophyton regulare Sabouraud, 1909.

Endothrix; very similar to *T. tonsurans*, the cultures being at first crateriform; then, the edges of the crater becoming undermined, the growth takes a peculiar pouch-like shape, with several radiating small sulci. The characters of the fungus show always the greatest regularity, never changing: hence the name *T. regulare* given to it by Sabouraud. This fungus was found by Dalla Favera.

Trichophyton umbilicatum Sabouraud, 1909.

Endothrix: cultures are deeply umbilicated: present at the periphery fine radiating hyphæ, forming a sort of aureola.

Trichophyton fumatum Sabouraud, 1909.

Cultures crateriform, taking when old a yellowish-brownish colour, compared by Sabouraud to the colour of a dead leaf. This *Trichophyton* is fairly common in some parts of Italy.

Trichophyton effractum Sabouraud, 1909.

Cultures at first very similar to those of *T. tonsurans*; being crateriform; when old, the growth becomes very dry, and the surface splits from the edge.

Trichophyton currii Chalmers and Marshall, 1914.

This fungus was found in an epidemic of ringworm in a Khartoum school. It is not the common fungus of the town, which appears to be *T. violaceum* var. *khartoumense*. *T. currii* is of the type endothrix, and grows aerobically, but not anaerobically. It forms ladder-like rows of mycelial spores in the hairs. These spores are usually 4·2 microns in breadth, and they and the mycelium resist the action of caustic potash. It forms neither acid nor gas in monosaccharids, disaccharids, trisaccharids, polysaccharids, glucosides, or alcohols. It does not alter litmus milk. It does not liquefy gelatine. On Sabouraud's agars it produces white growths with a central knob, a white plateau with a slight circular marking, and a peripheral fringe. It grows on carrot, potato, but was not characteristic on beetroot, and was poor on Buchanan's and Loeffler's media. Inoculations directly from the patients' heads failed in monkeys, cats, dogs, and mice. In man it gives rise to a type of tinea capitis tropicalis.

Genus Neotrichophyton Castellani and Chalmers, 1918.

Definition.—Trichophytineæ with mycelium and spores present in the lesions, and conidial-bearing hyphæ in cultures, attacking hairs, but with mycelial spores and filaments outside the hair shaft.

Type Species.—*Neotrichophyton flavum* Bodin, 1902.

Classification.—There are only two species, which may be distinguished as follows:—

A. Cultures cerebriform—*Flavum*.
B. Cultures crateriform and creased—*Plicatile*.

Neotrichophyton flavum Bodin, 1902.

Synonym.—*Trichophyton cerebriforme* Sabouraud, 1909.

Differs from *Trichophyton tonsurans* by the cultures being cerebriform, and by becoming creamy-white when old.

Pathogenicity.—Induces a type of tinea corporis and a form of sycosis. Inoculable into guinea-pigs.

Neotrichophyton plicatile Sabouraud, 1909.

Synonym.—*Tricophyton plicatile* Sabouraud, 1909.

Colonies closely resemble those of *Trichophyton tonsurans*, but have a creased appearance with white, powdery surface. Found by Sabouraud in cases of sycosis. Sequeira has observed it in a case of trichophytic granuloma.

Genus Ectotrichophyton Castellani and Chalmers, 1918.

Definition.—Trichophytoneæ with mycelium and spores present in the lesions, and conidial-bearing hyphæ in cultures; attack hairs and hair follicles, growing in and on the surface of the hairs; is often pyogenic and of animal origin.

Type Species.—*Ectotrichophyton mentagrophytes* Robin, 1853.

Classification.—The genus is capable of division into three subgenera by the following characters:

A. *Ectotrichophyton* :—

With small spores about 3 to 4 microns in diameter, forming a sheath outside the hair shaft, on dissociation of which they are seen to form chains; with sinuous and quadrangular hyphal segments, together with spores of varying diameter and air-bubbles, inside the hair shaft; with cultures easily obtainable, of rapid growth, and of considerable vitality, characterized by plaster-like or floury centres surrounded by a fringe, when grown on Sabouraud's proof media, and by successful inoculations into animals—Subgenus *Microtrichophyton*.

B. *Ectotrichophyton* :—

With large spores about 5 to 7 microns in diameter, forming a sheath outside the hair shaft, on dissociation of which they are seen to form chains, and with sinuous hyphal segments, together with large-sized spores and air-bubbles, inside the hair shaft; with cultures easily obtainable, but of slow growth in temperate climates, though much more rapid in tropical climates, characterized by their tendency to resemble (at all events when old) those of the Achorions, and capable of being inoculated into animals—

I. With early formation of a duvet—Subgenus *Ectotrichophyton*.
II. Culture sooner or later resembles that of *Achorion schoenleini*—Subgenus *Favotrichophyton*.

Ectotrichophyton (Favotrichophyton) Castellani and Chalmers, 1918.

Definition.—Ectotrichophyton with the characters given above for Favotrichophyton.

Type Species.—*Ectotrichophyton discoides* Sabouraud, 1909.

FIG. 506.—*Ectotrichophyton discoides*. NINETEEN DAYS' GROWTH ON SABOURAUD'S MALTOSE AGAR AT 32° C.

FIG. 507.—*Ectotrichophyton discoides*: FORTY-TWO DAYS' GROWTH ON SABOURAUD'S MALTOSE AGAR AT 32° C.

Classification. The Favotrichophyton species which are known are

E. verrucosum Bodin, 1902,
E. ochraceum Sabouraud, 1909,
E. album Sabouraud, 1909,
E. discoides Sabouraud, 1909,
E. luxurians Brault and Viguier, 1914,

which may be differentiated as follows:-

A. Condition of mycelium in hair not definitely stated. -
  I. Young cultures white in colour, and soon resembling those of *Achorion schoenleini*, but sunk into the medium—*Album*.
B. Condition of mycelium in hair that of an ecto-endothrix: -
  II. Cultures grey in colour, humid, with verrucose surface—*Verrucosum*.
  III. Young cultures of a yellow ochre colour—*Ochraceum*.
  IV. Cultures yellowish-brown or greyish-yellow, cupola-shaped, humid, with usually smooth surfaces, and not resembling the Achorion cultures until old—*Discoides*.
  V. Very rapid development—*Luxurians*.

Ectotrichophyton verrucosum Bodin, 1902

Synonym.—*Trichophyton verrucosum* Bodin, 1902.

Endo-ectothrix, megalosporon, faviform. This fungus, though producing typical trichophytic lesions when parasitic, shows cultural characters somewhat similar to an achorion, the growth, which is white, being often convoluted or cerebriform. It is found in donkeys, and may infect man. The same or similar species are found parasitic on the horse and on some birds, and may also infect man.

Ectotrichophyton ochraceum Sabouraud, 1909.

Synonym.—*Trichophyton ochraceum* Sabouraud, 1909.

Type Ectothrix, of animal origin; cultures somewhat similar to favus. On maltose and glucose agars the colonies are characterized by an ochre-yellow knob; portions of the growth may be covered by an extremely short, almost invisible, duvet. On ordinary agar the surface of the colonies is cerebriform. Optimum temperature, 25° C. It is easily inoculated into guinea-pigs.

Ectotrichophyton album Sabouraud, 1907.

Synonym.—*Trichophyton album* Sabouraud, 1907.

The cultures are extremely like favus, but are generally less bulging, more deeply umbilicated, and more regularly folded; the growth deepens in the medium; some white duvet present. Optimum temperature, 25 C. Can be inoculated into guinea-pigs.

Ectotrichophyton discoides Sabouraud, 1909.

Synonym.—*Trichophyton discoides* Sabouraud, 1909.

Endo-ectothrix, megalosporon, faviform. Somewhat similar to *E. album*, but the growth, which is almost a perfect disc, has a more flattened surface. There is often a central knob. The whole growth has a brownish-yellowish colour, with a moist surface, somewhat resembling the non-pigmented cultures of *Trichophyton violaceum*. It occurs in Egypt and in the Anglo-Egyptian Sudan, as described by one of us.

Ectotrichophyton luxurians Brault and Viguier, 1914.

Isolated from cases of kerion in Algeria. Very rapid growth with faviform appearance.

Ectotrichophyton (Microtrichophyton) Castellani and Chalmers, 1918.

Definition.—Ectotrichophyton with small spores 3-4 microns in diameter.

Type Species.—*Ectotrichophyton* (*Microtrichophyton*) *mentagrophytes* Robin, 1853.

Classification.—The following species are known:—

E. mentagrophytes Ch. Robin, 1853.
E. farinulentum Sabouraud, 1910.
E. persicolor Sabouraud, 1910.
E. granulosum Sabouraud, 1908.
E. lacticolor Sabouraud, 1910.
E. radiolatum Sabouraud, 1910.
E. felineum R. Blanchard, 1895.
E. denticulatum Sabouraud, 1910.

They may be differentiated as follows:—

- A. Grows best on agar without sugars—*Persicolor.*
- B. Grow best on agar with sugars:—
  - I. Growth white, elevated centre, powdery surface, radiating furrows.
    - (*a*) Furrows well marked. Pure white—*Mentagrophytes.*
    - (*b*) Furrows poorly marked. Not so white—*Radiolatum.*
  - II. Growth white, discoid, umbilicated, but later knob in centre; white powdery surface, radiating furrows—*Farinulentum.*
  - III. Growth white, yellowish, dotted with granular projections—*Granulosum.*
  - IV. Growth cream white to yellowish, not granular—*Lacticolor.*
  - V. Growth white, with umbilicated centre, with numerous radiating projections at periphery.
    - (*a*) Projections well marked—*Echineum.*
    - (*b*) Projections poorly marked—*Denticulatum*

Ectotrichophyton mentagrophytes Ch. Robin, 1853.

Synonyms.—*Microsporon mentagrophytes* Robin, 1853: *Sporotrichum mentagrophytes* Saccardo, 1886; *Trichophyton gypseum* Bodin, 1902; *T. asteroides* Sabouraud, 1909; *Trichophyton mentagrophytes* Robin, 1853.

Endo-ectothrix; mycelial spores are mostly situated outside the cuticle of the hair, while a few are found in the interior. The latter are 5 to 6 μ in size; those outside, forming the parasitic sheath, are of very unequal size (2 to 11 μ).

On Sabouraud's agar the growth is of white colour; the centre is somewhat elevated and covered by duvet; the rest of the growth has a powdery surface, and often presents several radiating furrows. At the periphery numerous tapering projections are observed. This *Trichophyton* is of animal origin, being found in horses, cows, dogs, and, perhaps, pigs and sheep. In man it is pyogenic, causing a type of trichophytic sycosis, kerion, and also a pustular type of tinea corporis.

The following five species are very closely allied to *E. mentagrophytes:*—

Ectotrichophyton farinulentum Sabouraud, 1910.

Synonyms.—*Trichophyton gypseum* Bodin, 1902, *pro parte; Trichophyton farinulentum* Sabouraud, 1910.

Found in cases of kerion by Sabouraud. On maltose agar the growth is at first discoid, umbilicated, with a white powdery surface and several radiating furrows. Later, the central part becomes raised, forming a knob covered with white duvet. On agar media not containing sugars the growth is at first smooth, without any duvet, of moist appearance and yellow colour; while later the central part becomes downy, and the peripheral portions take a powdery aspect.

Ectotrichophyton persicolor Sabouraud, 1910.

Synonym.—*Trichophyton gypseum* Bodin, 1902, *pro parte: Trichophyton persicolor* Sabouraud, 1910.

Found by Sabouraud in cases of pustular ringworm of the palms of the hands and of the beard. In contrast to all other species of *Trichophytons,* it grows better on agar without sugar than on sugar media. The cultures are of a pinkish-reddish colour. The appearance of the colonies has been aptly compared by Adamson to the skin of a very ripe peach.

Ectotrichophyton granulosum Sabouraud, 1908.

Synonym.—*Trichophyton gypseum* Bodin, 1902, *pro parte*, *Trichophyton granulosum* Sabouraud, 1908.

The growth on Sabouraud's agar is discoid, often umbilicated; powdery surface of a white-yellowish colour, with granular formations or prominences dotted all over.

This *Trichophyton* is found in the horse, in which it produces a peculiar type of trichophytosis, with extremely numerous, very small, patches. It has been observed in man in Italy by Dalla Favera.

Ectotrichophyton lacticolor Sabouraud, 1910.

Synonym.—*Trichophyton gypseum* Bodin, *pro parte*; *Trichophyton lacticolor* Sabouraud, 1910.

The cultures are discoid flattened, with shallow furrows radiating from the centre. The colour is cream-white, with occasionally a slight yellow tinge. In old cultures there is abundant pleomorphic duvet. Can easily be inoculated in guinea-pigs.

Ectotrichophyton radiolatum Sabouraud, 1910.

Synonym.—*Trichophyton gypseum* Bodin, *pro parte*. *Trichophyton radiolatum* Sabouraud, 1910.

Isolated by Sabouraud from cases of kerion. Very similar to *E. mentagrophytes*, from which it differs in culture by the colour being of less pure white, and by the radiating projections being less marked or absent. After three to four weeks abundant white pleomorphic duvet appears

Ectotrichophyton felineum R. Blanchard, 1895.

Synonyms. *Trichophyton niveum* Sabouraud: *T. radians* Sabouraud, 1909: *T. felineum* R. Blanchard, 1895.

Endo-ectothrix: causes often a pustular ringworm of the body; less frequently attacks the hairs. In the pustules free spores and a few mycelial elements are seen: in the affected hairs the spores forming the parasitic sheath are of large dimensions, 7 to 9 μ in diameter. The growth on Sabouraud's medium is umbilicated, with a white powdery surface and numerous radiating projections at the periphery.

Pathogenicity.—This fungus is found in the cat, and probably also in horses, cattle, dogs, sheep, and pigs. In man it causes a type of kerion celsi and also a type of vesiculo-pustular tinea corporis, called by Sabouraud 'trichophytosis circinata disidriformis,' and 'herpes iris vesiculosus' by Biett.

Ectotrichophyton denticulatum Sabouraud, 1910.

Synonym.—*Trichophyton niveum* Sabouraud, *pro parte*. *T. denticulatum*.

Almost identical with *E. felineum*, but in cultures the radiating projections are much shorter and more pointed.

Ectotrichophyton (Ectotrichophyton) Castellani and Chalmers, 1918.

Definition.—Ectotrichophyton with large spores about 5-7 microns.

Type Species.—*Ectotrichophyton* (*Ectotrichophyton*) *megnini* R. Blanchard, 1895.

Classification.—The following species are known:—

E. megnini (R. Blanchard, 1895).
E. equinum (Gedoelst, 1902).
E. vinosum (Sabouraud, 1909).
E. nodoformans (Castellani, 1912).

They may be distinguished as follows:—

A. Mycelial spores very large, 8-9 microns in diameter:—
  I. Old cultures pinkish—*Megnini*.
  II. Old cultures deep wine red—*Vinosum*.
B. Mycelial spores not large, 2-4 microns in breadth:—
  I. Surface growth abundant, dark red—*Equinum*.
  II. Surface growth scanty and colourless submerged portion brick red—*Nodoformans*.

Ectotrichophyton megnini R. Blanchard, 1895.

Synonyms.—*Trichophyton roseum* Bodin, 1902; *T. rosaceum* Sabouraud, 1902; *T. megnini* R. Blanchard, 1895.

Endo-ectothrix, megalosporon, downy-culture type. Mycelial spores found in the hairs are very large, 8 to 9 μ in diameter. On maltose agar the growth is at first white, with a velvety appearance; later, pinkish, or of a deep rose colour. Duvet becomes very abundant in old cultures. It is parasitic in fowls and pigeons: may infect man, causing a variety of tinea barbae without suppuration.

Ectotrichophyton vinosum Sabouraud, 1909.

Synonym.—*Trichophyton vinosum* Sabouraud, 1909.

Endo-ectothrix, megalosporon, of downy-culture type. Is very similar to *E. megnini*, but the colour of old cultures is of a deep wine red colour. Abundant duvet. Found by Sabouraud in a case of tinea circinata.

Ectotrichophyton equinum Gedoelst, 1902.

Synonym.—*Trichophyton equinum* Gedoelst, 1902.

Endo-ectothrix, megalosporon, downy-culture type. Mycelial spores of oval shape, 4 to 6 μ in length, 2 to 4 μ in breadth. On maltose agar the growth is orbicular, with abundant duvet; later on, the portion of the growth which is in contact with the medium becomes yellowish and afterwards dark red. It is parasitic in the horse, and may infect man.

Ectotrichophyton nodoformans Castellani, 1912.

Synonym.—*Trichophyton nodoformans* Castellani, 1912.

Found in Ceylon in cases of dhobi itch and tinea barbae: not very abundant in the lesions. On Sabouraud's agar the growth is white, with a powdery surface and a central small knob. The growth deepens in the medium, and the submerged portion has a characteristic brick-red colour, which generally disappears after repeated transplantations. The surface growth is whitish.

Glucose Agar.—Growth somewhat more abundant than in Sabouraud's agar. Colour of the surface and submerged growth white. Red pigment usually absent.

Maltose 4 per cent.—Scanty growth, no pigment.

Glycerine Agar.—Growth fairly abundant, no pigment.

Agar.—Scanty growth, whitish.

Saccharine.—Same as agar.

Adonite.—Same as agar.

Pathogenicity.—The fungus gives rise to a peculiar type of tinea cruris (p. 2042), with very thick, elevated margins and deep-seated nodules. It has pyogenic properties, and may spread to other parts of the body, in addition to the inguinal regions. It is capable of affecting the hair follicles. In one of our cases the fungus affected the hairs of the beard, producing a typical 'kerion barbæ.'

Genus Atrichophyton Castellani and Chalmers, 1918.

Definition.—Trichophytoneæ with mycelium and spores present in the lesions and conidia on short stalks, but they do not attack hairs.

Type Species.—*Atrichophyton albiscicans* Nieuwenhuis, 1907.

Classification.—The following table will indicate the characters of the species:—

A. *Has been cultivated*.—
  I. Culture whitish with powdery surface—*Albiscicans*.
  II. Culture brownish mass with deep furrows—*Macfadyeni*.
  III. Cultures pinkish with violet tinge—*Viannai*.

B. *Has not been cultivated*:—
  I. Spores are numerous and of various sizes—*Blanchardi*.
  II. Spores are few and about 4 microns in diameter—*Ceylonense*.

Atrichophyton albiscicans Nieuwenhuis, 1907.

Synonym.—*Trichophyton albiscicans* Nieuwenhuis, 1907.

Discovered by Nieuwenhuis in tinea albigena. In fresh preparations from scrapings spores are absent: the mycelial tubes are straight, occasionally showing a double contour; they are often dichotomous. On Sabouraud's agar the growth is very slow, whitish, with a powdery surface.

Atrichophyton blanchardi Castellani, 1905.

Synonym.—*Trichophyton sabouraudi* Castellani, 1905; *T. blanchardi* Castellani, 1905.

Temporary species, as the fungus has not been grown. In fresh preparations from the lesions the mycelial tubes are not, as a rule, quite straight; they are often banana-shaped; do not show a double contour; the mycelial segments are separated, the mycelial spores are shed without forming a filament by their union, and are of various sizes. All attempts at cultivation have failed. It is the cause of tinea Sabouraudi tropicalis.

Atrichophyton viannai de Mello, 1917.

Synonym.—*Trichophyton viannai* de Mello, 1917. Found by F. de Mello in a case of tinea corporis. Colonies on Sabouraud's maltose-agar pinkish with often a violet tinge.

Atrichophyton ceylonense Castellani, 1908.

Synonym.—*Trichophyton ceylonense* Castellani, 1908.
Found by Castellani in cases of tinea nigro circinata. Temporary species, cultivation having not been obtained; possibly a variety of *A. blanchardi*. In fresh preparations the spores are very few in number, roundish, rather large (4 μ), showing a double contour. The mycelial tubes are about 3½ μ in breadth, straight, or variously bent. It is found in tinea nigro circinata.

Atrichophyton macfadyeni Castellani, 1905.

Synonym. — *Trichophyton macfadyeni* Castellani, 1905.

Found by Castellani in some cases of tropical tinea corporis In fresh preparations mycelium and spores are rather of small dimensions. The mycelial tubes are regularly shaped, do not show swellings, and are about 2½ μ in breadth. The free spores are very numerous, and present a peculiar ovoid shape, the maximum diameter being 2½ to 3½ μ. In stained preparations the spores present a bipolar staining. The fungus grows with difficulty; on the rare occasions when the inoculations are successful, the growth is very slow, the colonies coalesce, forming a brownish mass, with deep furrows, and deeply rooted in the medium.

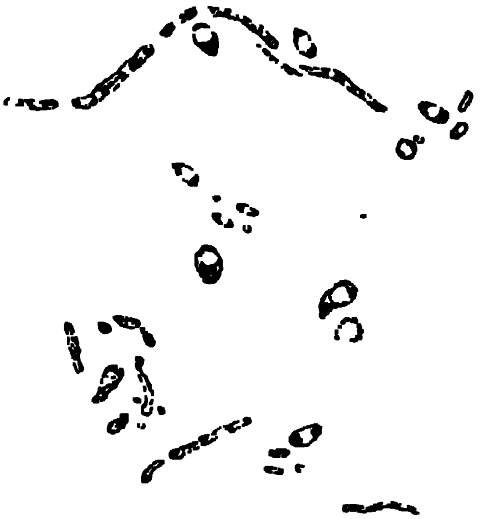

FIG. 508.—*Atrichophyton macfadyeni* CASTELLANI.
(Stained with fuchsin.)

INCERTÆ SEDIS.

Trichophyton balcaneum Castellani, 1916.

Found in cases of peculiar condition of the scalp in the Balkans, which clinically resembled more a diffuse type of severe *pityriasis sicca* than a trichophytic affection.

When grown on glucose agar from scales it slowly formed a somewhat crinkled growth of whitish colour. An interesting characteristic of this fungus is that apparently it does not become

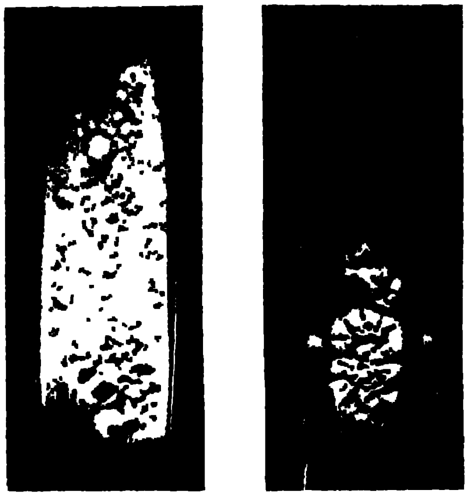
Abbreviations used in the Table.—A = acid ; G = gas ; C = clot ; s = slight ; vs = very slight ; O = negative result—viz., non-production of acid or gas in sugar media, non-liquefaction of gelatine or serum, as the case may be ; + = positive result.

pleomorphic, even after very numerous transplantations. Gelatine is rapidly liquefied. It does not form gas in any carbohydrate medium.

Microscopically the fungus shows features intermediate between a trichophyton *sensŭ lato*, a microsporum and an achorion.



FIGS. 509 AND 510.—CULTURES OF *Trichophyton balcaneum* CASTELLANI: GLUCOSE AGAR.

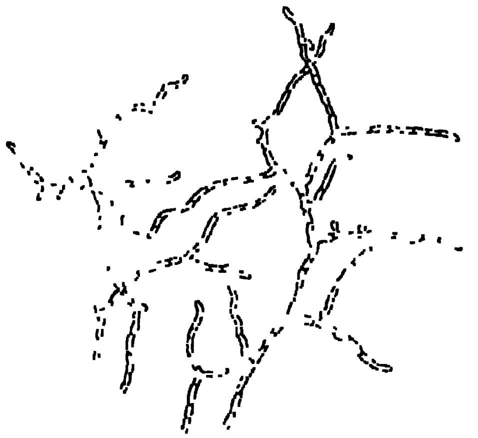


FIG. 511.—MICROSCOPICAL APPEARANCES OF *Trichophyton balcaneum* CASTELLANI: HANGING DROP CULTURE.

Genus Achorion Remak, 1845.

Definition.—Trichophytoneæ with mycelial filaments and spores in the lesions; in cultures conidial-bearing hyphæ present, with spores situate laterally and apically. Fusiform bodies in cultures in the form of swollen claviform ends of filaments. Yellow favic scutula present in lesions.

Type Species.—*Achorion schoenleini* Lebert, 1845.

Remarks.—The fungi belonging to this genus often show during parasitic life much longer mycelial segments than *Trichophytons* and *Microsporons*; masses of them, developing in hair follicles, form the well-known sulphur-coloured *scutula* which always develop round a hair. In the hairs the mycelial tubes are frequently trichotomous and tetrachotomous, forming structures which have been compared in appearance to the skeleton of the human foot, and called 'favus tarsi.'

Cultures.—Sabouraud has noted that in hanging-drop cultures the spores sometimes develop very slowly, sometimes rapidly. When the development is slow, there is formation of numerous chlamydospores of various sizes, with a double contour membrane. When the development is rapid, one notes that the mycelium ramifies quickly in every direction, with presence of very few or no chlamydospores. The following structures may be noted:

1. *Claviform Bodies.*—The terminal portion of some filaments becomes swollen and claviform. These claviform filaments have

been compared by some authorities to the 'spindles' of the *Trichophytons* and *Microsporons*, but they are slenderer, and not septate. The French authors call these formations 'chandeliers faviques,' on account of their shape somewhat resembling a candlestick.

2. *Favus Yellow Bodies.*—The protoplasm of some filaments collects itself at the terminal ends, the filaments becoming much thinner, and terminating in roundish or oval bodies, which must be considered to be terminal chlamydospores. It is to be noted that in the typical *Achorions* of human origin conidia-bearing hyphæ are not seen, while these are present in the *Achorions* of animal origin, in which separate spindles may be present.

Media.—*Achorions* grow well on all the usual sugar media, especially Sabouraud's agar and glucose agar. They generally liquefy gelatine fairly rapidly.

Pleomorphism.—Very common in all *Achorions*. If a culture becomes pleomorphic, it is impossible to make it revert to the original type.

Transmission.—In the case of *Achorions* of human origin infection takes place from man to man; in the case of *Achorions* of animal origin infection takes place from the lower animals. It is not impossible that *Achorions* may live saprophytically in nature.

TABLE OF ACHORIONS.

Genus.		Species.
Achorion Remak, 1815	Of human origin (typical)	A. schoenleini Lebert, 1845.
	Of animal origin (non-typical)	A. quinckeanum Zopf, 1890.
		A gypseum Bodin, 1907.
		A arloingi Blanchard, 1891.

These may be recognized as follows:—

A. Whitish-yellow cerebriform colonies—*Schoenleini*.
B. White downy colonies—*Quinckeanum*.
C. Yellowish colonies—*Gypseum*.

A. arloingi has not been properly described.

Achorion schoenleini Lebert, 1845.

Synonyms.—*Oidium schoenleini* Lebert, 1845; *O. porriginis* Montague; *Oöspora porriginis* Saccardo, 1886; *Oidium schoenleini* Zopf, 1890.

Causes the well-known affection called *favus*, which is characterized by the presence of peculiar disc-shaped crust formations, called *scutula*, of a sulphur-yellow colour, and emitting an offensive odour which has been compared to the smell of mice's urine.

The fungus may infect the hairs or glabrous parts of the body; it may attack the nails. In the hairs the mycelium is very abundant, the segments being comparatively long. Sometimes the mycelial threads divide into three or four branches, each of which terminates in a single row of roundish spores. This is known as *favic tarsus*.

Cultures.—The fungus is easily cultivated on various media. On Sabouraud's agar and on glucose agar the growth, when completely developed, is convoluted or cerebriform, and somewhat bulging. It has been compared by Sabouraud to the appearance of a sponge. The colour is white-yellowish, like that of old wax. After a time cultures become pleomorphic and abundant; white duvet is present. To prevent pleomorphism, media not containing sugars should be used (see p. 996).

A. schoenleini liquefies gelatine in between three to four days, while the *Trichophytons* take generally between fifteen to twenty days.

By inoculation of pure cultures of the fungus favus lesions are produced in man, dogs, mice, rabbits, and fowls. The inoculation in guinea-pigs does not give rise to typical favus lesions with scutula, but to circinate trichophytic-like lesions.

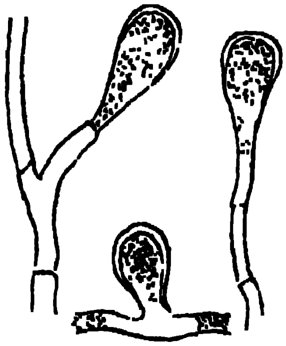

FIG. 512.—SO-CALLED YELLOW BODIES IN CULTURES OF *Achorion schoenleini* LEBERT.
(After Bodin.)

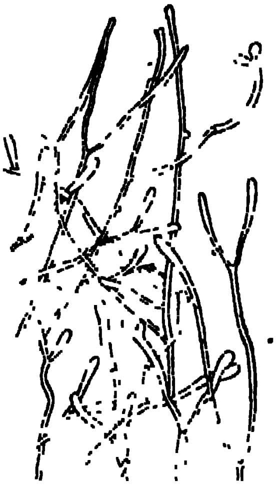

FIG. 513.—CLAVIFORM BODIES IN CULTURES OF *Achorion schoenleini* LEBERT.

Reproduction.—This takes place—

1. By sprouting.
2. By elongated fusiform structures analogous, according to some authorities, to the so-called 'spindles' of the *Trichophytons* and *Microsporons*, but they are slenderer and not septate. These formations are called by the French authors 'chandeliers faviques,' on account of their shape somewhat resembling a candlestick.
3. By so-called 'favus' or 'yellow bodies,' which are structures 8 to 15 μ in diameter, generally terminal, showing a double contour, and containing a granular substance. These structures should probably be considered to be chlamydospores (see also general remarks on the genus *Achorion*).

Sabouraud admits only one species of human *Achorion*, but Neeb and Unna have described as many as nine: *Achorion cysticum, A. tarsiferon, A. moniliforme, A. demergens, A. akromegalicum, A. dikroön, A. radians, A. euthythrix, A. atacton.* Sabouraud's opinion is the one generally accepted at the present time.

Achorion quinckeanum Zopf, 1890.

The fungus appears in the lesions in the shape of numerous mycelial filaments often dissociated in so many small segments constituting so-called spores. Grows readily on Sabouraud's agar, producing white, downy colonies.

This fungus botanically holds an intermediate position between the typical *Achorions* and the *Microsporons* and *Trichophytons*, conidia bearing hyphæ of the type *Acladium* being present. It produces, however, typical favus lesions with scutula.

Pathogenicity.—Is the cause of favus in mice, and may occasionally infect man, in whom, too, it induces typical favus. It can be inoculated into guinea-pigs.

Achorion gypseum Bodin, 1907.

Found by Bodin in 1907 in a typical case of favus. On Sabouraud's agar the growth, which is roundish, presents a little white duvet in the centre, while the rest has a glabrous surface of yellowish colour. Old cultures become pleomorphic, with presence of abundant white duvet all over the growth. Botanically the fungus is closely allied to the *Trichophytons* and *Microsporons*, but gives rise to typical favus, with scutula, when inoculated in mice and guinea-pigs. The inoculation of pleomorphic cultures does not cause any eruption.

Achorion arloingi R. Blanchard, 1891.

Synonym.—*Achorion arloingi* Busquet, 1891.

Incompletely known species. Was isolated from a human trichophytic-like eruption by Désir de Fortunet and Courmont. Is said to be inoculable into mice, rabbits, and man.

Genus Lophophyton Matruchot and Dassonville, 1899.

Mycelial filaments, either tortuous, very thin, or thick, with granular protoplasm. No spores present. One species only.

Lophophyton gallinæ Mégnin, 1881.

Synonyms.—*Epidermophyton gallinæ* Mégnin, 1881; *Lophophyton gallinæ* Matruchot and Dassonville, 1899; *Achorion gallinæ* Sabouraud, 910.

In the lesions mycelial filaments are seen, some thin and tortuous, without practically any protoplasm; others of much larger dimensions, with granular protoplasm. No spores observed. The fungus is easily cultivated, and is inoculable into rabbits, mice, and fowls, in which it gives rise to typical favus lesions. In man it does not produce favus, but merely trichophytic-like erythematous, squamous patches.

Genus Epidermophyton Lang, 1879, *emendavit* Sabouraud, 1907.

Definition.—Trichophytineæ with mycelial filaments and spores present in the lesions and with pluriseptate spindles present in the cultures. Does not attack the hairs or hair follicles, but grows in the superficial layers of the epidermis.

Type Species.—*Epidermophyton cruris* Castellani, 1905.

Remarks.—The fungi belonging to this genus, which has been investigated by Sabouraud and Castellani, grow superficially on the skin without invading the hairs and hair follicles; do not produce suppuration. Reproduction takes place principally by pluriseptate spindles, with, on the average, four to six cells. The septa, as noted by Pinoy, may not be complete, and the cavities may communicate. Spiral hyphæ, as found in most species of *Trichophyton*, absent; pectinate structures, as found in the *Microsporons*, absent; no spore-bearing hyphæ, with lateral conidia of type *Acladium*, as noted both in the *Trichophytons* and in the *Microsporons*. The cultures undergo rapid degenerative changes, losing their characteristics, and becoming covered with abundant uniform, long, whitish duvet (pleomorphism). They are not inoculable into guinea-pigs, except Pinoy's *Epidermophyton simii*. The species so far known have been isolated from human lesions, except the *Epidermophyton* discovered by Pinoy in monkeys.

TABLE OF EPIDERMOPHYTONS.

Epidermophyton Lang, 1879, *emendavit* Sabouraud, 1907	*E. cruris* Castellani 1905. *E. perneti* Castellani, 1907. *E. rubrum* Castellani, 1907.

These species may be recognized by their growths on Sabouraud's agar:—

A. Colour peculiar yellow—*Cruris*.
B. Colour pinkish—*Perneti*.
C. Colour deep red—*Rubrum*.

For *E. simii* Pinoy, 1911, we have created the genus *Pinoyella*.

Epidermophyton cruris Castellani, 1905.

Synonyms.—*Trichophyton cruris* Castellani, 1905; *Epidermophyton inguinalis* Sabouraud, 1907; *T. castellanii* Brooke, 1908.

Found in cases of tinea cruris in Ceylon by Castellani, and in France by Sabouraud. The fungus is very abundant in recent cases, extremely scarce in old ones. The mycelial tubes in recent cases are generally straight, have often a double contour, and the segments are somewhat rectangular, their breadth being $3\frac{1}{2}$ to $4\frac{1}{2}$ μ. Branching is not rare. The spores are rather large (4 to 7 μ), roundish, and have generally a double contour; they do not collect in clusters. In chronic cases degeneration forms of the fungus are met with; the mycelium may be banana-shaped, may show several constrictions, or long strings of ovoid elements may be seen.

This *Epidermophyton* grows well, but rather slowly, on Sabouraud's agar. The growth begins to be visible after four to eight days, the colonies being at first of a peculiar yellow colour, lemon-yellowish or orange-yellowish, occasionally with a greenish tinge. Later they become white, with pulverulent surface, and may be acuminate or crateriform. Pleomorphism, with abundant white duvet, develops quickly.

This fungus in Ceylon is the commonest species found in cases of tinea cruris. It is not inoculable into guinea-pigs. Attempts at reproducing the eruption in man by inoculating pure cultures have also failed.

Epidermophyton perneti Castellani, 1907.

This fungus has been described by Pernet. It differs from *E. cruris* by growing much more rapidly on Sabouraud's agar and by the cultures having a delicate pinkish colour, which is generally lost in subcultures. It is very rare in Ceylon.

Epidermophyton rubrum Castellani, 1909.

Synonym.—*Trichophyton purpureum* Bang, 1910.

This fungus was described by Castellani in Ceylon in 1909, and by Bang in France in 1910. On Sabouraud's agar the growth begins to appear four to six days after inoculation as a raised red spot, which gradually enlarges. At complete development the growth is of a deep red colour, either with a central knob or crateriform, and is partly covered with a white, delicate duvet. In old cultures the white duvet is much more abundant and thicker, and may hide the red pigmentation almost completely.

On *glucose agar* (4 per cent.), which is the best medium for this fungus, the growth is of a very deep blood-red colour, and the red pigmentation may spread to portions of the medium itself. In old cultures abundant white—occasionally white-greenish—duvet is present. This may hide the pigmentation, but, scraping out the duvet, the red pigmentation will be found to be still well marked. On ordinary agar and glycerine agar the fungus grows fairly well, but there is no red pigmentation.

Genus Endodermophyton Castellani, 1909.

Definition.—Trichophytoneæ with mycelial filaments and spores in the lesions, but no conidial filaments in cultures. Pluriseptate spindles unknown: grows between the superficial and deep layers of the epidermis, and does not attack the hairs or hair follicles.

Remarks.—The fungi belonging to this genus are characterized by their growth between the superficial and deep strata of the epidermis, forming an interlacing felt of mycelia, which detaches the horny and granular layers from the rete Malpighi. They do not invade the hair follicles, and do not cause suppuration. They have been cultivated by Castellani.

Cultures.—Botanically, these fungi are closely allied to the *Achorions*, as remarked by Sabouraud and Pinoy, who have examined Castellani's cultures. Attempts at cultivation failed for a long time, as they generally do not grow on solid media direct from the scales. These, after being treated with alcohol for five to ten minutes, must be placed in glucose-broth tubes, one scale in each tube. Most of the tubes become contaminated with bacteria, but in those which remain clear, after a time (five to ten days) a few delicate, short, white filaments will be seen originating from the scale. The growth slowly increases until, after three to four weeks, it takes the appearance of a small, white, fluffy mass, with a dark spot (the scale) in the centre. Portions of the broth cultures are sown on solid sugar media, on which growth takes place now quite easily. Fungi can then be indefinitely subcultured on solid media. The fungi grow much more abundantly on glucose agar, 4 per cent., than on Sabouraud or any other media.

Reproduction.—In hanging-drop cultures long mycelial filaments are seen; no conidia-bearing hyphæ are present; reproduction is apparently by sprouting, branching taking place; but further investigation is necessary on the subject.

Pleomorphism.—Pleomorphism is much less marked than in the *Trichophytons*, *Epidermophytons*, and *Achorions*, but old cultures may lose their characteristics, becoming covered with duvet.

TABLE SHOWING ENDODERMOPHYTONS FOUND IN MAN IN ORDER OF FREQUENCY.

E. tropicale Castellani.
E. indicum Castellani.
E. concentricum Blanchard.
E. mansoni Castellani.

These may be recognized as follows:—

A. Glucose agar cultures amber coloured, no duvet or only slight—*Tropicale*.
B. Glucose agar cultures deep red:—
  I. Causes *Tinea imbricata*—*Indicum*.
  II. Causes *Tinea intersecta*—*Castellanii*.
C. Glucose agar cultures after a time black:—
  I. Pigmentation fairly slow—*Concentricum*.
  II. Pigmentation very rapid—*Mansoni*.

Endodermophyton tropicale Castellani, 1914.

Remarks.—Manson, in 1872, described a trichophyton-like organism in the squamæ of *tinea imbricata;* with the laboratory techinque of that time attempts at cultivation did not succeed. Blanchard considered it non-cultivable, and called it *Trichophyton concentricum;* on the other hand, Nieuwenhuis stated that it was quite easily cultivable, and was characterized by the colonies being crateriform. His researches were not confirmed. In recent years the general opinion has been that aspergillus-like fungi were the real cause of the disease. Tribondeau described fructifications somewhat similar to those of an *Aspergillus*, and created for the fungus the genus *Lepidophyton*. Wehmer has described it as a true *Aspergillus*—*Aspergillus tokelau*. Castellani, from the investigations he has carried out in Ceylon, has come to the conclusion that *Aspergillus* and aspergillus-like fungi have nothing to do with the disease. When they are present in the squamæ, they are merely saprophytes or contaminations. By using a special technique he has succeeded in growing what he considers to be the true fungi causing the disease. He recognized at first two species, and more recently four, further investigation having shown that the term he used for one species (concentricum) covered more than one species.

Endodermophyton tropicale is very abundant in the lesions, forming a felting of interlacing mycelial threads with mycelial articles, regular in shape, rectangular or somewhat square-shaped, and usually straight. If the liquor potassæ be left to act some time, the mycelial articles, which are of very variable length, and 2½ to 3½ μ in breadth, will be seen to have a double contour. *Aspergillus* *fructifications*, described by so many authors, when present, are due to contaminations: they form no part of the fungus. Cultivation of this fungus has been obtained by Castellani, using the method mentioned in the paragraph above on the genus *Endodermophyton*.

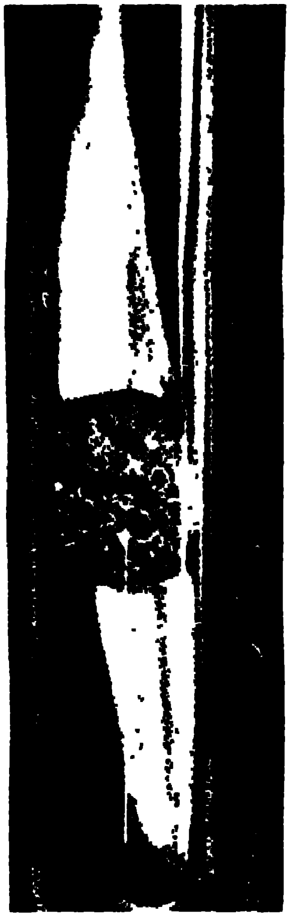

FIG. 514.—*Endodermophyton tropicale* CASTELLANI: GLUCOSE AGAR CULTURE.

FIG. 515.—*Endodermophyton tropicale* CASTELLANI: OLD GLUCOSE AGAR CULTURE.

The principal cultural characters on solid media, when the growth is fifteen to twenty-one days old, are as follows:—

Glucose Agar (4 *per cent.*).—Growth abundant; surface cerebriform or crinkled. The growth and the medium show a slight amber colour, which later on may become of much deeper hue. Duvet as a rule absent, but in old cultures which have been transplanted many times and are degenerating, some very scarce, short, whitish duvet may appear.

Sabouraud Agar.—Growth comparatively scanty, whitish-grey, mostly submerged. The colonies are whitish, have generally a small central knob and never show any duvet. The submerged portion is very firmly embedded, and often presents projections deepening in the medium. Colour of the medium unchanged.

Glycerine Agar.—Similar growth to Sabouraud's agar. When the colonies coalesce, the growth shows a knobby surface. No duvet.

Ordinary Agar.—Scanty growth, somewhat similar to Sabouraud. No duvet.

Mannite Agar (4 *per cent*).—Appearance somewhat similar to glucose, but growth less abundant. The medium may take a slight amber colour. No duvet.

Saccharose Agar (4 *per cent.*). Growth rather scanty, similar to Sabouraud. Duvet absent.

Nutrose Agar (4 *per cent.*). -Very slow growth. Separate young colonies have a central knob; they coalesce later into a knobby mass.

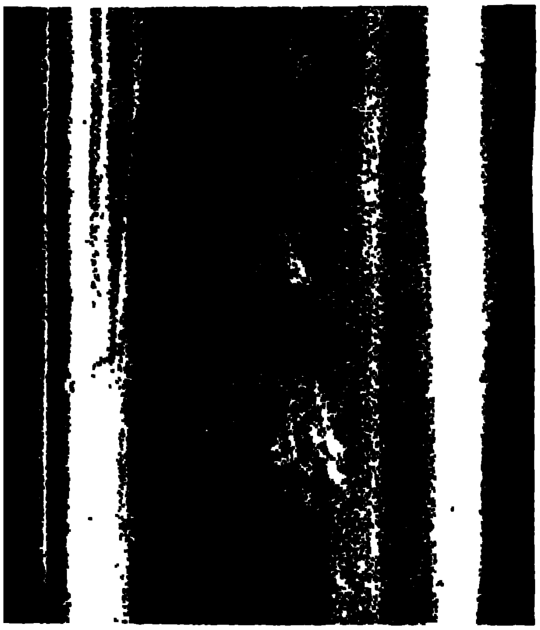

FIG. 516.—*Endodermophyton tropicale* CASTELLANI: AGAR CULTURE.

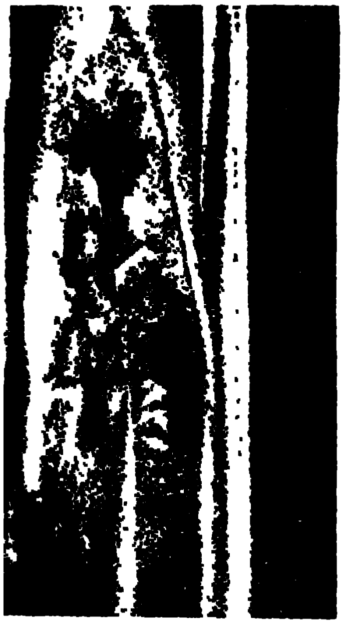

FIG. 517—*Endodermophyton tropicale* CASTELLANI: MALTOSE AGAR CULTURE.

Maltose Agar (*Acid*).—Similar to Sabouraud.

Maltose Agar (*Alkaline*).—Similar to Sabouraud.

Adonite Agar.—Not very abundant; cerebriform; duvet absent.

Galactose Agar.—Knobby or cerebriform.

Levulose Agar.—Knobby.

Raffinose Agar.—Cerebriform.

Inulin Agar.—Cerebriform.

Saccharine Agar (4 *per cent.*).—Somewhat knobby surface; duvet absent.

Lactose Agar.—Similar to Sabouraud, but surface growth more abundant.

Gelatine.—Very slow liquefaction of the medium.

Milk.—Very scanty growth. After a time the medium becomes separated

Sugar Broths (*Maltose, Lactose, etc.*).—Slight growth at the bottom of the tube; no production of acid or gas.

Hanging-Drop Cultures.—In hanging-drop cultures (Sabouraud's maltose broth) long mycelial threads are seen. Reproduction is apparently by sprouts from the mycelium, branching taking place.

Pathogenicity.—The fungus is the cause of a common type of tinea imbricata. Castellani has demonstrated that the inoculations into human beings of cultures of the fungus reproduce a typical form of tinea imbricata, and that from the scales of the eruption, experimentally induced, the same fungus is recoverable. For further details see Chapter XCII. on Tinea Imbricata (p. 2509).

Endodermophyton indicum Castellani, 1911.

This fungus was found by Castellani in some cases of *tinea imbricata.* The microscopical appearance of the fungus in the scales is identical with *E. tropicale.* The principal cultural characters on solid media, when the growth takes place in the dark, about 80° to 85° F., without rubber caps on the tubes, and is between fifteen and twenty-one days old, are as follows:—

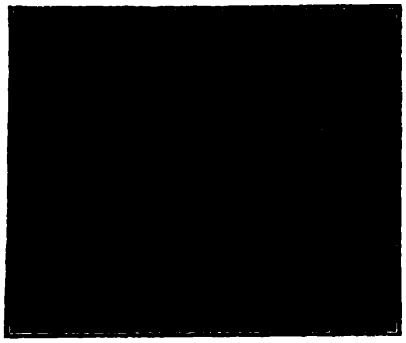

FIG. 518. — PATCH OF EXPERIMENTAL TINEA IMBRICATA IN A SINGHALESE BOY, OBTAINED BY INOCULATING A CULTURE OF *Endodermophyton indicum.*

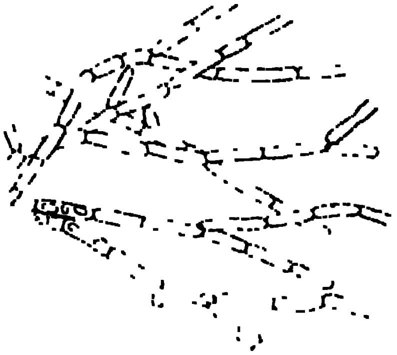

FIG. 519. — *Endodermophyton indicum* CASTELLANI: HANGING-DROP CULTURE.

Glucose Agar (4 *per cent.*).—Growth fairly abundant, with surface somewhat convoluted or furrowed. Portions of the growth, often the central, is of a deep orange, or pinkish-orange, or red-orange, occasionally of bright red colour. The surface of the rest of the growth often appears white and powdery, being covered by a very short delicate white duvet.

Sabouraud Agar.—Slow growth, with powdery surface, either with central knob or convoluted. The growth does not deepen in the medium so much as *E. concentricum.*

Glycerine Agar.—Growth abundant, white or amber colour; delicate white short duvet present on some portions of the growth.

Ordinary Agar.—Growth fairly abundant; knobby surface covered by snow-white very short delicate duvet.

Mannite Agar.—Growth knobby or convoluted, covered by short white duvet.

Saccharose Agar.—Cerebriform, covered by white duvet.

Saccharine.—Crinkled surface; delicate white duvet present.

Maltose Agar (*Acid*).—Somewhat similar to Sabouraud's, but the surface growth is more abundant.

Maltose Agar (*Alkaline*).—Similar to acid maltose, but the white duvet is more abundant.

Lactose Agar.—Knobby surface covered by snow-white duvet.

Nutrose Agar.—Yellowish crinkled surface; short white duvet present.

Levulose Agar.—Scanty growth, yellow or orange; scarce; very short white duvet present.

Galactose Agar.—Fairly abundant; surface convoluted with abundant, short snow-white duvet.

Raffinose Agar.—Same appearance as galactose.

Inulin Agar.—Same appearance as in galactose and raffinose agars.

Adonite Agar.—Cerebriform; surface covered with snow-white duvet.

Gelatine.—Very slow liquefaction.

Litmus Milk.—Very scanty growth. After a time the medium may become separated.

Various Sugar Broths (*Maltose, Lactose, etc.*).—Slight growth at the bottom of the tube. No production of acid or gas.

The annexed table shows at a glance the different cultural characteristics of the two fungi in the principal media.

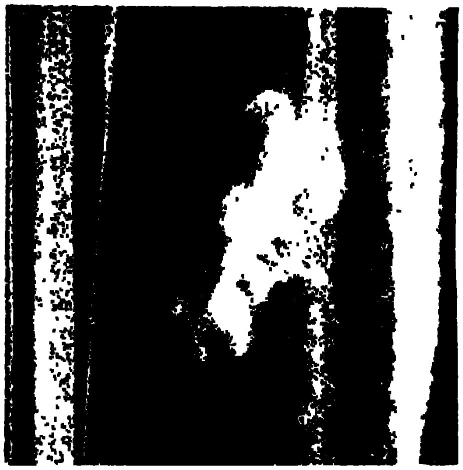

FIG. 520.—*Endodermophyton indicum* CASTELLANI: AGAR CULTURE.

FIG. 521.—*Endodermophyton indicum* CASTELLANI: GLUCOSE AGAR CULTURE.

COMPARISON BETWEEN THE CULTURAL CHARACTERS OF *Endodermophyton tropicale* AND OF *Endodermophyton indicum*.

Media.	*E. tropicale.*	*E. indicum.*
Glucose agar ..	Amber colour, duvet absent in young cultures.	Deep orange, at times, pinkish or red, very short white delicate duvet often present.
Sabouraud agar	Growth scanty, mostly submerged, grey-whitish duvet absent.	Surface growth more abundant, powdery white.
Agar	Scanty, mostly submerged; similar to Sabouraud agar; no duvet.	Fairly abundant, knobby well-marked snow-white duvet.
Glycerine agar ..	Growth mostly submerged; surface growth very scanty; similar to Sabouraud agar; no duvet.	Surface growth very abundant; crinkled appearance; white short duvet present.

The above characters are based upon the appearance of cultures kept in the dark at a temperature 80° to 90° F., and without rubber caps. If any of these conditions are altered, the cultural characters are changed. If rubber

caps are used, both *E. indicum* and *E. tropicale* may assume a bright red colour. If, however, subcultures are made from these, using tubes without rubber caps, the fungi again show the characters given above.

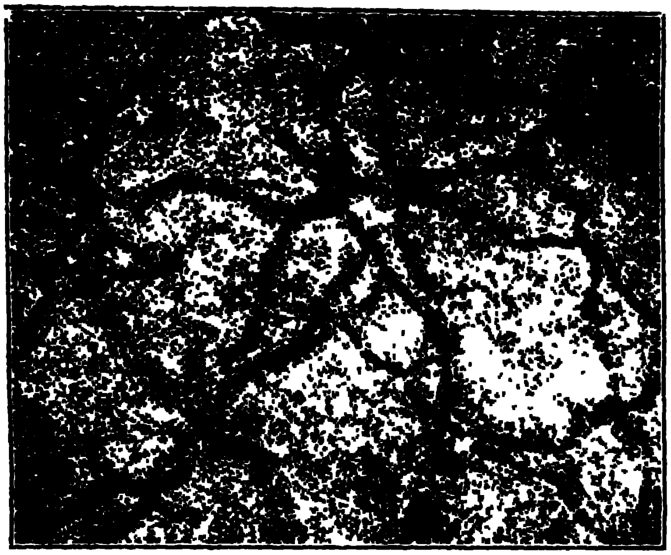

FIG. 522.—*Endodermophyton indicum* CASTELLANI IN THE SCALES.

Hanging-Drop Cultures.—Long mycelial filaments are present. No free spores are seen; reproduction is apparently by sprouts from the mycelium.

Pathogenicity.—The fungus is the cause of a certain number of cases of tinea imbricata. The type of the disease caused by this fungus seems to be more superficial than that caused by *E. tropicale*, but further researches are required on this subject. Castellani has succeeded in experimentally reproducing the disease by inoculating coolies, who had volunteered, with pure cultures of the fungus. The skin was first scarified with a sterile knife; then a certain amount of a pure agar culture of *E. indicum* was well rubbed in. After fifteen to twenty-one days the first signs of the eruption appeared, and the typical patches of tinea imbricata developed. From the scales of the experimental cases a fungus was grown absolutely identical with the strain of *E. indicum* with which the individuals had been inoculated.

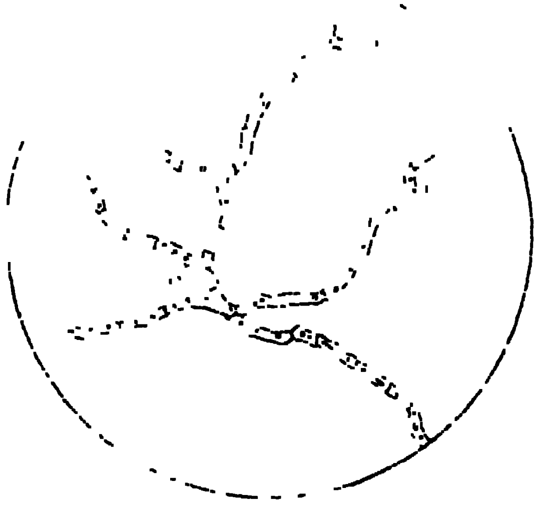

FIG. 523.—*Endodermophyton castellanii* PERRY.

Endodermophyton castellanii
Perry, 1907.

Found by Castellani in cases of *tinea intersecta*. In the scales the mycelium is fairly abundant; no free spores are seen. Mycelial segments uniform, rather straight, and, provided the liquor potassæ be left to act for sufficient time, they often show a double contour. Their breadth is $2\frac{1}{2}$ to $3\frac{1}{2}$ μ. Each mycelial segment has two roundish refringent dots, one at each extremity. Has been cultivated only on one occasion, the cultures being apparently similar to those of *E. indicum*. It is the cause of tinea intersecta.

Endodermophyton concentricum Blanchard, 1901.

Cultures on glucose agar are at first amber colour, but after four to eight weeks become jet-black and covered with abundant duvet.

Endodermophyton mansoni Castellani, 1914.

Portions of the growth are black from the very first, scanty duvet.

Genus Pinoyella Castellani and Chalmers, 1908.

Definition.—Trichophytoneæ with mycelial filaments and spores in the lesions, and in cultures conidial-bearing hyphæ, with the spores situate laterally only.

Type and only Species.—*Pinoyella simii* (Pinoy, 1911); *Epidermophyton simii* Pinoy, 1911.

Discovered by Pinoy in a trichophytic-like eruption observed in a monkey. On Sabouraud's agar the growth is at first yellowish-orange, somewhat similar to *Epidermophyton cruris*; later, the growth is whitish and covered with white duvet.

Pinoy's fungus has several interesting botanical features, some of which are those of the genera *Microsporon* and *Trichophyton*. In contrast to the typical *Epidermophytons*, it presents spore-bearing hyphæ with lateral conidia, and is inoculable into guinea-pigs, in which it produces a trichophytic-like eruption.

Genus Montoyella Castellani, 1907.

Definition.—Trichophytoneæ with mycelial filaments and spores in the lesions, in cultures conidial-bearing hyphæ with only terminal spores.

Remarks.—Temporary genus. Two kinds of mycelial threads: some slender, ramified, septate; others much thicker, having numerous intermediate chlamydospores. From the thicker filaments delicate hyphæ take origin, which terminate in large pear-shaped or globular conidia.

Type Species.—*Montoyella nigra* Castellani, 1907.

Classification.—There are two species, which may be differentiated as follows:—

A. **Cultures black—*Nigra*.**
B. **Cultures whitish or greenish—*Bodini*.**

Montoyella nigra Castellani, 1907.

Temporary species. Colonies on maltose agar are black. If glycerine agar is used, the medium takes a black colour. This species, discovered by Montoya, is common in black pinta.

Montoyella bodini Castellani, 1907.

Temporary species. Colonies whitish or greenish.

FAMILY ASPERGILLACEÆ.

Definition.—Aspergillales with compact peridium, small sessile closed perithecia.

Type Genus.—*Aspergillus* Micheli, 1729.

Classification.—The genera of the Aspergillaceæ can be recognized as follows:—

A. *Spores unicellular* :—
  I. Perithecium beaked—*Microascus*.
  II. Perithecium not beaked:—
    (*a*) Perithecia with appendages—*Cephalotheca*
    (*b*) Perithecia without appendages:—
      1. *Conidiophores* absent - *Thelavia*.
      2. *Conidiophores* present:—
        (A) Conidia solitary—*Aphanoascus*.
        (B) Conidia in chains:—
          (i.) Conidiophores simple—*Emericella*.
          (ii.) Conidiophores enlarged apically and bearing sterigmata:—
            (1) Sterigmata simple—*Aspergillus*.
            (2) Sterigmata branched—*Sterigmatocystis*.
          (iii.) Conidiophores branched:—
            (1) Sympodially branched—*Eurotiopsis*.
            (2) Bushy branched:—
              (*a*) In bundles, perithecia stalked—*Penicilliopsis*.
              (*b*) Not in bundles, perithecia sessile—*Penicillium*.
B. *Spores bicellular*—*Testudina*.

We are concerned with the genera *Penicillium*, *Aspergillus*, and *Sterigmatocystis*, of which the following species are parasitic in man:

Penicillium Link, 1809	*P. crustaceum* Linnæus, 1763.
	P. minimum Siebenmann, 1889.
	P. barbæ Castellani, 1907.
	P. montoyai Castellani, 1907.
	P. pruinosum Salisbury.
	P. brevicaule var. *hominis* Brumpt and Langeron, 1910.
Sterigmatocystis Cramer, 1869	*S. antacustica* Cramer, 1859.
	S. nidulans Eidam, 1883.
Aspergillus Micheli, 1725	*A. fumigatus* Fresenius, 1775.
	A. flavus Link, 1791.
	A. bronchialis Blumentritt, 1901.
	A. nigrescens Robin, 1851.
	A. repens De Bary, 1870.
	A. malignus Lindt, 1889.
	A. pictor R. Blanchard, 1895.
	A. barbæ Castellani, 1907.
	A. bouffardi Brumpt, 1905.
	A. herbariorum Wiggers, 1780.
	A. fontoynonti Guéguen, 1909.

Genus Penicillium Link, 1809.

The whole fruit-bearing hypha with its sterigmata and conidia resembles a hair-pencil, hence the name of the genus (*Penicillium*= hair-pencil). The conidiophore hypha shows verticillate branches, which give rise to slender fusiform formations (sterigmata) abstricting chains of conidia.

Penicillium crustaceum Linnæus, 1763.

Synonyms.—*Mucor crustaceus albus* Linnæus, 1763; *Monilia digitata* Persoon; *Penicillium glaucum* Linnæus, 1809: *P. expansum* Linnæus; *P. crustaceum* Fries, 1829.

An extremely common saprophyte found on bread, cheese, fruits, and various organic substances in a state of decomposition. The conidia are spherical or slightly elliptical, of bronze colour, with smooth surface; maximum diameter 4 µ. This fungus grows well at any temperature between 2° and 35° C., and is very resistant.

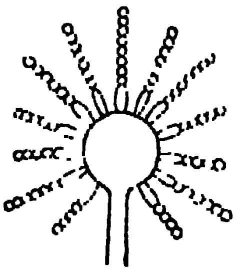

FIG. 524.—ASPERGILLUS FRUCTIFICATION.

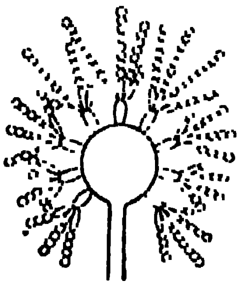

FIG. 525.—STERIGMATOCYSTIS FRUCTIFICATION.

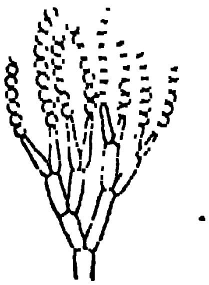

FIG. 526.—PENICILLIUM FRUCTIFICATION.

(After Brumpt.)

It has been found by Maggiora and Gradenigo in two cases of otitis media. Heinhorn has observed it in the vomiting of four cases of acid dyspepsia together with *Aspergillus herbariorum*.

Wertheim has observed that the intravenous inoculation of *P. crustaceum* is pathogenic to rabbits, dogs, and lambs.

Penicillium minimum Siebenmann, 1889.

Conidia are roundish, smooth, of a brownish-black colour: smaller than in *P. crustaceum*, being 2·5 to 3 µ in diameter. Was found in a case of acute otitis by Siebenmann.

Penicillium montoyai Castellani, 1907.

Synonym.—*P. pictor* Neveu-Lemaire, 1908.

Conidia roundish or slightly oval, smooth, 3 to 4½ µ in diameter. Grows well on maltose agar and ordinary agar; cultures of dark greyish colour. Discovered by Montoya in cases of pinta, of the greyish-violet variety. Similar species, not yet well defined, are found in other varieties of pinta.

Penicillium brevicaule var. hominis Brumpt and Langeron, 1910.

Found by Brumpt and Langeron in two cases of onychomycosis. In the lesions septate mycelial threads were seen, 2 to 10 μ in diameter, and large groups of chlamydospores, generally terminal, 10 to 30 μ in diameter. The fungus is easily cultivated on Sabouraud's agar and other sugar media, also on potatoes and carrots. Optimum temperature 25° C., but grows well also at 37° C. Conidia spherical or occasionally ovoid, of a chocolate colour.

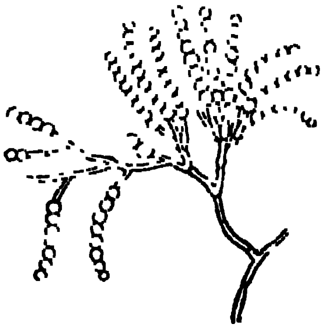

FIG. 527.—*Penicillium brevicaule* VAR. *hominis* BRUMPT AND LANGERON. (After Brumpt.)

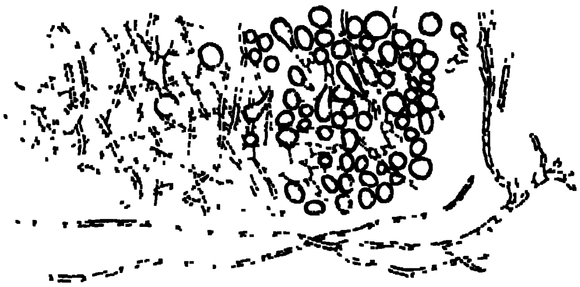

FIG. 528.—*Penicillium brevicaule* VAR. *hominis* BRUMPT AND LANGERON. (Preparation from the diseased nails, after Brumpt.)

Penicillium barbæ Castellani, 1907.

Found by us growing on the beard of natives of equatorial Africa, and in natives of Ceylon.

Penicillium pruriosum Salisbury.

Doubtful species found by Salisbury in the vaginal mucus of a woman suffering from intense vaginal pruritus.

Genus Aspergillus Micheli, 1725.

The conidiophore hypha are not ramified, and terminate into ovoid or roundish formations, which support numerous claviform elements (sterigmata), each of which supports a chain of roundish conidia.

Aspergilli are generally saprophytes, but they may become parasites. They are easily grown on acid media, liquid or solid, and also on alkaline media. Iron and manganese have a favourable influence on the growth and sporulation of these fungi.

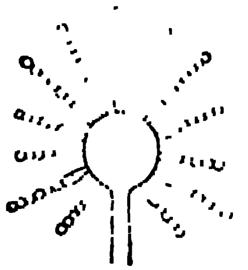

FIG. 529.—ASPERGILLUS FRUCTIFICATION. (After Brumpt.)

A medium much used is Raulin's liquid, the formula of which is: Cane-sugar, 70 grammes; tartaric acid, 4 grammes; ammonium nitrate, 4 grammes; ammonium phosphate, 0·60 gramme; potassium carbonate, 0·60 gramme; magnesium carbonate, 0·40 gramme; ammonium sulphate, 0·25 gramme; zinc sulphate, 0·07 gramme; ferrous sulphate, 0·07 gramme; potassium silicate, 0·07 gramme.

Fungi of the genus *Aspergillus*, when growing parasitically in the tissues, often lose their characteristics; the typical fructifications are absent, and only mycelial threads and roundish or oval yeast-like bodies are seen.

The various species may be differentiated with difficulty as follows, or cannot be differentiated :

- A. *Green species* :—
  - I. Spores 5 microns and more Can hardly be differentiated - *Repens, Flavus*
  - II Spores less than 5 microns:
    - (*a*) Lives saprophytically - *Fumigatus*.
    - (*b*) Not known to live saprophytically: -
      - 1. Very pathogenic for rabbits -*Malignus*.
      - 2. Found in bronchial sputum -*Bronchialis*.
- B. *Blackish-brown* species -*Nigrescens*.
- C. *Golden, brownish*, gold-brown, or reddish - -*Herbariorum*.

Aspergillus fumigatus Fresenius, 1775.

This is the commonest *Aspergillus*, and is very often found on various cereals, straw, hay, etc. On solid media it produces a brownish-black culture if the medium is alkaline or neutral, greenish if the medium is acid. The mycelial filaments are more or less ramified, the breadth varying between 2 and 3 μ. The conidiophore hyphae are much thicker than the mycelial tubes, being, on the average, about 5 μ in breadth. The sterigmata, which are situated very close together, are 6 μ long; the conidia are roundish, 2·5 to 3 μ in diameter, smooth, colourless. Optimum temperature, 37° C.; the growth stops below 20 or above 55°C.

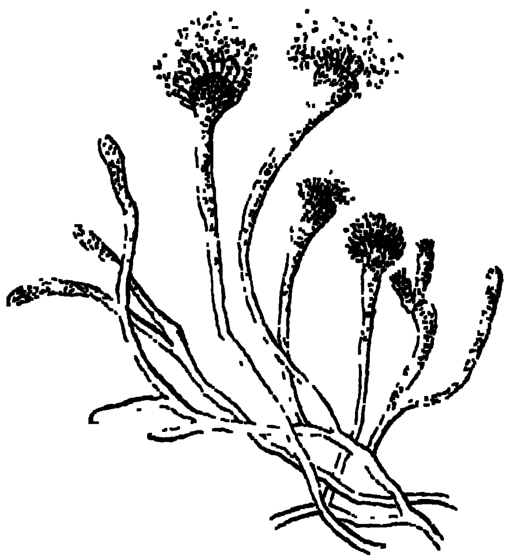

FIG. 530.—*Aspergillus fumigatus* FRESENIUS.

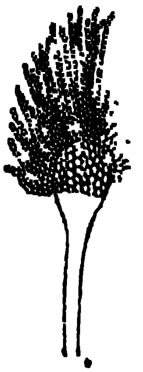

FIG. 531.—*Aspergillus bronchialis* BLUMENTRITT. (After Blumentritt.)

Pathogenicity.—This *Aspergillus* is the species most frequently found in man, giving rise to an aspergillosis of various organs. The spores are very resistant. Perchloride of mercury is the antiseptic which has the greatest destructive action on the spores. The effects on the human organism are due, in addition to mechanical action, to toxins secreted by the fungi. Lucet has found in cultures of *A. fumigatus* in Raulin's liquid a pyrogenic substance; Ceni and

Besta have isolated toxic products soluble in ether and alcohol, which act on the muscular and nervous system of dogs and rabbits. (See also remarks on Aspergillomycoses, p. 1031.)

Aspergillus flavus De Bary, 1870.

Synonyms.—*Monilia aurea* Gmelin, 1791; *Eurotium flavum* De Bary, 1870; *Aspergillus flavescens* Wreden, 1874.

Mycelium colourless; conidiophore hyphæ terminate in roundish formations of a gold-yellow colour. The conidia are dark yellow, roundish, 5 to 7 μ in diameter, with a surface showing numerous minute mammillar prominences. Found by several observers (Wreden, Siebenmann, etc.) in the ear. Optimum temperature, 37° C.

Aspergillus bronchialis Blumentritt, 1901.

Mycelium of a white colour, much ramified; conidiophore hyphæ are 6·2 to 12·6 μ in diameter, 280 to 300 μ in length. Conidia roundish, 3 to 4 μ in diameter, with a smooth surface, of a greyish-greenish colour. This *Aspergillus* was found by Chiari in the bronchi of a patient who had died from diabetes; it was investigated by Blumentritt. It has not yet been found as a saprophyte.

Aspergillus fontoynonti Guéguen, 1909.

Found by Fontoynont and Carougeau in a European living in Madagascar, who was suffering from multiple abscesses of the neck. In the pus and in the first cultures obtained the fungus had no true aspergillar appearance; it had to be subcultured several times before the typical aspergillar fructifications appeared. Conidia 4 to 5 μ in diameter, with surface finely verrucose. Optimum temperature, 22° to 25° C.

Aspergillus malignus Lindt, 1889.

Synonym.—*Eurotium malignum* Lindt, 1889.

Colourless mycelium, composed of short articles. Conidiophore hyphæ erected, terminating in pyriform formations, 22 to 24 μ in diameter, on which are situated the sterigmata, which are 10 μ long and 4 to 5 μ in breadth. Conidia roundish, of a greenish-bluish colour.

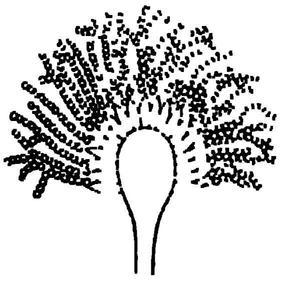

FIG. 532.—*Aspergillus malignus* LINDT.
(After Lindt.)

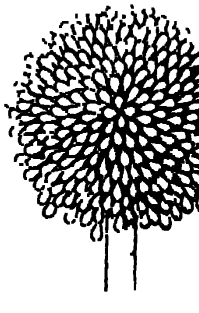

FIG. 533.—*Aspergillus repens* DE BARY.
(After Siebenmann.)

Pathogenicity.—This *Aspergillus* was found by Lindt in a case of otomycosis; according to this author, it is very pathogenic for rabbits.

Aspergillus herbariorum Wiggers, 1780.

Synonyms.—*Mucor herbariorum* Wiggers, 1780: *Aspergillus glaucus* De Bary, 1870.

Mycelium at first colourless, later yellow or reddish-yellow. This *Aspergillus* is characterized by the large size of the conidia, which are 9 to 15 μ in diameter. It is in nature a common saprophytic fungus. It has been found by Dunn in 1896 in the nasal cavities of a man, and by Einhorn in 1900 in the vomit of a case of hyperchloridia.

Aspergillus repens De Bary, 1870.

Synonym.– *Eurotium repens* De Bary, 1870.

This fungus is very similar to *A. herbariorum*, but for the smaller size of the conidia. Mycelium of a yellowish-green colour. Conidia large, 7 to 8·5 μ. Found by Siebenmann in the ear three times. Its pathogenic rôle is doubtful.

Quevedo has described an aspergillus very similar to *A. repens*, which he believes to be the cause of a type of encephalo-myelitis in horses in South America. He calls the organism *A. mayidis*.

Aspergillus pictor R. Blanchard, 1895.

Synonym. -- *Trichophyton pictor* R. Blanchard, 1895.

The term *Aspergillus* (*Trichophyton*) *pictor*, introduced by Blanchard in 1895, before the plurality of species of the fungi found in pinta was demonstrated, is now used to denote the species of *Aspergillus* which is found in the pure violet variety of pinta. This fungus shows the typical morphological characters of the genus *Aspergillus*. It grows easily on various sugar media. On maltose agar the growth has at first a whitish colour, which afterwards changes into greenish, to become violet or greenish with a violet tinge at a later period. The colour of the growth may vary according to the medium on which cultivation takes place. The conidiophores are comparatively thick; the conidia are globular, with a smooth surface.

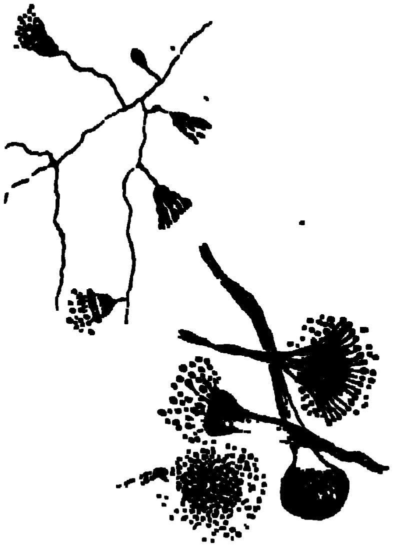

FIG. 534.—*Aspergillus pictor* R. BLANCHARD. (After Montoya y Florez.)

Several other species of aspergillar and aspergillar-like fungi are found in pinta, but their botanical position has not yet been defined with certainty.

Aspergillus bouffardi Brumpt, 1905.

Found by Bouffard in a case of black mycetoma, and completely described by Brumpt. Mycelium whitish in some zones, dark brown in others. Conidiophores erect, white, each terminating in a claviform structure, bearing some short chains of roundish conidia. Conidia 1·3 to 2 μ in diameter, roundish with a smooth surface, white. Chlamydospores present, 5 to 10 μ in diameter. Attempts at cultivation did not succeed.

Aspergillus barbæ Castellani, 1907.

Found by us in natives of Uganda, and in natives of Ceylon. Conidia spherical, 4 to 5 μ of a brownish colour.

Aspergillus nigrescens Robin, 1889.

Doubtful species, which, according to Wienfeld, causes a faviform eruption.

Genus Sterigmatocystis Cramer, 1859.

Definition.- Aspergillales with conidiophores terminating in roundish or ovoid formations, on which are situated short cylindrical structures *primary sterigmata* surmounted by similar elements—*secondary sterigmata*. Each of the secondary sterigmata supports a chain of roundish conidia.

Remarks. The genus was created by Cramer for a fungus found in a man's ear.

Type Species. *Sterigmatocystis antacustica* Cramer, 1859.

Classification. The two species of importance to us can be recognized as follows

A. Young conidial forms green; later strongly grey to brown. Conidia small 3 microns in diameter *Nidulans*

B Conidial forms blackish brown Conidia small, 2·5 microns in diameter—*Antacustica*.

Sterigmatocystis antacustica Cramer, 1859.

Synonyms. *Sterigmatocystis antacustica* Cramer, 1859; *Eurotium nigrum* De Bary, 1870; *Monilia pulla* Persoon; *Aspergillus nigricans* Wreden, 1874; *A. niger* von Tieghem, 1867.

Primary and secondary sterigmata: erected conidiophores: hyphæ more than 1 millimetre in length (3·5 to 4·5). Conidia globular, 2·5 μ in diameter, provided with a membrane of a brownish colour. Commonly found in decaying organic substances. It was first observed in man by Cramer, who observed it in the ear of a deaf patient. Later it was observed by Fürbringer and others in mycotic affections of the lungs.

Sterigmatocystis nidulans Eidam, 1883.

Synonym.—*Aspergillus nidulans* Eidam, 1883.

Mycelium of a greenish colour. Conidiophores are erect, 0·5 to 0·8 millimetre in length. Presence of primary sterigmata, supporting secondary sterigmata, each of which gives rise to a chain of conidia. Conidia small (2 to 3 μ in diameter), globular, of a greenish colour. The fungus has been completely investigated by Pinoy: grows badly in Raulin's liquid, better on Sabouraud's: is non-pathogenic for rabbits. This species is found living saprophytically in certain nests, hence the name *S. nidulans*. In man it has been found in several cases of otomycosis. Nicolle and Pinoy have found it, or a very similar species, in a case of mycetoma with white granules.

General Remarks on Mycoses due to Species of the Family Aspergillaceæ.

These mycoses are generally called aspergillomycoses. They have been recorded several times in man.

1. ASPERGILLOSIS OF THE LUNGS; ASPERGILLAR PSEUDO-TUBERCULOSIS; PNEUMOMYCOSIS OF ASPERGILLAR ORIGIN.—*Aspergilli* develop sometimes in the mucosa of the trachea, of the bronchi, and even in the pulmonary alveoli, without giving rise to any pathogenic effect. In other cases the fungi induce pseudo-membranous and ulcerative lesions. A very serious affection is a form of pseudo-tuberculosis (pseudo-tuberculosis aspergillina), characterized by the presence of mycotic nodules in the lungs, liver, kidneys, and other organs. This affection, due to *A. fumigatus*, is very common in some parts of France among pigeon-breeders (*gaveurs de pigeons*). The same affection attacks the pigeons. The infection is probably caused by spores of *A. fumigatus* being present in the grains used for feeding the pigeons.

2. ASPERGILLOSIS OF THE EYE.—*A. fumigatus* has been found several times in ulcers of the cornea (keratomycosis aspergillina).

3. ASPERGILLOSIS OF THE EAR (OTOMYCOSIS ASPERGILLINA).—Various species of *Aspergillus* have been found in the ear. In some cases they may give rise to a serious otitis, deafness, and tinnitus. Aspergillosis of the ear is not rare in the tropics. Syringing with hydrogen peroxide two parts and alcohol one part is useful.

4. ASPERGILLOSIS OF THE NOSE.—*A. glaucus* and *A. fumigatus* have been found in the nasal cavities; the first apparently does not

cause any disturbance. The second causes various inflammatory symptoms.

5. ASPERGILLOSIS OF WOUNDS AND ULCERS.—In wounds not properly treated, and in old ulcers, *Aspergilli* have been occasionally found.

6. ASPERGILLOSIS OF THE URETHRA.—In several cases a black urethral discharge has been observed, due to *Sterigmatocystis nigra.*

7. ASPERGILLOSIS OF THE SKIN.—Montoya's investigation has shown that several varieties of pinta are due to fungi of the genus *Aspergillus.* Another important tropical skin disease, tinea imbricata, was believed until recently to be due to an *Aspergillus*—*A. tokelau* Wehmer, 1903. In our experience the fungi of tinea imbricata never show aspergillar fructifications, and cannot be considered to be *Aspergilli.*

Aspergilli may also cause some varieties of mycetoma.

PYRENOMYCETES.

Ascomycetous fungi in which the asci are contained in a perithecium presenting an orifice at the apex for the escape of the spores. According to some authors, species of this family have been found parasitic in man. This is very doubtful, though Schubert states that he found in the nasal mucus of a patient an organism closely allied to *Botrytis bassiana,* which latter species, as is well known, causes the disease of silkworms called muscardin.

CLASS BASIDIOMYCETES.

Basidiomycetes have a septate mycelium, and are devoid of sexual reproduction. They reproduce by formation of basidia. Other accessory fructifications may be present—as, for example, chlamydospores. The basidia are of two principal types: (1) autobasidia; (2) protobasidia.

The autobasidia are large, unseptated cells, giving rise at their apices to four delicate sterigmata, each of which bears a spore.

The protobasidia are septated, and appear in two chief forms:—

A. Septated into four cells, each giving rise to a spore from a lateral inserted sterigma.

B. Septated by walls intersecting at right angles, each cell ending in an elongated tubular sterigma.

Of the Basidiomycetes, one species (*Ustilago phyodytes*) of the family Ustilagineæ is of special importance, while two others (*U. carbo* and *Tilletia lævis*) may produce otomycosis.

Ustilago hypodytes Schlecht.

Synonyms.—*Dendrodochium microsporus* Brigi; *Sporotrichum dermatodes* Kane.

The mycelium penetrates the stem and leaves of reeds (*Arundo donax*) in some parts of Provence, Italy, and Greece. After a time the mycelium produces innumerable so-called brand spores by a process of segmentation of its profusely branched hyphæ. In this way the mycelium is transformed into a brown dark mass of spores.

These brand spores, as regards the mode of their formation, may be considered chlamydospores. The brand spores are resting spores; they are scattered by the wind, and after an interval of rest they germinate, producing conidiospores of a basidium-like type.

The spores of *U. hypodytes* are the cause, according to most authors, of a peculiar affection found among workers who have to do with the cutting, etc., of reeds (*Arundo donax*). This affection is called 'frienite,' or 'frien disease.' The patient complains of symptoms somewhat resembling hay-fever—sneezing, headache, etc.—and, in addition, shows an erythematous erysipeloid eruption on the uncovered part of the body, and often also on the genital organs, which may become greatly œdematous. Desquamation follows.

According to other observers, the cause of this peculiar disease is to be found, not in the spores of *Ustilago*, but in an insect—*Aclerda berlesei*, discovered by Berlese—which often swarms on various reeds. The workers, in manipulating the canes, squash some of these insects, and the irritating juice exuding therefrom produces a dermatitis of an erythematous type.

CHAPTER XXXIX

FUNGI IMPERFECTI

Preliminary—Fungi imperfecti—Hyphales—Vuillemin's classification—Microsiphonales — Thallosporales — Hemisporales — Conidiosporales — References.

PRELIMINARY.

We now come to the last class of Schroeter's Eumycetes—viz., the Fungi Imperfecti; that is to say, Eumycetes with a septate mycelium and with spores which are not contained in asci or basidia, but are carried on conidiospores, which may or may not be enclosed in pycnidia.

This class contains a large number of genera of importance in tropical medicine, but everyone who has studied these fungi must have felt, as we have, the great difficulty of determining to what genus the organism belonged at which he was working.

Various systems have been proposed, such as the mode of bearing spores and the colour of the fungus, matters which change with environment. Further septation of the spores often depends upon their age and other factors. Similarly new species have been made for a fungus, very like another fungus, but found on a new host. In this way the classification has become almost hopeless.

Vuillemin has, however, proposed a new classification, which prevents the same fungus being variously classified in different stages of its life-history. We adopt it for purposes of utility.

CLASS: FUNGI IMPERFECTI Fuckel, 1869.

Synonym.—*Deuteromycetaceæ* Saccardo ('Sylloge,' vol. xvi., p. 825).

Definition.—Fungi, almost invariably minute, in which asexual reproduction takes place by means of conidia produced on conidiophores, which are either enclosed in perithecia, placed on discs, or unprotected.

Remarks.—Fuckel gathered together under the above name all forms of fungi, the complete life-history of which was unknown, and made this class in contradistinction to his other class of Fungi Perfecti. Vuillemin, in 1910, suggested dividing the class into two subclasses, Deuteromycetes and Hyphales.

Classification.—The Class Fungi Imperfecti may be subdivided into two classes as follows:—

A. Accessory fructifications present in the form of closed or open receptacles—Subclass 1, *Deuteromycetes* Saccardo, 1886, ***emendavit*** Vuillemin, 1910.

B. No such accessory fructifications present. Reproduction by means of spores, isolated or in groups, situate on isolated or fasciculated hyphæ—Subclass 2: *Hyphales* Vuillemin, 1910.

SUBCLASS 1: DEUTEROMYCETES SACCARDO, 1886, *emendavit* VUILLEMIN, 1910.

Definition.—Fungi Imperfecti possessing accessory fructifications in the form of open or closed receptacles.

A. Conidiophores minute and enclosed in a perithecium—Order 1, *Sphæropsidales* Léveillé, ***emendavit*** Saccardo, 1882.

B. Conidiophores not enclosed in a perithecium, but crowded on a disc arising from a deeply embedded mycelium—Order 2, ***Melanconiales*** Corda, 1842, ***emendavit*** Saccardo, 1882.

SUBCLASS 2: HYPHALES VUILLEMIN, 1910.

Synonyms.—*Nematomyci* Nees, 1816; *Hyphomyceteæ* Martius, 1817, *pro parte*; *Hyphomycetes* Fries, 1833; *Moniliales* Clements, 1909.

Definition.—Fungi Imperfecti with hyphæ more or less developed, lax, or more or less compact, superficial or subsuperficial, or more rarely, as in man, vertebrates, and insects, endoparasitic. Conidiophores never situate in closed or on open receptacles. Reproduction by means of spores isolated or in groups, situate on isolated or fasciculated hyphæ.

Remarks.—The Hyphales of Vuillemin correspond to the Hyphomycetes of Fries, but the subdivision into families is so entirely different that it appears better to adopt a change of name in order to prevent confusion.

Vuillemin's classification appears to us to be more suitable from the point of view of tropical medicine, and therefore we adopt it in this chapter; but, in order to permit comparison, we give the outlines of the old division of the Hyphomycetes, which is as follows:—

ORDER HYPHOMYCETES Fries, 1833.

A. Hyphomycetes with hyaline or brightly coloured hyphæ which do not cohere in fascicles and with concolorous conidia—Family 1, *Mucidinaceæ* Link, 1809.

B. Hyphomycetes with dark-coloured or black hyphæ rarely hyaline, and then with dark-coloured conidia. The hyphæ do not cohere into fascicles—Family 2, ***Dematiaceæ*** Fries, 1832.

C. Hyphomycetes with hyaline or dark-coloured hyphæ of which the sterile are scanty and creeping, while the fertile are erect, cohering into elongated fascicles bearing conidia at the top or more rarely along the side—Family 3, ***Stilbellaceæ*** Vuillemin, 1910.

D. Hyphomycetes with hyaline or dark-coloured hyphæ compacted into a globose, discoid, or verruciform body called a sporodochium—Family 4, ***Tuberculariaceæ*** Ehrenberg, 1818.

With reference to the name of Family 3, this has been changed from *Stilbaceæ* Fries, 1825, to its present name, because Juel has demonstrated that some of the species of the genus Stilbum belong to the Basidiomycetes, and has given the name Stilbella to those left in Fungi Imperfecti.

The basis of reference with regard to fungi must for all time be Saccardo's 'Sylloge Fungorum,' because it details some 60,000 species of fungi, and this is based upon the colour of the hyphæ and conidia and the number of septa in the spore, as will be indicated when detailing the hyphales. Clements has published a most useful key in English to Saccardo's 'Sylloge.'

Leaving this form of classification, we will consider Vuillemin's new system.

Vuillemin's Classification.—Vuillemin has pointed out a difficulty which we have also experienced in classifying the fungi of the Hyphomycetes—viz., one and the same fungus may, under different conditions, show a mucedine type, a stilbelline type, and a tubercularine type, which makes its recognition most difficult. To obviate this difficulty he has concentrated his attention upon the 'spore,' in order to form the orders of the class Hyphales. and has given definitions of his terms so as to prevent confusion.

Terminology.—The following terms require to be carefully studied: Thallospore, Blastospore, Arthrospore, Chlamydospore, Hemispore, Protoconidium, Deuteroconidium, Conidium, Aleuriospore, Sporophore, Phialide, and Prophialide.

I. The *Thallospore* is a sporiform element which is really only a portion of the thallus secondarily adapted to the purposes of reproduction. The various forms of the Thallospore are named Blastospores, Arthrospores, and Chlamydospores.

> A blastospore (Fig. 537) is a thallospore, round or ovoidal in shape, developed by budding from the summit or sides of a hypha which may be the same size and appearance as the blastospore, as in Cryptococcus, or may be an elongated filament.
>
> An arthrospore is a thallospore developed by the disarticulation of hyphal elements at first with square cut ends, which subsequently become rounded off, and with thin walls which subsequently become thickened. A Chlamydospore (Fig. 538) is merely a variation of an arthrospore, and may be defined as an intermediate or terminal spore larger than the ordinary hypha, which, without becoming isolated, undergoes a kind of encystment, with the formation of a thick and sometimes coloured wall containing cytoplasm loaded with food material.

II. The *Hemispore* (Figs. 539 and 540) starts by a differentiation from the thallus, the 'Protoconidium,' but this remains where formed while the hypha continues to grow. Eventually the protoconidium forms secondary functional spores called 'Deuteroconidia,' which are the reproductive spores.

III. The *Conidia* (sing. *Conidium*) are spores which differ from the thallus in being incapable of forming new spores or hyphæ while still attached to the parent mycelium. They show great variety of form, being rounded, stellate simple or septate (staurospore); needle-shaped, simple or septate (scolecospore); or spirally twisted, simple or septate (helicospore), and of structure being simple (amerospore) or divided by septa (didymospores with two cells and one transverse septum; phragmospores with two or more transverse septa and three or many cells; dictyospores in which there are longitudinal septa as well as transverse septa). The variation of colour is also of importance as a means of classification. The colouring matter usually occurs in the membrane.

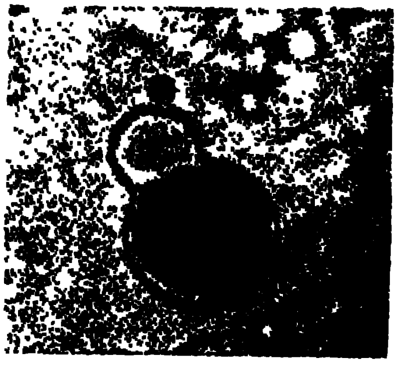

FIG. 537.—A BLASTOSPORE FROM *Cryptococcus myremeciæ* CHALMERS AND CHRISTOPHERSON.

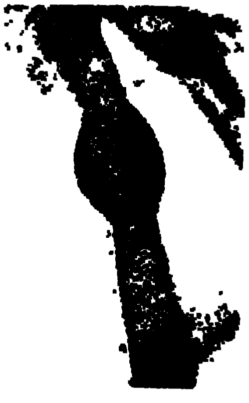

FIG. 538.—A CHLAMYDOSPORE FROM *Trichophyton currii* CHALMERS AND MARSHALL.

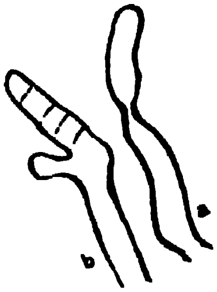

FIG. 539.—A HEMISPORE: DEVELOPMENT FROM *Hemispora stellata* VUILLEMIN.

(*a*) Protoconidia,
(*b*) Deuteroconidia.

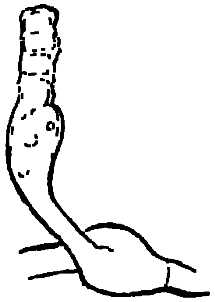

FIG. 540. A HEMISPORE FROM *Hemispora stellata* VUILLEMIN.

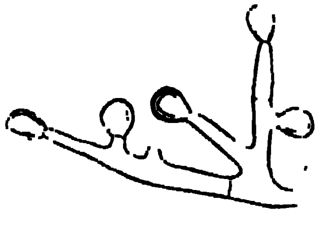

FIG. 541.—ALEURIOSPORES FROM *Aleurisma flavissimum* (LINK, 1816), EMENDAVIT CHEVALIER, 1836.

(After Vuillemin.)

Their number is also important, as they may be single, formed in basipetal chains which are more or less persistent, or they may be glued together into masses by agglutinating material.

The Conidia show two main types—viz., the Aleuriospore and the Conidium Verum.

An Aleuriospore (Fig. 541) is not a true conidium. It may be terminal, lateral, or intercalary, but in each case it is not originally distinct from the thallus, and is only set free by the death of the filament to which it is attached. It has the morphological significance of a chlamydospore.

FIG. 542.—SPOROPHORES AND CONIDIA FROM A CLADOSPORIUM.

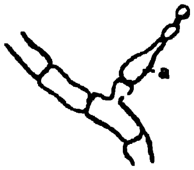

FIG. 543.—A PHIALIDE FROM *Spicaria aphodii* VUILLEMIN (*a*) PHIALIDE.

(After Vuillemin.)

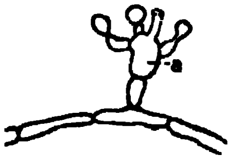

FIG. 544.—A PROPHIALIDE FROM *Urophial amycophiala* VUILLEMIN, 1910. (*a*) PROPHIALIDE.

(After Vuillemin.)

A Conidium Verum (Fig. 542) is quite distinct from the thallus, from which it is easily detachable. It may or may not be carried on a conidiophore, the varieties of which are as follows:—

A Sporophore (Fig. 542) is another name for a conidiophore—*i.e.*, for the hypha which carries the conidia.

A Phialide (Fig. 543) is a flask-shaped segment on the sporophore comparable to the sterigmata of the Basidiomycetes and interposed between the sporophore and the conidia.

A Prophialide (Fig. 544) is a special article on the sporophore from which phialides arise.

Having thus made clear Vuillemin's differentiation of the spores, it is possible to consider his classification of the Hyphales.

Classification.—Vuillemin divides the Hyphales as follows:—

A. Mycelium composed of fine bacilliform hyphæ in which the nuclei are usually indistinct—Order 1, *Microsiphonales* Vuillemin, 1912.

B. Mycelium not so composed:—
  1. Reproduction by thallospores—Order 2, *Thallosporales* Vuillemin, 1910.
  2. Reproduction by hemispores—Order 3, *Hemisporales* Vuillemin, 1910.
  3. Reproduction by conidia—Order 4, *Conidiosporales* Vuillemin, 1910.

ORDER I. MICROSIPHONALES Vuillemin, 1912.

Definition.—Hyphales with the mycelium composed of fine bacilliform hyphæ, usually 1 micron or less in diameter. Usually Gram-positive, when young, and without distinct nuclei. Parasitic on man, animals, and plants, or saprophytic.

Remarks.--This is a most interesting order, as its members (Fig. 545) are nearly always mistaken at first sight, by persons unaccustomed to them, for bacilli (Fig. 548). Hence the descriptions of bacilli as the cause of so many fungal diseases due to these organisms, among which could be classified the diphtheria organisms, the tubercular and leprotic bacilli.

Thus one form of division into families is as follows:—

A. **Nocardiaceæ** Castellani and Chalmers, 1918. **Synonyms.**—*Actinomycetes* Lachner-Sandoval, 1898; *Trichomycetes* Petrusky, 1903.
  Definition.- Microsiphonales with a mycelium.
  Type Genus.- -*Nocardia* Toni and Trevisan, 1889.

B. **Mycobacteriaceæ** Miehe, 1909. **Definition.**—Microsiphonales without a mycelium.
  GENUS 1.- -*Mycobacterium* Lehmann and Neumann, with the diphtheria bacillus as a type.
  GENUS 2.- -*Corynebacterium* Lehmann and Neumann, with the tubercle bacillus as a type.

We have, however, placed the *Mycobacteriaceæ* under the *Schizomycetes*, and therefore have only the *Nocardiaceæ* to consider.

FAMILY NOCARDIACEÆ.

Synonyms.—*Actinomycetes* Lachner-Sandoval, 1898; *Trichomycetes* Petrusky, 1903.

Definition.- -Microsiphonales with a mycelium.

Type Genus. *Nocardia* Toni and Trevisan, 1889.

Classification.- -Until quite recently all the species of this order were considered to belong to one genus- -*i.e.*, *Nocardia* Toni and Trevisan, 1889; but Pinoy has made an excellent subdivision, separating certain species into another genus, which he calls *Cohnistreptothrix* Pinoy, 1911. In doing this, he points out that the original discoverers of actinomycosis- -viz., Harz and Bollinger in 1877 and Rivolta in 1878- -thought that they were dealing with one organism, but when cultures were attempted it became apparent that more than one organism was implicated. Thus Bostrom isolated a parasite which grew well aerobically, producing a dry membrane on the surface of broth and capable of growth at 20° C. on gelatine, but growing better on potato at 37° C. and forming chains of arthrospores. Inoculation into animals was, however, negative. This form is commonly called *Nocardia bovis* (Harz, 1877).

Wolf and Israel, on the other hand, obtained a parasite which only grew anaerobically and was not capable of growth at ordinary European air temperatures. In broth it formed small granules or scales, which fell to the bottom of the tube. These cultures often contained club-like forms, and the branching filaments broke up into bacillary or coccal-like forms. Inoculations of gelatine cultures into the peritoneal cavities of guinea-pigs produced actinomycosis. This form is commonly called *Nocardia israeli* (Kruse, 1896). Wright maintains that this organism is the true cause of actinomycosis and that *N. bovis* is merely a contamination, but this cannot be accepted.

There are, therefore, two distinct organisms which can cause actinomycosis in man and oxen—viz., *N. bovis* (Harz 1877) and *N. israeli* (Kruse, 1896), but the difference between them is considerable; and therefore Pinoy has separated off the latter and its allies from the former and has founded the new genus *Cohnistreptothrix* Pinoy, 1911. The name is derived from the fact that in 1874 Cohn described a fungus in lachrymal concretions under the term *Streptothrix foersteri*, which was considered to be a Nocardia and is now one of the species of Pinoy's Cohnistreptothrix. These two genera are distinguished as follows:—

A. Grows aerobically, easy of cultivation, and producing arthrospores (Fig. 549)—Genus 1, *Nocardia* Toni and Trevisan, 1889.

B. Grows best anaerobically, but can often grow aerobically; difficult of culture, and not producing arthrospores—Genus 2, *Cohnistreptothrix* Pinoy, 1911.

Genus Nocardia Toni and Trevisan, 1889.

Synonyms.—*Actinomyces* Harz, 1877, *nec* Meyen, 1829; *Discomyces* Rivolta, 1878, *nec Discomycetaceæ* Fries, 1836; *Bacterium* Affanasieff, 1888, *nec* Ehrenberg, 1830, *emendavit* Cohn, Hüppe; *Streptothrix* Rossi-Doria, 1891, *nec* Cohn, 1875; *Oöspora* Sauvageau and Radais, 1892, *nec* Wallroth, 1833; *Cladothrix* Macé, 1897, *nec* Cohn, 1875.

Definition.—Nocardiaceæ growing aerobically, usually easy of culture, and producing arthrospores.

Type Species.—*Nocardia bovis* (Harz, 1877).

Nomenclature.—Bollinger's ray fungus (*Nocardia bovis*) belongs to a genus of which the correct name is *Nocardia* Toni and Trevisan, 1889, a term derived from Nocard, the celebrated French parasitologist, who was the first investigator to clearly recognize this fungus in France. We state that it is the correct name for the following reasons:—

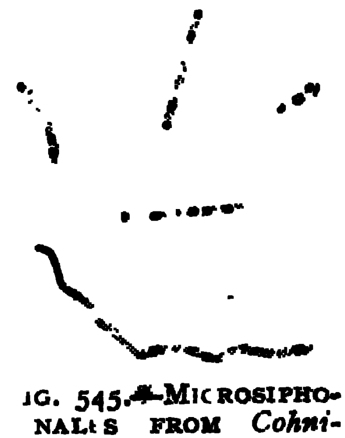

FIG. 545.—MICROSIPHONALES FROM *Cohnistreptothrix tenuis* CASTELLANI, 1911.

1. It is the oldest name, against which no objections can be raised.
2. It has been formally adopted by the Botanical Section of the First International Congress of Pathology.
3. The objections to the other names in use are as follows:—
    - (*a*) *Streptothrix*, as proposed by Rossi-Doria, cannot be used, as it was originally suggested by Corda in 1839 for *S. fusca*, which is quite a different fungus. It was also used in 1875 by Cohn for another organism closely allied to a 'Nocardia,' so that Cohn's and Rossi Doria's names can only be utilized as synonyms of the organisms to which they were wrongly applied because of the priority of Corda's name.
    - (*b*) *Discomyces* was used by Rivolta in 1878 merely as a trivial name, and though it has not been applied to any other genus, still the word *Discomycetaceæ* was introduced in 1836 by Fries for a large fungal family, and has come into general use, and therefore has the double claim of priority and general use; and as its type genus should bear the name *Discomyces*, confusion is bound to arise if the same term is retained as the generic name of Bollinger's organism.
    - (*c*) *Bacterium* was suggested by Affanasieff in 1888, but Ehrenberg had used this name in 1830 for the organisms popularly known as bacteria, and therefore Affanasieff's suggestion falls to the ground.
    - (*d*) *Oöspora*, as utilized by Sauvageau and Radais in 1892, is not available because it is younger than the name 'Nocardia,' and because it was previously used in 1833 by Wallroth for certain fungi previously classified as *Torula* Persoon, 1801.
    - (*e*) *Cladothrix*, as brought forward by Macé in 1897, cannot be used because the name 'Nocardia' has priority, and because it was originally used by Cohn in 1875 for the organism *Cladothrix dichotoma*, which is septate and is only falsely branched, and hence is quite different from Bollinger's fungus.

Remarks.—The genus *Nocardia* contains a large number of species which live saprophytically in soils, from whence their spores can be spread by the agency of air or water to sewage, sputum, etc. Some of them have acquired parasitic habits, living in plants in which they cause root tubercles, or, in other instances, tumours with ray fungi, thus somewhat resembling the actinomycosis of animals. They have also been found living in molluscs and in the alimentary canals of larval insects, as well as in the form of pathogenic fungi in reptilia, aves, and mammalia, in which they mostly occur in the

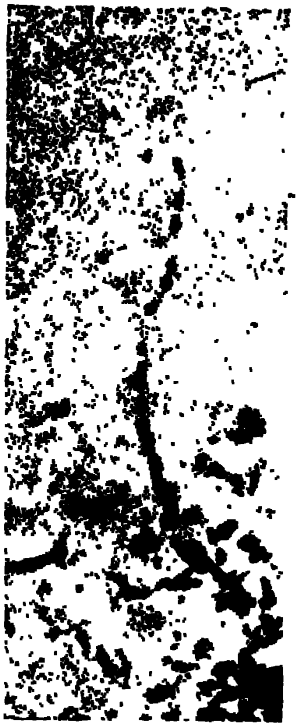

FIG. 546.—*Nocardia convoluta* CHALMERS AND CHRISTOPHERSON, 1916. HYPHA SHOWING BEADING AND ALSO COMMENCING SEPARATION INTO THREE PORTIONS. (× 1,500 DIAMETERS.)

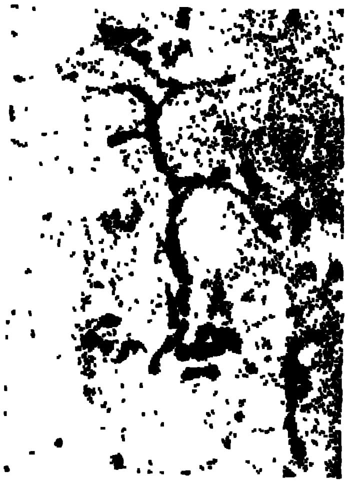

FIG. 547.—*Nocardia convoluta* TO SHOW BRANCHING.

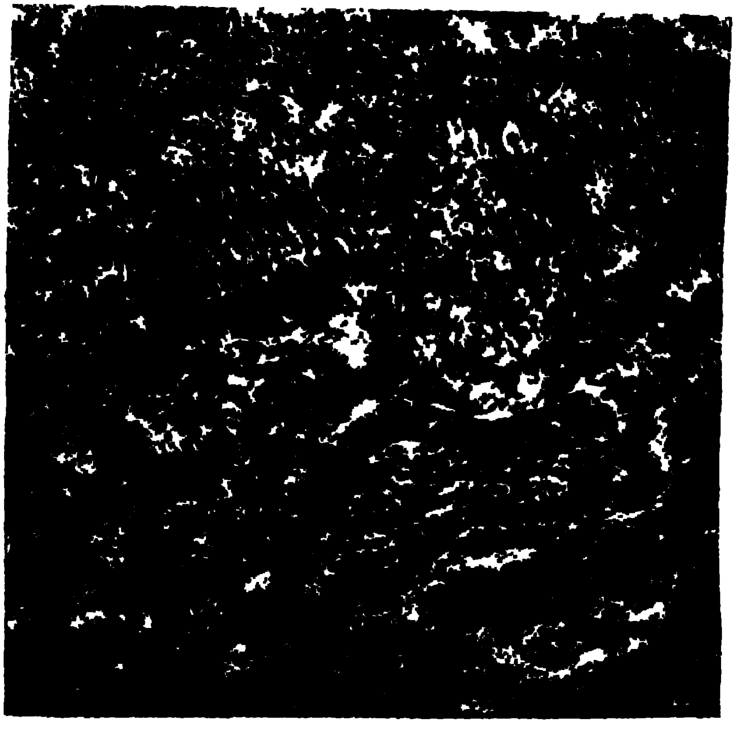

FIG. 548.—*Nocardia convoluta* IN SITU IN A GRAIN TO SHOW BACILLIFORM APPEARANCE.

herbivora or in omnivorous man, though they are known in the grass-eating dog, but are rare in other carnivora. Their geographical distribution appears to be world wide.

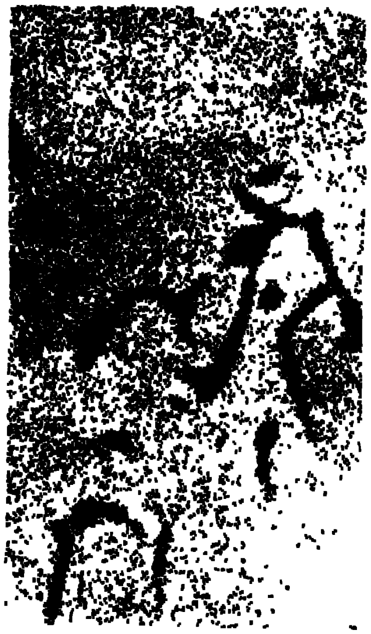

FIG. 549.—*Nocardia convoluta* TO SHOW ARTHROSPORES.

With reference to their method of entry into the human body, it appears to be often associated with some slight traumatism with some vegetal substance, such as a thorn, while the best treatment is undoubtedly complete removal wherever possible; still, partial extirpation, associated with treatment by iodide of potash, as first advocated for this purpose in 1885 by Tomassen, but in large doses such as 90 grains per diem, as used by Carroll with success in 1905, is sometimes also capable of effecting a cure.

Morphology.—Mycelial filaments of various sizes, but generally very thin (1 μ or less), often branching, non-septate, and without differentiated nuclei. In certain species during parasitic life some mycelial threads terminate in club-like formations and show a radial arrangement. It is doubtful whether these club-like formations are intrinsic parts of the fungus or partly products of reaction of the invaded tissues. Masses of mycelia may form in the

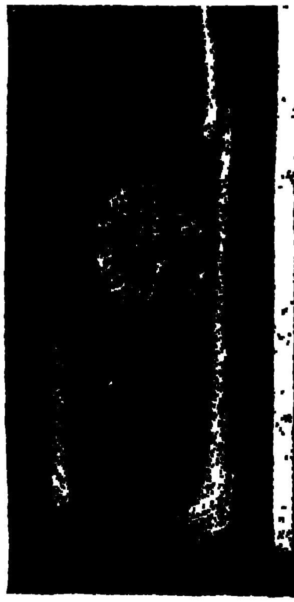

Fig. 550.

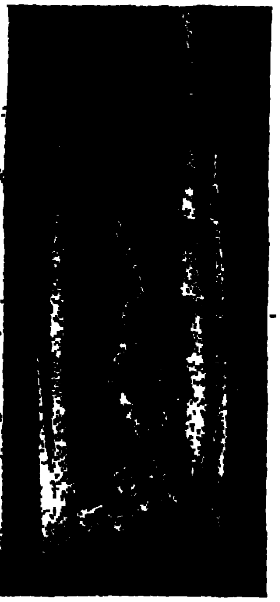

Fig. 551.

FIG. 550.—*Nocardia convoluta* TO SHOW EASY CULTURE AND LIMITED GROWTH ON SABOURAUD'S PRESERVATIVE MEDIUM.

FIG. 551.—*Nocardia convoluta* TO SHOW EASY CULTURE ON INSPISSATED BLOOD SERUM.

tissues peculiar grains (sclerotia) of various size, shape, colour, and consistency. Some species are facultative aerobes, others strictly anaerobic. All are Gram-positive, and several acid-fast. In cultures the mycelium very often undergoes fragmentation, and only bacillary and coccus-like bodies may be seen.

Classification.—The very large number of species in this genus can be classified as follows:—

A. Habitat, soil; can be found in air or water—Section 1, *Saprophytica* Foulerton, 1910.

B. Habitat, plants or animals—Section 2, *Parasitica* Foulerton, 1910.

C. Habitat, soils, plants, or animals, but imperfectly described —Section 3, *Incertæ sedis*.

Section 1: Saprophytica Foulerton, 1910.

This section can be divided into subsections as follows:—

SUBSECTION 1: *Majora*.	SUBSECTION 2: *Minora*.
1. Grow freely under artificial conditions at 22° C., and generally at 37° C., with a few exceptions.	1. Grow moderately under artificial conditions at 22° C. and 37° C.
2. Growth usually large and spreading.	2. Growth usually moderate and circumscribed.
3. Development of aerial hyphæ marked by a bright chalky efflorescence.	3. Development of aerial hyphæ marked by a dull dry powdery appearance.
4. Earthy or mouldy smell often present in the cultures.	4. Earthy or mouldy smell either faint or absent.
5. Generally peptonize gelatine and blood serum.	5. Rarely peptonize gelatine and blood serum.
6. Diastatic action often present.	6. Diastatic action usually absent.
7. Hyphal filaments usually coarser, and branching more marked than in next series.	7. Hyphal filaments usually finer, and branching rarer than in the preceding series.

SAPROPHYTICA SUBSECTION *Majora*.

This subsection contains the following species:—

1. *Nocardia saprophytica* (Foulerton, 1902):—
   Streptothrix leucea saprophytica Foulerton, 1902.
2. *Nocardia dichotoma* (Macé, 1888):—
   Cladothrix dichotoma Macé, 1888, *nec* Cohn, 1875.
   Streptothrix chromogena Gasperini, 1890.
   Streptothrix nigra Rossi-Doria, 1890.
   Oospora metschnikovi Sauvageau and Radais, 1892.
   Cladothrix brauner Hesse, 1892.
   Cladothrix odorifer Rullman, 1895, *nec C. odorifer* Rullman, 1898, parasitic in man.
   Streptothrix melanotica Price-Jones, 1900.
   Streptothrix humifica Beijernick, 1900.
   Streptothrix nigrescens Foulerton, 1902.

- *Actinomyces erythrochromogenes* Krainsky, 1914.
- *Actinomyces diastaticochromogenes* Krainsky, 1914.
- *Actinomyces viridochromogenes* Krainsky, 1914.
- *Actinomyces flavochromogenes* Krainsky, 1914.

3. *Nocardia violacea* (Rossi-Doria, 1891):—
   - *Streptothrix violacea* Rossi-Doria, 1891.
   - *Actinomyces violaceus* Berestneff, 1897.
   - ? *Actinomyces alni* Peklo, 1910.
   - ? *Actinomyces myricæ* Peklo, 1910.
4. *Nocardia beta* (Price-Jones, 1900):—
   - *Streptothrix beta* Price-Jones, 1900.
5. *Nocardia alba* (Rossi-Doria, 1891):—
   - *Streptothrix alba* Rossi-Doria, 1891.
   - *Actinomyces chromogenes* B Gasperini, 1890.
   - Streptothrix I., II., and III. Almquist.
   - *Actinomyces albus* Lehmann and Neumann.
   - *Oōspora guiguardi* Sauvageau and Radais, 1892.
   - *Actinomyces albus* Gasperini, 1890.
   - *Oōspora doriæ* Sauvageau and Radais, 1892.
   - *Streptothrix foersteri* Gasperini, 1890, *nec* Cohn.
   - *Streptothrix leucea* Foulerton, 1902.
   - *Streptothrix alpha* Price-Jones, 1900.
   - *Streptothrix pyogenes* Caminiti, 1907.
   - *Actinomyces grisea* Krainsky, 1914.
   - *Actinomyces diastatica* Krainsky, 1914.
   - *Actinomyces cellulosæ* Krainsky, 1914.
   - *Actinomyces nivea* Krainsky, 1914.
6. *Nocardia rosea* (Krainsky, 1914):—
   - *Actinomyces roseus* Krainsky, 1914.
7. *Nocardia citrea* (Krainsky, 1914):—
   - *Actinomyces griseoflavus* Krainsky, 1914.
   - *Actinomyces flavus* Krainsky, 1914.
   - *Streptothrix flava* Sanfelice, 1904.
   - *Streptothrix flava* Brins, 1899.
8. *Nocardia cinereonigra* (Berestneff, 1897):—
   - *Streptothrix cinereonigra aromatica* Berestneff, 1897.
9. *Nocardia orangica* (Berestneff, 1897):—
   - *Streptothrix orangica* Berestneff, 1897.
10. *Nocardia albida* (Rossi-Doria, 1891):—
    - *Streptothrix albido-flava* Rossi-Doria, 1891.
    - *Actinomyces farcinicus* Rossi-Doria, 1891.
    - *Nocardia farcinica* Rossi-Doria, 1891.
11. *Nocardia invulnerabilis* (Acosta and Grande Rossi, 1893):—
    - *Cladothrix invulnerabilis* Acosta and Grande Rossi, 1893.
12. *Nocardia rubea*, Chalmers and Christopherson, 1916.
    - *Actinomyces ruber* (no name).
    - *Nec Actinomyces ruber* Krainsky, 1914.

*Nec **Streptothrix rubra*** Casabó, 1894.
*Nec **Streptothrix rubra*** Kruse, 1896.

13. ***Nocardia cœlicolor*** (R. Müller, 1904):—
    Streptothrix cœlicolor R. Müller, 1904.
    Streptothrix cœlicolor Schurman, 1909.
14. ***Nocardia glauca*** (Lehmann and Schulze):—
    Actinomyces glaucus Lehmann and Schulze.
15. ***Nocardia thermophila*** (Gilbert, 1904):—
    Actinomyces thermophilus Gilbert, 1904.
    Cladothrix thermophilis Kedzior.
    Actinomyces thermophilus Berestneff, 1891.
16. ***Nocardia monospora*** (Schulze, 1908):—
    Actinomyces monosporus Schulze 1908.

These species may be recognized as given on p. 1048.

SUBSECTION *Minora*.

This subsection contains the following species:—

1. ***Nocardia pluricolor*** (Terni, 1894):—
    Streptothrix pluricolor Terni, 1894.
    Actinomyces gruberi Terni, 1894.
2. ***Nocardia carnea*** (Rossi-Doria, 1891):—
    Streptothrix carnea Rossi-Doria, 1891.
3. ***Nocardia aurantiaca*** (Rossi-Doria, 1891):—
    Streptothrix aurantiaca Rossi-Doria, 1891.
4. ***Nocardia melanosporea*** (Krainsky, 1914):—
    Actinomyces melanosporeus Krainsky, 1914.
5. ***Nocardia melanocycla*** (Krainsky, 1914):—
    Actinomyces melanocyclus Krainsky, 1914.
6. ***Nocardia albosporea*** (Krainsky, 1914):—
    Actinomyces albosporeus Krainsky, 1914.
7. ***Nocardia krainskii*** Chalmers, 1916.
    Actinomyces ruber Krainsky, 1914, ***nec*** Carabó, 1894, ***nec*** Kruse, 1896.
8. ***Nocardia parva*** (Krainsky, 1914):—
    Actinomyces parvus Krainsky, 1914.
9. ***Nocardia microparva*** (Krainsky, 1914):—
    Actinomyces microparvus Krainsky, 1914.
10. ***Nocardia chalcea*** (Foulerton, 1905):—
    Streptothrix chalcea Foulerton, 1905.
11. ***Nocardia erythrea*** (Foulerton, 1910):—
    Streptothrix erythrea Foulerton, 1910.
12. ***Nocardia hoffmanni*** (Gruber, 1891):—
    Micromyces hoffmanni Gruber, 1891.

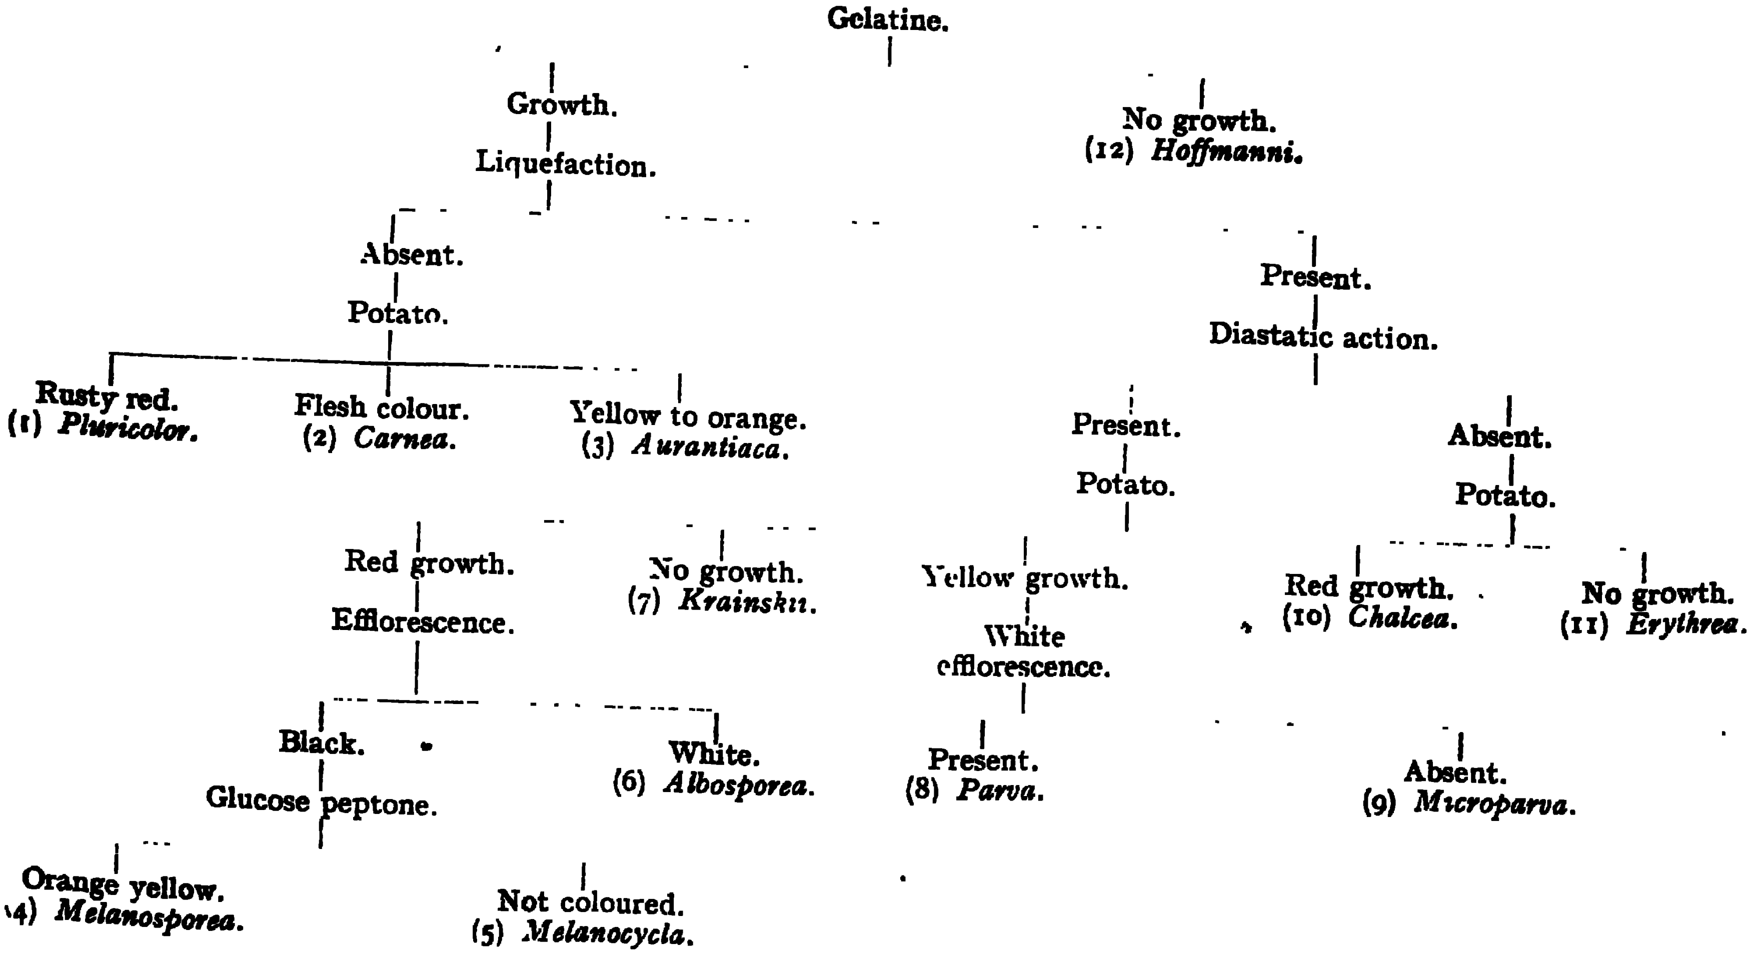
These species may be recognized as given on p. 1049.

DIAGNOSTIC TABLE OF THE SPECIES OF THE SECTION *SAPROPHYTICA*, SUBSECTION *MAJORA*.

Temperature Growth.

- Not at 37° C (1) ***Saprophytica.***
- At 22° C. and 37° C.
  - Gelatine liquefied.
    - Pigmentation.
      - Present.
        - Diastatic action.
          - Present. (2) ***Dichotoma.***
          - Absent.
            - Potato.
              - Violet. (3) ***Violacea.***
              - Buff. (4) *Beta.*
      - Absent.
        - Diastatic action.
          - Present.
            - Potato.
              - Grey to brown. (5) *Alba.*
              - Yellow.
                - Maltose agar.
                  - Rose. (6) ***Rosea.***
                  - Yellow. (7) ***Citrea.***
          - Absent.
            - Maltose agar.
              - Grey to yellow. (8) ***Cinereonigra.***
              - Transparent yellow.
                - No pigmentation of medium. (10) ***Albida.***
              - Orange red. (9) ***Orangica.***
          - Unknown.
            - Potato.
              - White.
                - Medium black. (11) ***Invulnerabilis.***
              - Red. (12) ***Rubea.***
              - Blue. (13) ***Cœlicolor.***
- Not below 35° C.
  - Spores.
    - In chains.
      - Coloration.
        - Green. (14) ***Glauca.***
        - White. (15) ***Thermophila.***
    - Single. (16) ***Monospora.***

DIAGNOSTIC TABLE OF THE SPECIES OF SECTION *SAPROPHYTICA*, SUBSECTION *MINORA*.



Section 2: Parasitica Foulerton, 1910.

The parasitic section can be classified into three subsections, as follows:—

No.	*Test.*	*Subsection* 1: *Majora.*	*Subsection* 2: *Minora.*	*Subsection* 3: *Brevis.*
1	Cultivation at 22° C. and 37° C.	Easy	Not difficult	Difficult at 37° C. Usually nil at 22° C.
2	Growth	Spreading	Circumscribed	Slight
3	Efflorescence	Bright chalky	Dull powdery	Usually absent
4	Hyphal branching	Well marked	Poorly marked	Rare, hypæ often bacilliform
5	Acid-fast species	Rare	Common	Rare
6	Odour of cultures	Earthy or mouldy	Absent or faintly as 1	Sometimes fæculent
7	Liquefaction of gelatine and blood serum	Often present	Rare, and usually only one liquefied	Often very slight indications
8	Potato	Growth	Usually growth	Often no growth
9	Diastatic action	Often present	Usually absent	Not known

SUBSECTION 1: *Majora*.

This subsection contains the following species:—

1. *Nocardia garteni* (Brumpt, 1910):—
   Cladothrix liquefaciens II. Garten, 1895.
   Discomyces garteni Brumpt, 1910.
2. *Nocardia liquefaciens* (Hesse, 1892):—
   Cladothrix liquefaciens Hesse, 1892.
   Streptothrix liquefaciens (Hesse, 1892).
   Streptothrix buccalis Goadby, 1903, *nec* Roger, Bory, and Sartory, 1909.
3. *Nocardia modoré* (Thiry, 1897):—
   Cladothrix modoré Thiry, 1897.
   Cladothrix polychromes Thiry, 1897.
   Actinomyces rubidaureus Lachner-Sandoval, 1898.
4. *Nocardia luteola* (Foulerton, 1910):—
   Streptothrix luteola Foulerton, 1910.
5. *Nocardia appendicis* Chalmers and Christopherson, 1916.
   Streptothrix hominis III. Foulerton, 1910.
   Streptothrix hominis IV. Foulerton, 1906.

6. ***Nocardia candida*** (Petruschky, 1898):—
 Streptothrix candida Petruschky, 1898.
 Streptothrix gedanensis II. Petruschky, 1898.
 Streptothrix lathridii Petruschky, 1898.

7. ***Nocardia bovis*** (Harz, 1877):—
 Actinomyces bovis Harz, 1877.
 Bacterium actino-cladothrix Affanasieff, 1888.
 Actinomyces hominis (Affanasieff, 1888).
 Nocardia actinomyces de Toni and Trevisan, 1889.
 Streptothrix actinomyces Rossi-Doria, 1891.
 Oöspora bovis Sauvageau and Radais, 1892.
 Actinomyces bovis sulphureus Gasperini, 1894.
 Cladothrix actinomyces Macé, 1897.
 Discomyces bovis Blanchard, 1900.
 Streptothrix hominis III. Foulerton, 1905, ***nec*** Foulerton, 1910.
 Streptothrix hominis IV. Foulerton, 1910, ***nec*** Foulerton, 1906.

8. *Nocardia graminarium* (Berestneff, 1891):—
 Streptothrix graminarium Berestneff, 1891.

9. *Nocardia rubra* (Carabò, 1894).
 Actinomyces rubra Carabò, 1894.
 Streptothrix rubra Kruse, 1896.
 Nec Actinomyces ruber Krainsky, 1914.

10. *Nocardia lingualis* (Weibel, 1888):—
 Vibrio lingualis Weibel, 1888.
 Spirosoma lingualis Migula, 1892.
 Streptothrix lingualis Bajardi, 1900.

11. *Nocardia odorifera* (Rullman, 1898):—
 Cladothrix odorifera Rullman, 1898, in sputum, not in air.

12. *Nocardia enteritidis* (Pottien, 1902):—
 Streptothrix enteritidis Pottien, 1902.

These species may be differentiated as given on p. 1052.

SUBSECTION 2: *Minora*.

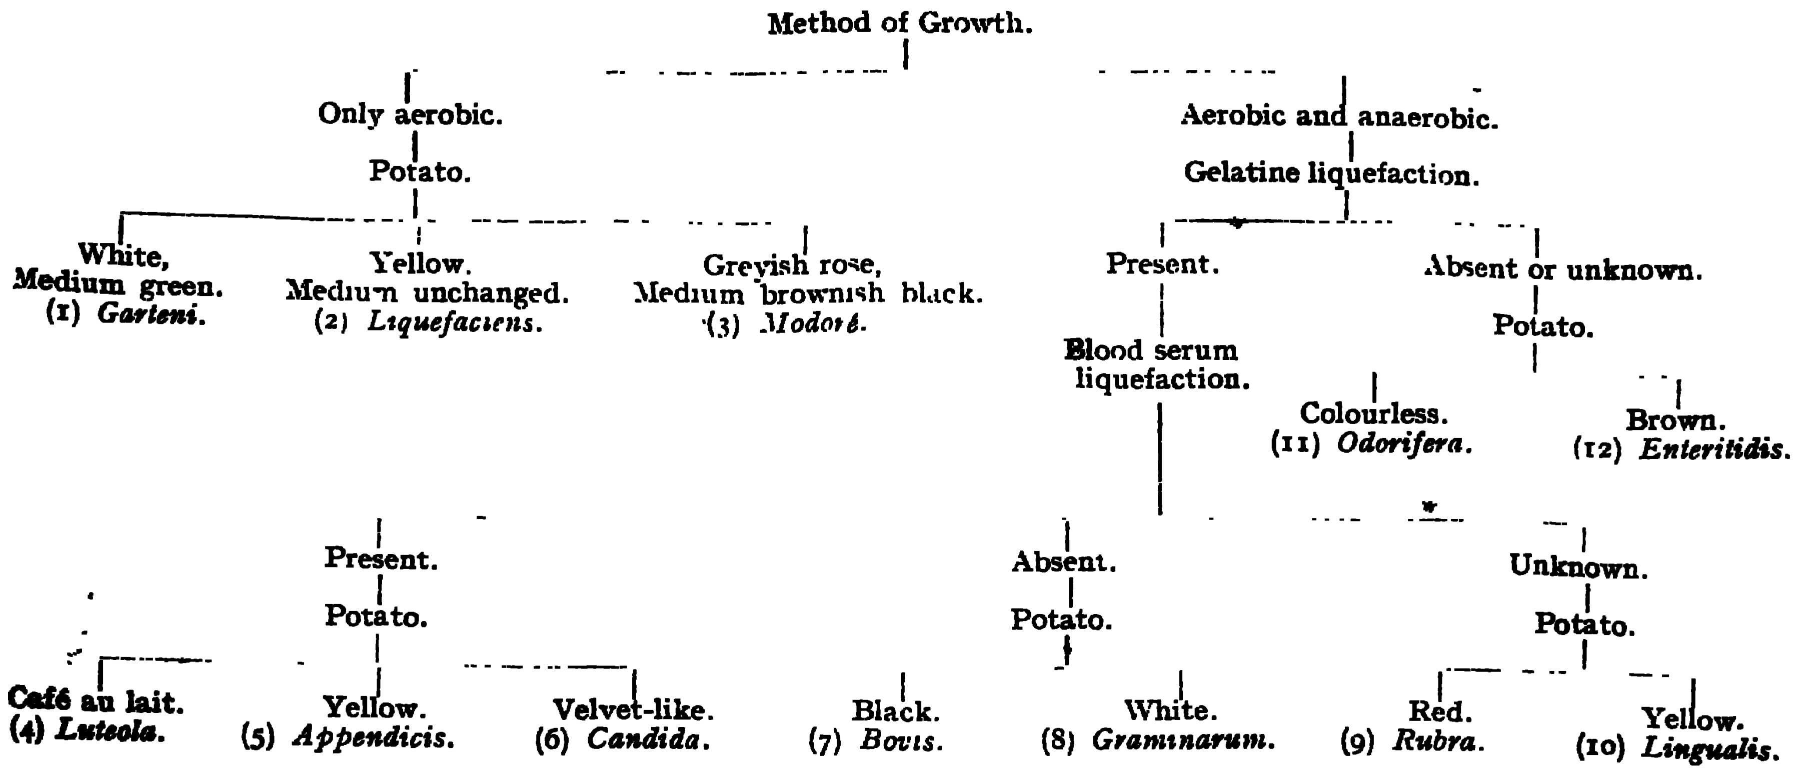
The species belonging to this section are:—

1. *Nocardia farcinica* Trevisan, 1889:—
 Bacillus du Farcin Nocard, 1888.
 Streptothrix farcinica Rossi-Doria, 1891.

2. ***Nocardia somaliensis*** (Brumpt, 1906):—
 Indiella somaliensis Brumpt, 1906.
 Indiellopsis somaliensis (Brumpt, 1913).
 Discomyces somaliensis Brumpt, 1913.

3. ***Nocardia indica*** (Kanthack, 1893):—
 Oöspora indica Kanthack, 1893.
 Streptothrix maduræ Vincent, 1894.
 Discomyces maduræ Vincent, 1895.

DIAGNOSTIC TABLE OF THE SPECIES OF THE SECTION *PARASITICA*, SUBSECTION *MAJORA*.



Method of Growth.
Only aerobic.
Potato.
White, Medium green. (1) *Garteni.*
Yellow. Medium unchanged. (2) *Liquefaciens.*
Greyish rose, Medium brownish black. (3) *Modoré.*
Present.
Potato.
Café au lait. (4) *Luteola.*
Yellow. (5) *Appendicis.*
Velvet-like. (6) *Candida.*
Black. (7) *Bovis.*
Aerobic and anaerobic.
Gelatine liquefaction.
Present.
Blood serum liquefaction.
Absent or unknown.
Potato.
Colourless. (11) *Odorifera.*
Brown. (12) *Enteritidis.*
Absent.
Potato.
White. (8) *Graminarum.*
Unknown.
Potato.
Red. (9) *Rubra.*
Yellow. (10) *Lingualis.*

Nocardia maduræ R. Blanchard, 1895.
Micrococcus pelletieri Laveran, 1906.
Oöspora pelletieri Thiroux and Pelletier, 1912.
Nocardia pelletieri Pinoy, 1912.
Nocardia rivierei Verdun, 1912 (?).

4. *Nocardia leishmani* Chalmers and Christopherson, 1916:—
New acid-fast streptothrix pathogenic to man and animals described by Birt and Leishman in 1902.

5. *Nocardia gedanensis* (Scheele and Petruschky, 1897):—
Streptothrix gedanensis I. Scheele and Petruschky, 1897.

6. *Nocardia convoluta* Chalmers and Christopherson, 1916.

7. *Nocardia minutissima* (Burchardt, 1859):—
Microsporum minutissimum Burchardt, 1859.
Trichothecium J. Neumann, 1868.
Microsporon gracile Balzer, 1883.
Sporotrichum minutissimum Saccardo, 1886.
Microsporoides minutissimus Neveu-Lemaire, 1908.
Discomyces minutissimus Brumpt, 1910.
Oöspora minutissima Ridet, 1911.
Nocardia minutissima Verdun, 1912.

8. *Nocardia rosenbachi* (Kruse, 1896):—
Streptothrix rosenbachi Kruse, 1896.

9. *Nocardia canis* (Rabe, 1888):—
Cladothrix canis Rabe, 1888.
Streptothrix capræ Silberschmidt, 1899.

10 *Nocardia asteroides* (Eppinger, 1890):—
Cladothrix asteroides Eppinger, 1890.
Streptothrix eppingeri Rossi-Doria, 1891.
Oöspora asteroides Sauvageau and Radais, 1892.
Nocardia asteroides R. Blanchard, 1895.
Streptothrix hominis Sabrazès and Rivière, 1895.
Actinomyces asteroides MacCallum, 1902.
Discomyces asteroides Brumpt, 1906.
Streptothrix freeri Musgrave and Clegg, 1907.
Discomyces brasiliensis Lindenberg, 1909.
The organisms described by Ferré and Faguet, by MacCallum, by Schabad, probably belong to this species.

11. *Nocardia hominis* (Berestneff, 1897):—
Nec Actinomyces hominis Bostroem, synonym of *N. bovis*.
Nec Actinomyces hominis Affanasieff=*N. bovis*.
Nec Actinomyces hominis Wolff and Israel=*N. israeli*.
Nec Streptothrix hominis Sabrazès and Rivière=*N asteroides*.
Nec Streptothrix hominis Hayo Bruns, 1899.
Nec Streptothrix hominis Foulerton, 1902.
Nec Streptothrix hominis II. Foulerton, 1910.

   Nec Streptothrix hominis III. Foulerton, 1905=*N. bovis*.
   Nec Streptothrix hominis IV. Foulerton, 1910=*N. bovis*.
   Nec Streptothrix hominis III. Foulerton, 1910.

12. *Nocardia nigra* (Castellani, 1913).
    Synonym, *Streptothrix nigra* Castellani, 1913.
13. *Nocardia pijperi* Castellani and Chalmers, 1918.

As there is so much confusion with regard to the specific name *hominis*, Chalmers and Christopherson proposed that—

S. hominis Bruns be changed to *Nocardia bruni*.
S. hominis Foulerton be changed to *Nocardia foulertoni*.
S. hominis II. Foulerton be changed to *Nocardia londinensis*.
S. hominis III. Foulerton be changed to *Nocardia appendicis*.

These species may be separated as given on p. 1055.

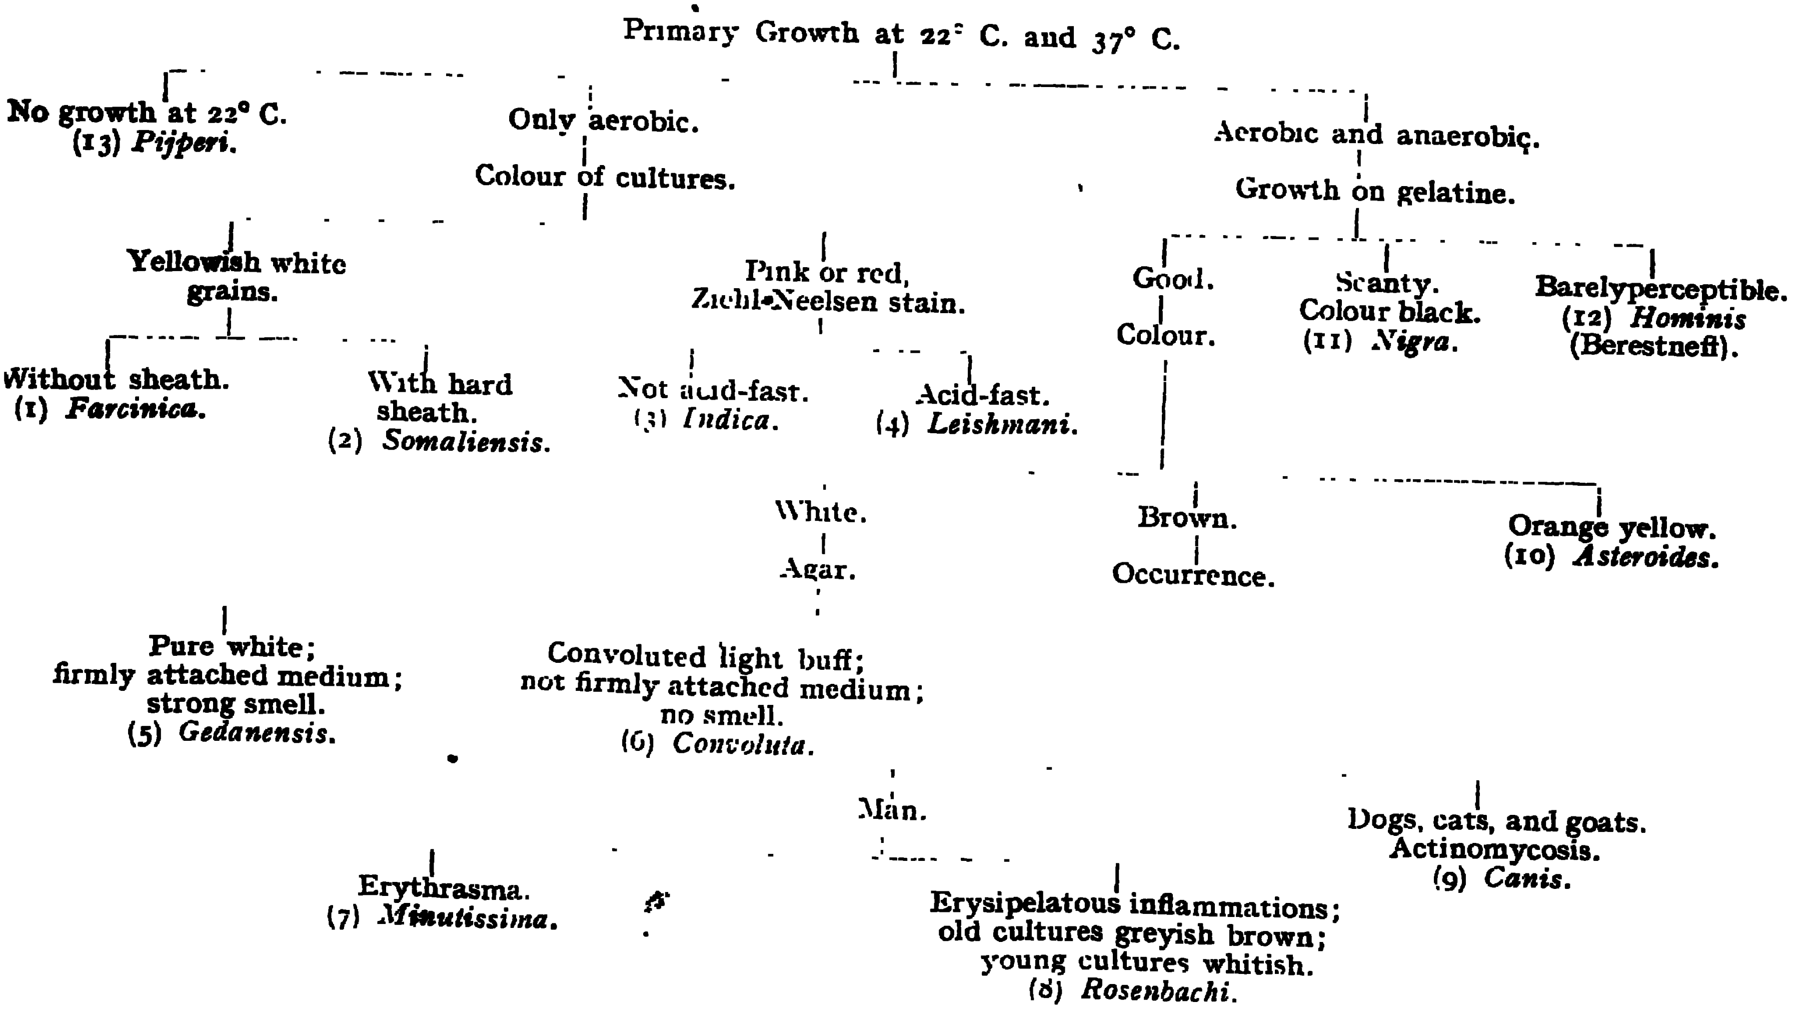
SUBSECTION 3: *Brevis*.

This subsection contains:-

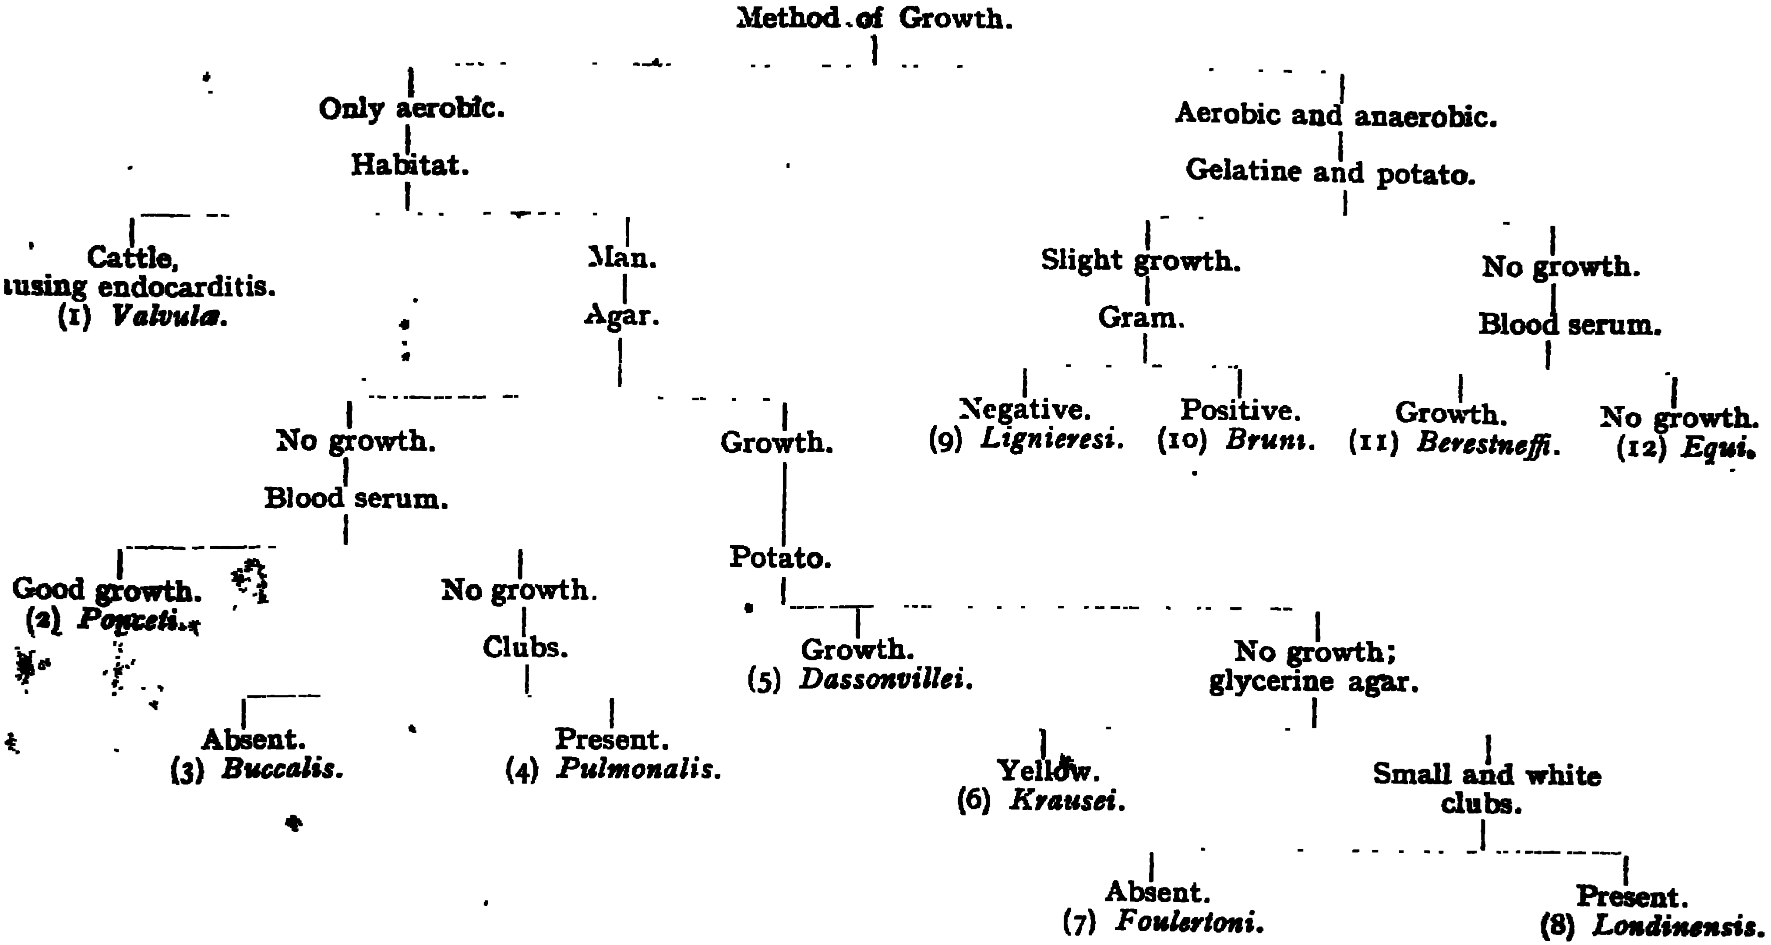
1. *Nocardia valvulæ* (Luginger, 1904):—
   Streptothrix valvulæ destruens bovis Luginger, 1904.
2. *Nocardia ponceti* Verdun, 1912.
3. *Nocardia buccalis* (Roger, Bory, and Sartory, 1909):—
   Oöspora buccalis Roger, Bory, and Sartory, 1909.
   Nec Streptothrix buccalis Goadby, 1903.
4. *Nocardia pulmonalis* (Roger, Bory, and Sartory, 1909):—
   Oöspora pulmonalis Roger, Bory, and Sartory, 1909.
5. *Nocardia dassonvillei* Brocq Rousseu, 1907:—
   Gasperini's Streptothrix, 1890.
6. *Nocardi krausei* (Chester, 1901):-
   Streptothrix krausei Chester, 1901.
7. *Nocardia foulertoni* Chalmers and Christopherson, 1916:—
   Streptothrix hominis Foulerton, 1902.
   Streptothrix hominis I. Foulerton, 1906.
8. *Nocardia londinensis*, new name:—
   Streptothrix hominis II. Foulerton, 1906.
9. *Nocardia lignieresi* (Brumpt, 1910):—
   Actinobacillus lignieresi Brumpt, 1910.
10. *Nocardia bruni* Chalmers and Christopherson, 1916:—
    Streptothrix hominis Hayo Bruns, 1899.
11. *Nocardia berestneffi*, new name:—
    Streptothrix cases 1 and 2 Berestneff, 1897.
12. *Nocardia equi* (Dean, 1900):—
    Streptothrix from a horse of Dean, 1900.
    Probably the organism described by Norris and Larkin should come here, but we have been unable to see a description.

These species may be differentiated as given on p. 1056.

DIAGNOSTIC TABLE OF THE SPECIES OF SECTION *PARASITICA*, SUBSECTION *MINORA*.



DIAGNOSTIC TABLE OF THE SPECIES OF THE SECTION *PARASITICA*, SUBSECTION *BREVIS*.



Section 8: Incertæ Sedis.

In this list we have included the forms concerning which we have been unable to obtain full information, and have, therefore, been unable to classify according to the above tables:—

1. *Actinomyces lacertæ* Terni, 1891.
2. *Streptothrix pseudotuberculosa* Flexner, 1898.
3. Streptothrix of Bonvicini, 1899.
4. *Streptothrix polychromogenes* Vallée, 1900.
5. *Actinomyces bicolor* Trollender, 1903.
6. *Nocardia liguire* Urizer, 1904.
7. *Actinomyces verrucosus* Adler, 1904.
8. *Nocardia lasserei* Verdun, 1912.
9. *Nocardia decussata* Langeron and Chevalier, 1912.
10. *Actinomyces musculorum suis* Duncker.
11. *Actinomyces pseudotuberculosis* Hamm and Keller.
12. *Discomyces holmesi* mentioned by Goedelst.
13. *Streptothrix gelatinosa*
14. *Streptothrix aquatilis*
15. *Streptothrix lehmann*
16. *Streptothrix chondri* Olsen, 1897 } mentioned by Peklo.
17. *Nocardia urinaria* Pijper, 1918.

Nocardia bovis Harz, 1877.

Synonyms.—*Actinomyces bovis* Harz, 1877; *Discomyces bovis* Rivolta, 1877; *Bacterium actino-cladothrix* Affanasieff, 1888; *Nocardia actinomyces* Toni and Trevisan, 1889; *Streptothrix actinomyces* Rossi-Doria, 1891; *Oöspora bovis* Sauvageau and Radais, 1892; *Actinomyces bovis sulphureus* Gasperini, 1894; *Nocardia bovis* R. Blanchard, 1895; *Actinomyces bovis sulphureus*, Gasperini, 1894; *Cladothrix actinomyces* Macé, 1897; *Discomyces bovis* R. Blanchard, 1900; *Streptothrix spitzi* Lignières and Spitz, 1903; *Nocardia bovis* Vuillemin, 1912.

This *Nocardia* is the cause of some cases of human and bovine actinomycosis, and of the actinomycotic mycetoma. The fungus lives parasitically in most tissues, in which it gives rise to degenerative and purulent changes. In the pus small, soft yellow granules—so-called 'sulphur grains'—are seen. These sulphur grains consist of masses of mycelium. At the periphery of the granule the threads are radially arranged, and their free extremities become club-like, 10 to 20 μ in length and 8 to 10 μ in breadth. These peculiar club-like formations have been considered by some authorities to be degeneration forms of the fungus, but Brumpt has demonstrated that they are young active forms, and disappear in old granules. Other writers consider that these club-like formations do not form an intrinsic part of the fungus, but are due to reactive changes in the tissues.

Cultures.—The fungus grows easily on agar, glycerinated agar, gelatine, broth, potato, and other media. Optimum temperature, 35° to 37° C. On glycerinated agar the fungus grows fairly rapidly, giving rise to small, dry, coarsely granular, brown-yellowish colonies, which latter coalesce together. The fungus is Gram-positive, but not acid-fast.

Saprophytic Life.—The fungus is found saprophytic on the spikelets of some cereals (*Phleum pratense* Linnæus, *Hordeum miurnum* Linnæus, etc.).

Pathogenicity.—The experimental reproduction of the disease by inoculating pure cultures has not so far succeeded. Wright therefore goes so far as to say that *Actinomyces bovis* is a contamination.

Varieties.—Gasperini describes three varieties: *N. bovis sulphurea, N. bovis sulphurea-alba, N. bovis luteo-rosea.* Caminiti has described a variety which he thinks may be a new species. *N. lanfranchii* Luigi Sani is also a variety of this Nocardia.

Nocardia rosenbachi Kruse, 1896.

Synonym.—*Streptothrix rosenbachi* Kruse, 1896.

Isolated by Rosenbach in a case of dermatitis, called by him 'erysipeloid.' Mycelial threads very slender; some terminate in club-like swellings. Can be cultivated on the usual laboratory media. Does not liquefy gelatine.

Nocardia asteroides Eppinger, 1890.

Synonyms.—*Cladothrix asteroides* Eppinger, 1890; *Streptothrix eppingeri* Rossi-Doria; 1891; *Oöspora asteroides* Sauvageau and Radais, 1892; *Nocardia asteroides* R. Blanchard, 1895; *Discomyces freeri* Musgrave and Clegg, 1907; *N. brasiliensis* Lindenberg, 1909.

Found in mycetoma and in cases of abscess of the brain. Mycelial threads very slender (0·2 μ wide); the mycelial articles become easily dissociated, when they look bacillus-like. This fungus is acid-fast and is very similar to *Bacillus tuberculosis*, but grows much more quickly on ordinary media: obligative aerobe. Inoculations in the rabbit and guinea-pig produce a form of pseudo-tuberculosis histologically indistinguishable from true tuberculosis.

McCallum has found a *Nocardia* very similar to *N. asteroides* in a case of peritonitis.

Nocardia indica Kanthack, 1893.

Synonyms.—*Streptothrix maduræ* H. Vincent, 1894; *Nocardia maduræ* R. Blanchard, 1895; *Micrococcus pelletieri* Laveran, 1906; *Oöspora pelletieri* Thiroux and Pelletier, 1912; *Nocardia pelletieri* Pinoy, 1912.

It causes Vincent's white mycetoma, very commonly found in Africa and Asia. The 'grains' which are found in the pus of such cases are soft, white, or slightly yellowish, and have a *mulberry-like* surface. At the periphery of the grains radiating filaments are found, but claviform swellings are usually absent; mycelial threads are always very slender (1 to 1½ μ). The fungus can be grown on the ordinary media: facultative aerobe. On glycerinated agar it forms discoid colonies, white in the centre and reddish at the periphery. In the cultures the mycelial threads are as slender as in the grains. Some of the mycelial threads have at their extremities short chains of small conidial elements. Gram-positive, but not acid-fast.

It is to be noted that this fungus very rarely produces bone lesions. Most strains are inoculable into monkeys.

Nocardia dassonvillei Brocq-Rousseu, 1907.

Synonym.—*Streptothrix foersteri* (Gasperini, 1890).

Very thin ramified, mycelial threads, which easily become fragmented and dissociated into bacillary-like bodies. Numerous spherical coccus-like bodies (spores) present. Gram-positive. The fungus grows fairly well on gelatine, giving rise to small white, roundish colonies. This fungus has been found by Landrieu and Liégard in a case of conjunctivitis in an old lady who powdered her face extensively several times daily with rice-powder. The authors suggest that the fungus may have been present in the rice-powder, as the same fungus is known to be found in several decaying cereals.

Gasperini isolated in 1890 from the air a *Nocardia* which he identified as *N. foersteri*. Further researches (Landrieu) have shown Gasperini's fungus to be *N. dassonvillei*.

Nocardia decussata Langeron and Chevalier, 1912.

Synonym.—*Discomyces decussatus* Langeron and Chevalier, 1912.

Found by Langeron and Chevalier in a patient presenting peculiar whitish, dry, squamous patches. The fungus grows on ordinary media extremely slowly. Colonies milk-white, the central portion of which is slightly elevated and flattened, but has a minute nodule in the middle; very often four furrows, forming a cross, are seen. The mycelial threads are thin, non-septate, and are easily dissociated into roundish bodies, 1 to 1·5 μ in diameter.

The pathogenic rôle of this fungus is doubtful.

Nocardia pulmonalis H. Roger, Bory, and Sartory, 1909.

In the parasitic stage may appear in the shape of bacillary-like bodies, about 0·5 μ in diameter. In cultures (maltose broth) thin mycelial filaments, 0·5 μ in diameter, are present, some branching, some terminating in club-like formations. Some mycelial threads are very fragile, and become fragmented into strings of bacillary or coccus-like bodies.

Pathogenicity.—Causes a type of pseudo-tuberculosis. In the expectoration occasionally small white granules, composed of masses of the fungus, are present. Sartory has found the fungus in a case of otitis

Nocardia pijperi Castellani and Chalmers, 1919.

Discovered and described by Pijper in a case of chronic bronchitis in South Africa. The fungus is non-motile, Gram-positive, not acid-fast. It grows on agar, giving rise to small whitish colonies, becoming visible after forty-eight to seventy-two hours. The colonies increase in size, slowly becoming hard like cartilage, and very adherent to the medium. The surface is crinkled. The fungus does not grow on gelatine nor on Sabouraud's maltose agar. Broth remains clear, growth taking place at the bottom.

The fungus can be grown also anaerobically. It is pathogenic to guinea-pigs by intraperitoneal injection. Nodules develop on the peritoneum, consisting of an outer wall of epithelioid cells and leucocytes surrounding a cavity filled with fluid, in which asteroid colonies of the fungus are found.

Nocardia candida Petruschky, 1901.

Found in sputum.

Nocardia aurea Du Bois St.-Sévérin, 1902.

Found in a case of ulcerative conjunctivitis.

Nocardia odorifera Rullman and Perutz, 1898.

Found by Rullmann in a case of chronic bronchitis. Merely a synonym of *N. chromogena* Gasperini.

Nocardia liquefaciens Hesse, 1892.

Synonym.—*Cladothrix liquefaciens* Hesse, 1892.

Gives rise to white colonies on *gelatine*, and later liquefies the medium. Was isolated from a case of actinomycosis. Liquefies serum.

Nocardia ponceti Verdun, 1912.

Not cultivable on agar or gelatine. Grows well on serum, where it takes a bacillary-like form. Found by Moorhof, Dor, and Poncet in a case of myomycosis resembling actinomycosis.

Nocardia fusca Karwacki, 1911.

Isolated by Karwacki from the sputum of a tubercular patient. Dark yellowish colour.

Nocardia luteola Foulerton and Jones.

Found in a case of purulent conjunctivitis.

Nocardia carnea Rossi-Doria, 1891.

Isolated by Baldoni from a case of chronic bronchitis. Red colonies.

Nocardia garteni Brumpt, 1910.

Synonyms.—*Cladothrix liquefaciens* No. 2 Garten, 1895; *Discomyces garteni* Brumpt, 1910.

Liquefies gelatine. On potatoes gives rise to white colonies, while the medium takes a greenish colour. Was isolated from a case of actinomycosis.

Nocardia enteritidis Pottien, 1902.

Found in cases of enteritis by Pottien.

Nocardia buccalis H. Roger, Bory, and Sartory, 1909.

Synonyms.—*Oöspora buccalis* H. Roger, Bory, and Sartory, 1909; *Discomyces buccalis* Brumpt, 1910.

Thin mycelial filaments (0·7 to 0·8 μ). Some ramified mycelial threads are very fragile, becoming fragmented into strings of bacillary-like or coccus-like bodies. Can be cultivated.

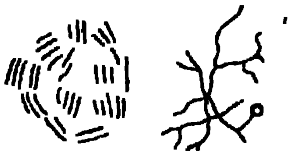


FIG. 552. - *Nocardia pulmonalis* H. ROGER, BORY, AND SARTORY.

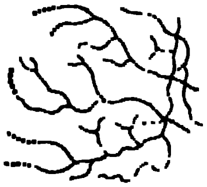

FIG. 553.—*Nocardia buccalis* ROGER, BORY, AND SARTORY.

(After Roger and Sartory.)

Pathogenicity.—May give rise to a form of stomatitis somewhat resembling thrush. It has been found also in tonsillar abscesses.

Nocardia lasserrei Verdun, 1912.

Synonym.—*Nocardia* sp. (?) Lassere, 1904.

Found by Lasserre in 1904 in an ulcerative lesion situated on the pharynx and upper lip. Mycelial filaments very thin (0·5 to 0·75 μ); fragile, club-like formations present. Can be cultivated. Pathogenic to rabbits and guinea-pigs, but only by intracerebral injection.

Nocardia lingualis Guéguen, 1908.

Synonyms.—*Oöspora lingualis* Guéguen, 1908; *Discomyces lingualis* (Brumpt, 1910).

In the parasitic stage the fungus appears in the shape of bacillary bodies, less than 0·3 μ in diameter. In cultures it shows a mycelial type with very thin filaments. It is probably non-pathogenic; it has been found in cases of lingua nigra in association with *Cryptococcus linguæ pilosæ*.

Nocardia rivierei Verdun, 1912.

Isolated by Rivière (1895) in a case of multiple abscesses. Is cultivable on ordinary media.

Nocardia appendicis Chalmers and Christopherson, 1916.

Synonyms.—*Streptothrix hominis* Foulerton, 1906; *Oöspora hominis* Ridet, 1911.

Discovered by Foulerton in a case of multiple abscesses; was present also in the expectoration of the same patient. Foulerton has found similar fungi (*N. hominis III.*) in cases of appendicitis.

Nocardia minutissima Burchardt, 1869.

Synonyms.—*Microsporum minutissimum* Burchardt, 1869; *M. gracile* Balzer, 1883; *Sporotrichum minutissimum* Saccardo, 1896; *Discomyces minutissimus* P. Verdun, 1907; *Microsporoides minutissimus* Neveu-Lemaire, 1906; *Oöspora minutissima* Ridet, 1911.

Mycelial threads extremely thin (0·6 μ); seldom ramified. The mycelial segments get easily dissociated, and have then the appearance of bacilli. Is the cause of erythrasma. Michele, Ducrey, and Reale claim to have cultivated it.

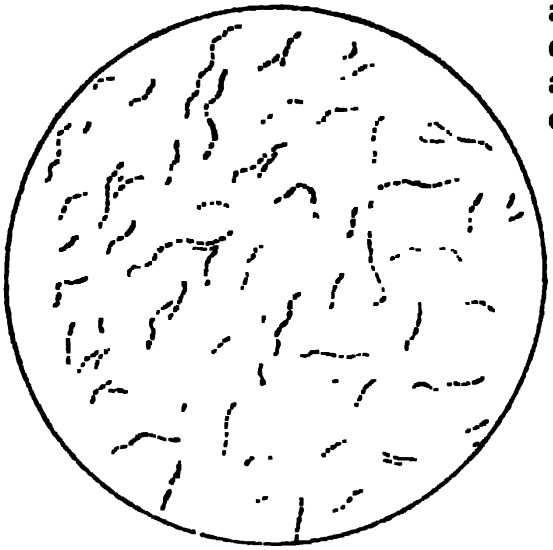

FIG. 554.—*Nocardia minutissima* BURCHARDT.

FIG. 555.—*Cohnistreptothrix tenuis* CASTELLANI.

Nocardia convoluta Chalmers and Christopherson, 1916.

NOCARDIA.—Gram-positive, but not acid-fast, without club formations; found parasitic in man; easy of cultivation, growing aerobically and anaerobically at 22° C. and 37° C., with a marked preference for alkaline media, and with the production of good but limited growths on the different agars, and the same at first on blood serum and potato, on which, however, it becomes more profuse later. Not liquefying gelatine, but causing liquefaction of inspissated ox-blood serum, without diastatic action. Colonies usually somewhat translucent when young, of a light to warm buff colour (Ridgway's Plate XV., 17, O-Y, f or d), and either convoluted or having the appearance of a jelly turned out of a mould, later developing a whitish powdery efflorescence, without distinct odour, never pigmenting the medium on which it is grown; not fermenting or peptonizing milk. Non-pathogenic for monkeys and other laboratory animals.

Remarks.—It is fairly frequently found in the actinomycotic type of Madura foot in Khartoum, Anglo-Egyptian Sudan.

Nocardia nigra Castellani, 1913.

Nocardia, Gram-positive, some strains acid-fast, no definite club formations. Grows aerobically and anaerobically at 22° C. and 35° C. Colonies on maltose agar and ordinary agar are black. Most strains liquefy gelatine.

Nocardia lutea was found by Christopherson and Archibald in 1918 in the lachrymal canal of a case in Khartoum.

Genus Cohnistreptothrix Pinoy, 1911.

Definition.—Nocardiaceæ growing best anaerobically, but can grow aerobically; usually difficult to cultivate and do not produce arthrospores.

Type Species.—*Cohnistreptothrix israeli* (Kruse, 1896).

Historical.—In 1891 Wolff and Israel published a beautifully illustrated account of a streptothrix, which they had isolated from two cases of actinomycosis in man—viz., from the lungs and from a retromaxillary growth. This organism was considered to differ from *N. bovis* in that it grew best anaerobically, that branching was absent, and that its injections into animals were regularly positive in their result. These three characteristics induced Kruse, in 1896, to make a new species for it under the name *Streptothrix israeli*. In 1911, for reasons already set forth, Pinoy founded a new genus, *Cohnistreptothrix*, with Israel's organism as the type species, and therefore its name becomes *Cohnistreptothrix israeli* (Kruse, 1896).

It appears to us to be of importance to give a brief history of the species.

Lachrymal concretions have been known since Césoin described them in 1670. In 1848, Gruby, examining one of these objects, found it to be composed of a fungus, which he believed to be the same as that causing favus, but Cohn, in 1875, examining another such concretion, also saw a fungus, for which he created a new genus streptothrix, calling the fungus in question *Streptothrix foersteri* Cohn, 1875, which may be the same organism as *S. aureus* Du Bois de Saint Sévérin, 1895, and must be closely related to *Nocardia tenuis* Castellani, 1911, which belongs to the same genus, and as its colonies on agar are 'cerebriform' it may possibly be the same as, or related to, *Streptothrix radiatus* and *S. cerebriformis* (both described from cases of keratitis by Namyslowski in 1909), as well as the more aerobic hyphal form of Silberschmidt's organism.

Unfortunately, a mistake was made, for Cohn was not aware that the name Streptothrix had already been given by Corda, in 1839, for another and quite different fungus, which is known as *Streptothrix fusca* Corda, 1839, and is to be found in all works of any importance on systemic mycology Therefore, as streptothrix is not available, after many changes, the generic name has become *Cohnistreptothrix* Pinoy, 1911, and to this genus Israel's human organism belongs. It differs from Bollinger's type of fungus in growing best anaerobically, in being difficult to cultivate, and in not producing arthrospores. Other allied organisms are *Cohnistreptothrix thibiergei* (Ravaut and Pinoy, 1909), also found in actinomycosis in man; *Streptothrix spitzi* Lignières, 1903, found in cattle, is probably identical with *C. israeli*, as may be Doyen's streptothrix; while *Nocardia carougeaui* Gougerot, 1909, in juxta-articular nodules, and *Streptothrix cuniculi* Schmorl, 1891, probably also belong to this genus, as well as the streptothrix recently discovered in a liver abscess in America by Bloomfield and Bayne-Jones (1915). Perhaps the bacillus described by Sawtschenko, in 1896, as the causal agent of a pseudo-mycetomatous condition may also belong to this genus, and it is also possible that the *Coccobacillus pseudo-actinomycosis polymorphus* Berestneff, 1898, may be the same as the chromogenic anaerobic streptothrix obtained from human pus by Neschezadimenko in 1908.

Classification.—The species included in this genus are:—

1. *Cohnistreptothrix silberschmidti* Chalmers and Christopherson, 1916:—

   This name is given to distinguish the obligatory anaerobic streptothrix found by Silberschmidt, in 1900, in dacryocystitis, and described in the *Centralblatt für Bakteriologie*, xxvii., and further cases in *Zeitschrift für Hygiene* (1901), xxxvii.

2. *Cohnistreptothrix cuniculi* (Schmorl, 1891):—
   Streptothrix cuniculi Schmorl, 1891.
   Actinomyces cuniculi Gasperini, 1894.
   Streptothrix necrophora Kitt, 1906.
   ? *Bacillus necroseos* Salmonsen.
   ? Necrosis bacillus of Bang.
   ? *Bacillus diphtheriæ vitulorum* Flügge.
   ? *Bacillus necrophorus* Flügge.

3. *Cohnistreptothrix neschezadimenki* Chalmers and Christopherson, 1916:—
   This name is given to distinguish the obligatory anaerobic streptothrix found by Neschezadimenko, in 1908, in human pus, and described in the *Centralblatt für Bakteriologie*, xlvi.
   ? *Coccobacillus pseudo-actinomycosis polymorphus* Berestneff, 1898.

4. *Cohnistreptothrix americana* Chalmers and Christopherson, 1916:—
   This name is given to distinguish the streptothrix which only grows under partial anaerobic and aerobic conditions, obtained from a liver abscess by Bloomfield and Bayne-Jones in 1915, and described in *Johns Hopkins Hospital Bulletin*, xxvi., No. 292.

5. *Cohnistreptothrix israeli* (Kruse, 1896):—
   Streptothrix israeli Kruse, 1896.
   Streptothrix spitzi Lignières, 1903.
   Possibly the streptothrices described by Doyen in 1891, by Jurinka in 1896, and some of those by Silberschmidt in 1901, by Schukewitsch in 1902, by Doepke in 1903, and by Wright in 1904.

6. *Cohnistreptothrix thibiergei* (Ravaut and Pinoy, 1909):—
   Discomyces thibiergei Ravaut and Pinoy, 1909.

DIAGNOSTIC TABLE OF THE SPECIES WHICH MAY POSSIBLY BELONG TO THE GENUS *COHNISTREPTOTHRIX* PINOY, 1911.

- Cultivation.
  - Cultures known.
    - Method of growth.
      - Obligatory anaerobes.
        - Bacillary forms in cultures.
          - Cultivation.
            - Easy.
              - Gelatine.
                - (1) *Silberschmidti.*
            - Very difficult.
              - No liquefaction of gelatine.
                - (2) *Cuniculi.*
        - Hyphæ in cultures; no growth gelatine or potato.
          - (3) *Neschezadimenki.*
      - Facultative anaerobes.
        - Grains.
          - Absent.
            - (4) *Americana.*
          - Present.
            - Laboratory animals.
              - Pathogenic.
                - Character of grains.
                  - Yellow.
                    - (5) *Israeli.*
                  - Very small and white.
                    - (6) *Thibiergei*
              - Non-pathogenic.
                - (7) *Foersteri.*
  - Cultures unknown.
    - Habitat.
      - Nodules on hair.
        - (8) *Tenuis.*
      - Juxta-articular nodules.
        - (9) *Carougeaui.*

7. *Cohnistreptothrix foersteri* (Cohn, 1874):—
    Streptothrix foersteri Cohn, 1874.
    Leptothrix oculorum Sorokin, 1881.
    Oöspora foersteri Sauvageau and Radais, 1892.
    Streptothrix aurea Du Bois de Saint Sévérin, 1895.
    Streptothrix foersteri Kruse, 1896.
    The aerobic streptothrix of Silberschmidt obtained from a case of dacryocystitis, 1901.
    ? *Streptothrix radiata* Namyslowski, 1909.
    ? *Streptothrix cerebriformis* Namyslowski, 1909.
8. *Cohnistreptothrix tenuis* (Castellani, 1911):—
    Nocardia tenuis Castellani, 1911.
9. *Cohnistreptothrix carougeaui* (Gougerot, 1909):—
    Discomyces carougeaui Gougerot, 1909.
    Nocardia carougeaui Castellani and Chalmers, 1913.

These species may be differentiated as given on p. 1065.

Cohnistreptothrix israeli Kruse, 1896.

Synonyms.—*Streptothrix israeli* Kruse, 1896; *Cohnistreptothrix israeli* Pinoy, 1911.

Found in some cases of human and bovine actinomycosis. It differs from *N. bovis* by being strictly anaerobic. Inoculations of pure cultures have reproduced actinomycotic lesions, while so far such experimental lesions have not been obtained by using cultures of *N. bovis*.

Wright states that *N. israeli* is the real cause of actinomycosis, while *N. bovis* would be only a contamination or a saprophytic agent. We agree, however, with Pinoy's opinion that the clinical features of actinomycosis may be due to several germs: in man Pinoy has found *N. bovis* and *N. israeli*; in oxen *N. israeli* in most cases, but also *N. bovis*, the actinobacillus, and mixed infections.

The actinobacillus of Lignières and Spitz, very common in South America, gives rise to a type of actinomycosis of cattle affecting generally the tongue and neck, in which no grains are found. The germ in the affected tissues appears in the shape of a club-like bacillus. Cultivation is difficult, the best medium being glucose serum agar. The colonies are minute, bluish, or translucid, with irregular edge. The germ generally dies out after two or three subcultures. Pinoy and Ravaut have described a case of meningitis in man due to this bacillus.

Cohnistreptothrix thibiergei Pinoy and Ravaut, 1909.

Synonym.—*Nocardia thibiergei* Pinoy and Ravaut, 1909.

Discovered by Pinoy and Ravaut in a case of peculiar nodular affection of the subcutaneous tissues and muscles. In the lesions very thin (0·2 μ) fragile mycelial threads are seen, often dissociated in bacillary-like bodies. Masses of mycelia embedded in amorphous cementing substance form minute grains or sclerotia, with a maximum diameter of about 80 μ. Some filaments terminate in club-like formations about 3 μ in breadth, which are acid-fast.

The fungus is easily cultivated, aerobically and anaerobically. On maltose agar it produces small white colonies; on broth it develops only at the bottom of the tube.

Cohnistreptothrix foersteri Cohn, 1874.

Synonyms.—*Streptothrix foersteri* Cohn, 1874; *Oöspora foersteri* Radais et Sauvageau, 1892; *Discomyces foersteri* Blanchard, 1895; *Cohnistreptothrix foersteri* Pinoy, 1911.

Mycelial threads very slender, seldom ramified, often terminating in a chain of rod-like or coccus-like elements. Masses of the fungus form some peculiar white bodies or concretions (Désmarres' dacryolithes), about 2 millimetres in diameter, which are occasionally found in the lachrymal canals of man.

The fungus has been cultivated with difficulty aerobically and anaerobically by several authors, among whom Kastalky, Axenfeld, Morax, and Landrieu. The last named has made a thorough investigation of the fungus, which, according to him, shows a slow growth and gives rise on maltose agar to small cerebriform colonies of a grey-stone colour.

The peculiar concretions found in the lachrymal canals were first studied by Césoin in 1670 and Sandifors in 1779. Désmarres, in 1842, considered them to be calculi composed of lime salts, and indicated them by the name of dacryolithes. Gruby believed they were induced by the fungus of Favus, but his observations remained unpublished. A. de Graefe, in 1854, first stated in a published work that these concretions were of mycotic origin. He thought they were due to *Achorion schoenleini*, while Conheim and others believed them to be caused by *Nocardia* (*Streptothrix*) *buccalis*. In 1875 Cohn described the fungus under the name of *Streptothrix foersteri*.

Cohnistreptothrix tenuis (Castellani, 1911).

Synonym.—*Nocardia tenuis* Castellani, 1910.

Found by Castellani in a nodular affection of the hair of the axillary regions. In the parasitic stage, the germ appears in the shape of bacillary-like bodies, varying in breadth (0·2 to 0·6 μ) and in length (2 to 10 μ), packed together and embedded into an amorphous cementing substance. The bacillary bodies are either straight or bent, seldom branching. Gram-positive, but not acid-fast. Masses of this fungus embedded in amorphous cementing substance form the nodules of trichomycosis flava of the axillary regions. (See Plate VI., p. 1034).

In the black variety of the affection *Nocardia tenuis* is associated with a black pigment-producing coccus—*Nigrococcus nigrescens* Castellani, 1911. In the red variety the same *Nocardia* is associated with a red pigment-producing coccus found by Castellani, and called by Chalmers and O'Farrell *Rhodococcus castellanii* Chalmers and O'Farrell, 1913.

For the growth of the black pigment-producing coccus, sugar media are more suitable than ordinary agar. On Sabouraud's agar the colonies of this coccus appear twenty-four to forty-eight hours after inoculation. They are roundish, at first white, but after a couple of days the centre of each colony turns black; at this pigmentation slowly spreads excentrically. After a time the colonies coalesce into a jet-black mass. On glucose agar the coccus presents the same characters. On ordinary agar the pigmentation is much less marked or almost absent.

The red pigment-producing coccus, on the other hand, grows better and shows more pigmentation on ordinary agar than on maltose or glucose agar.

ADDENDUM.

A few words may be inserted on certain filamentous vegetal organisms, on the classification of which there is much discussion—viz., organisms of the genus *Leptothrix*, of the genus *Cladothrix*, of the genus *Vibriothrix*.

Genus Leptothrix Kützing, 1843.

Definition.—Filamentous fungi with long, very thin mycelial threads, with no capsule or only a very delicate one; non-branching, non-septate, generally non-cultivable.

Type Species.—*Leptothrix maxima* Miller.

The following species concern us:—

Leptothrix maxima Miller, 1882.

Synonym.—*L. buccalis maxima* Miller.

Long thin filaments, unsegmented, or with very long segments. When treated with iodine and dilute sulphuric acid gives a blue granulose reaction. Has not been cultivated.

Leptothrix innominata Miller, 1882.

Morphologically identical with *L. maxima*, but when treated with iodine and dilute sulphuric acid does not give a blue reaction. Has not been cultivated.

Leptothrix racemosa Miller, 1882.

Filaments somewhat thicker than those found in the two preceding species. On staining shows a peculiar beaded appearance. Has not been cultivated.

Leptothrix placoides Dobrzyniecki.

Very long thin filaments, Gram-positive, non-motile. Gelatine liquefied. Growth on agar very slow; produces very hard granular colonies. Isolated from human mouth by Dobrzyniecki.

Leptothrix filiformis Flexner, 1896.

Synonym.—*Bacillus (Leptothrix ?) pyogenes filiformis* Flexner, 1896. Isolated by Flexner from a rabbit. Is non-motile, of difficult cultivation, pathogenic.

Leptothrix vaginalis Donné, 1885.

Found in vagina of women and mammals.

Genus Cladothrix Cohn, 1875.

Definition.—Filamentous fungi with mycelial threads very long, thin, showing pseudo-branching. The only species concerning us is *Cladothrix dichotoma* Cohn.

Cladothrix dichotoma Cohn, 1875.

Long thick mycelial threads straight or slightly undulating. They are not dichotomous, as the name would suggest; it is merely a case of pseudo-branching. The organism can be cultivated on ordinary laboratory media, forming on agar a brownish, wrinkled, tough, membranous layer, very adherent. The medium may become stained, slightly brownish. The organism is found often in waters. We have found it, or a very similar species, in an ulcer of the foot in association with many other organisms.

Genus Vibriothrix Castellani, 1917.

The mycelial articles are motile, of very different shape: bacillary, vibrio-like, spirillum-like, at times club-ended. Globular or pear-shaped bodies of very variable size may be present. Gram-negative, not acid-fast. Cultivable on ordinary media.

Type Species.—*Vibriothrix zeylanica* Castellani, 1910.

Synonyms.—*Spirillum zeylanicum* Castellani, 1910; *Vibrio zeylanicus* Castellani, 1913; *Bacillus zeylanicus* Castellani, 1913; *Vibriothrix zeylanica* Castellani, 1917; *Spirobacillus zeylanicus* Castellani, Spagnolo, and Russo, 1918.

Remarks.—Very polymorphic organism, vibrio-like, bacillus-like, and undulating forms being often found in the same preparation. Very small, medium size, and occasionally large roundish bodies are at times observed, and club-like forms may also be present (*vide* Figs. 764, 765, p. 1839).

The organism is motile, Gram-negative, not acid-fast. Easily grown on ordinary media. On potato the growth is often of a reddish colour. In broth there is often a pellicle; preparations from the fluid medium generally show a predominance of vibrio-like or bacillary forms, while in the pellicle long undulating forms are often found. On MacConkey's medium the colonies are white, and somewhat resemble those of the typhoid-dysentery group. The organism does not ferment any of the usual laboratory carbohydrates or alcohols: glucose, levulose, galactose, maltose, lactose, saccharose, mannitol, dulcite, raffinose. There is, in fact, frequently a production of alkalinity. Milk is not clotted and is rendered alkaline, and certain strains after several weeks may induce a certain degree of peptonization. The great majority of strains are non-pathogenic to rabbits and guinea-pigs.

The germ was first isolated by Castellani from cases of dysenteric enteritis in Ceylon, and has recently been observed by the same author and by Spagnolo, Russo, Taylor, Douglas, and Ghiron, in Europe (see p. 1839).

The germ is found in great abundance in a number of cases of dysentery, while it seems to be rare in other conditions; it is very doubtful, however, whether it can really become pathogenic, Castellani having found it also in cases in which the typical Shiga-Kruse bacillus was present. It may, perhaps, be considered to be a so-called 'nosoparasite' similarly to what is the case with certain species of proteus found in cholera, in typhus fever, and other conditions.

ORDER II. THALLOSPORALES Vuillemin, 1910.

Definition.—Hyphales with the mycelium composed of hyphæ more than one micron in diameter, and either short and resembling the conidia or longer and distinct therefrom. Reproduction by means of thallospores. Parasitic on man, animals, and plants, or saprophytic.

Classification.—This order may be divided as follows:—

Reproduction by means of the form of thallospore called blastospore—Suborder 1, *Blastosporineæ* Vuillemin, 1911.

Reproduction by means of the form of thallospore called arthrospore—Suborder 2, *Arthrosporineæ* Vuillemin, 1911.

SUBORDER 1. BLASTOSPORINEÆ Vuillemin, 1911.

Definition.—Thallosporales with hyphæ similar to or dissimilar from the spores, and reproducing by means of blastospores, which are in turn capable of immediately reproducing themselves.

Remarks.—This order includes *Cryptococcus*, which, in its old position among the Ascomycetes, was certainly an anomaly, being an Ascomycete without an ascus, and if an ascus was found in a species, then it at once became a saccharomyces. The researches of many observers, but particularly Busse, tend to show that the genus *Cryptococcus* Kützing, 1833, is good, and therefore should find a suitable place in a fungal classification.

Saccharomyces and its allies and cryptococcus and its allies are, however, so closely related that it is necessary to give some simple scheme whereby laboratory workers and clinicians may easily differentiate those found in pathological work; and such a scheme is as follows:—

I. In cultures budding forms present; mycelium absent, or only traces thereof present; asci present—*Saccharomyces*.
II. As I., but no asci present—*Cryptococcus*.
III. Budding forms present; mycelium well developed; septate or not, branched or not; asci present—*Endomyces*.
IV. As III., but asci not present—*Monilia*.
V. Budding forms absent; mycelium well developed, septate; oval or rectangular arthrospores (thallospores) present—*Oidium*.

Classification.—The various families of the Blastosporineæ with which we are concerned may be recognized as follows:—

A. *Hyphæ not manifestly different from the spores*:—
   I. Spores not in chains. Usually do not ferment carbohydrates with the production of gas—Family 1, *Cryptococcaceæ* Kützing, 1833.
   II. Spores in chains. Usually ferment carbohydrates with the production of gas—Family 2, *Oösporaceæ* Saccardo, 1886.

B. *Hyphæ manifestly different from the spores*:—
   I. Spores not in chains, but arranged verticillately—Family 3, *Enantiothamnaceæ* Chalmers and Archibald, 1915.
   II. Spores in chains—Family 4, *Haplographiaceæ* Saccardo, 1886.
   III. Spores in short chains or solitary—Family 5, *Cladosporiaceæ* Saccardo, 1886.

FAMILY 1: CRYPTOCOCCACEÆ Kützing, 1833.

Definition.—Blastosporineæ in which the hyphæ are little different from the conidia, both being yeast-like in form. The conidia are entirely formed by gemmation from the hyphæ and are never in chains.

Remarks.—This family, of which the type genus is Cryptococcus, is very commonly classified with the class Ascomycetes, which includes an order established by Brefeld and variously named hemiascomycetes, hemi-asci, proto-asci, and gymnascales. This order is looked upon by many authorities as a link between the Phycomycetes and the true Ascomycetes, and, indeed, its founder, Brefeld, believed that, in process of evolution, the sporangium of the Phycomycetes had been converted into the ascus of the Ascomycetes.

Classification.—The family contains the following genera:—*Torula* Persoon, 1801; *Cryptococcus* Kützing, 1833; *Pityrosporum* Sabouraud, 1895; and *Mycoderma* Persoon, 1822; which may be differentiated as follows:—

A. Vegetative elements not elongate:—
  I. *Non-pathogenic* :—
    Vegetative elements roundish or oval, containing a large globule of fat. Budding takes place, and often by several buds at one and the same time. Pigment is frequently present. In fluid sugar media a thick pellicle, without bubbles of air, is slowly produced—*Torula*.
  II. *Pathogenic* :—
    (*a*) Vegetative elements with well-developed double contour; no large globule of fat. Budding takes place with a single bud at a time. No thick pellicle on fluid sugar media. Cultivated—*Cryptococcus*.
    (*b*) Vegetative elements often without double contour. Not cultivated—*Pityrosporum*.
B. Vegetative elements elongate:—
  In fluid sugar media a thick pellicle containing bubbles of gas is quickly produced—*Mycoderma*.

The genera with which we are concerned are Cryptococcus and Pityrosporum.

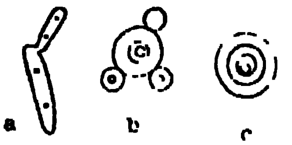

FIG. 556.—DIAGRAM SHOWING BUDDING CHARACTERISTIC OF *Mycoderma* (*a*) and *Torula* (*b*). (After Hansen.)

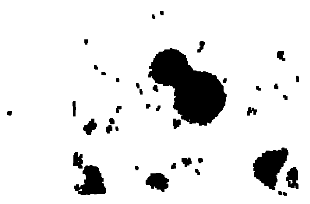

FIG. 557. *Cryptococcus myrmeciæ*.

Genus Cryptococcus Kützing, 1833.

Definition.—Cryptococcaceæ with vegetative elements not elongate; pathogenic, with well-developed double contour, but no globule of fat and only one bud at a time, and no formation of thick pellicle on fluid sugar media. Can be cultivated.

Type Species.—*Cryptococcus hominis* Vuillemin, 1901.

Remarks and Classification.—The name Cryptococcus was introduced by Kützing in 1833 as the generic name for certain forms of his algæ, which he classified as belonging to the subclass Malacophyceæ, tribe Gymnospermeæ, order Eremospermeæ, suborder Mycophyceæ, and family Cryptococcaceæ. This family he defined as: '*Globuli gonimici minutissimi mucosi in stratum indefinitum aggregati*,' and in this family he placed three genera, Cryptococcus, Ulvina, and Sphærotilus. The genus Cryptococcus was characterized as: '*Globuli gonimici in stratum amorphum diffusum aggregati.*' In this genus he gathered no less than thirteen species, all described by himself and mostly found in water or in pharmaceutical preparations.

His twelfth and thirteenth species were, however, more interesting, as they were called *Cryptococcus cerevisiæ* and *C. vini*.

In 1837 Meyen separated *C. cerevisiæ* from the genus Cryptococcus, because it reproduced by ascospores as well as by budding, and to this new genus he gave the name *Saccharomyces*, so that *Cryptococcus cerevisiæ* became *Saccharomyces cerevisiæ*.

Cryptococcus therefore remained for those yeast-like fungi which do not reproduce by ascospores, but only by budding.

The removal of the species *cerevisiæ* from *Cryptococcus* was not recognized by Charles Robin, and with it he grouped the fungus found by Remak in 1845 in the biliary passages and intestines of rabbits, to which in 1847 he gave the name *Cryptococcus guttulatus*. Later, however, it was also shown to belong to the genus Saccharomyces.

In 1873 Rivolta noticed peculiar bodies in a form of lymphangitis in horses, and in 1883 he and Micellone named this organism *Cryptococcus farciminosus*.

During this period one or two organisms had a temporary resting-place in this genus—*e.g.*, Fresenius's *Cryptococcus glutinus*.

The first case in which a cryptococcus was definitely proved to be the cause of disease was Busse's case of cystic swellings of the tibia in a woman, aged thirty-one. The bodies in question were first seen by Buschke, but it was Busse who first proved that they were the true cause of the disease, and showed that they were pathogenic to animals. These yeast-like organisms were found at the autopsy some thirteen months later to occur in sarcomatous-like growths consisting of young granulation tissue and giant cells, not merely in the cysts, but also in the lungs, kidneys, spleen, and in a vesicle on the cornea. The organism grew well on potato and in acid media. It fermented glucose and was specially pathogenic for rats. It only reproduced by budding, and no endospores or mycelium were ever seen. It was this that induced Vuillemin to give it the name *Cryptococcus hominis*, 1901.

Including *C. hominis*, and after excluding several wrongly classified forms, there are about fourteen species parasitic in man which can at present be referred to the genus Cryptococcus, *e.g.*:—

Cryptococcus breweri Verdun, 1912, described in an abscess of the vertebral column; *C. tonkini* Legendre, 1911, found in two cases of blastomycosis in Indo-China.

In addition a number of cryptococci have been found associated with cancers, sarcomata, and innocent tumours—*e.g.*, *C. plimmeri* Constantin, 1901; *C. degenerans* Vuillemin, 1896; *C. corsellii* Neveu-Lemaire, 1908; *C. hessleri* Rettger, 1904.

The following have been found in the mouth or throat:—*C. sulfureus* Beauverie and Lesieur, 1912; *C. lesieuri* Beauverie and Lesieur, 1912; *C. salmoneus* Sartory, 1911; *C. guillermondi* Beauverie and Lesieur, 1912; *C. rogeri* Sartory, 1911; and *C. linguæ-pilosæ* Lucet, 1901.

According to most authors, *Histoplasma capsulatum* Darling, 1906, is not an animal but a vegetal parasite, and should be classified as a cryptococcus.

The parasite found in cases of chronic ulcerative dermatitis in America, and named *Cryptococcus dermatitis* Gilchrist and Stokes, according to some authors, does not belong to the genus Cryptococcus of Kützing, but to the genus *Mycoderma* of Persoon, 1822; but we have retained it under Cryptococcus.

Recently Chalmers and Christopherson in the Anglo-Egyptian Sudan have found a cryptococcus in a peculiar disease consisting of spreading warts, to which they have given the name Murmekiasmosis amphilaphes. As the cryptococcus is closely associated with the condition, they have named it *C. myrmeciæ* Chalmers and Christopherson, 1914, but they were unable to prove conclusively that it was the ætiological factor, though they brought forward some facts to support such a contention.

Cryptococcus dermatitidis Gilchrist and Stokes, 1898.

Synonyms.- *Blastomyces dermatitis* Gilchrist and Stokes, 1898; *Cryptococcus gilchristi* Vuillemin; *Zymonema gilchristi* de Be and Gougerot.

Found by Gilchrist and Stokes in a case of chronic ulcerative dermatitis, and later in a case which had been diagnosed as a tuberculide of the skin. After Gilchrist and Stokes's cases, other cases of blastomycosis due to an identical or similar organism have been described by Hyde, Oppenheim, Ricketts, and others. Ricketts considered these fungi to be species of *Oidium*, and proposed the name '*oidiomycosis*' to indicate the disease produced by them.

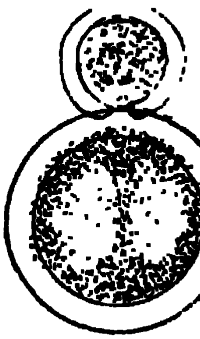

Fig. 558. *Cryptococcus dermatitis* Gilchrist and Stokes. (After Gilchrist.)

C. dermatitidis in the affected tissues has the appearance of a typical yeast- *i.e.*, large globular cells, 10 to 16 μ in diameter, reproducing by budding. In cultures, which are white, besides these globular elements, rudimentary mycelial tubes may occasionally be found, presenting lateral or terminal conidia; asci are absent. The fungus does not ferment sugars, and there is no formation of a pellicle. Gelatine not liquefied.

Cryptococcus hominis Vuillemin, 1901.

Synonyms.- *Saccharomyces* (sp. ?) Busse, 1894; *Atelosaccharomyces busse-buschki* de Beurmann and Gougerot, 1909; *Atelosaccharomyces rudeli* de Beurmann and Gougerot, 1911.

Found in abscesses in a woman by Busse. In the pus the fungus presented itself in the shape of oval bodies, with a membrane having a double contour. These elements were arranged in groups, each group embedded in an amorphous substance and surrounded by a capsule. Culturally the fungus showed only roundish budding forms, no mycelium, no asci. Growth on solid media generally white. Gelatine not liquefied. Glucose fermented. Pathogenic to rabbits, white mice, and dogs.

Cryptococcus linguæ-pilosæ Lucet, 1901.

Synonym.—*Saccharomyces linguæ-pilosæ* Lucet, 1901.

Found by Lucet and others in cases of so-called 'black tongue.' It appears on the surface of the hypertrophied lingual papillæ in the shape of roundish bodies, with double contour, 3 to 6 *μ* in diameter. Grows easily on sugar media. Often produces pellicle in sugar media. Glucose and levulose fermented. Attempts to reproduce the disease have failed. Guégen and Thaon believe that this fungus becomes pathogenic only when associated with *Nocardia lingualis*.

The condition known under the name of 'lingua nigra' is caused in addition to the above fungus, in some cases by *Rhizopus niger*, in other cases by *Nocardia lingualis*.

Fig. [illegible].—*Cryptococcus pilosæ* Lucet.
(After Lucet, from Brumpt.)

Cryptococcus plimmeri Constantin, 1901.

Found by Plimmer in many cases of cancer; is probably only a saprophyte. In the tissues roundish bodies of various sizes, 4 to 40 *μ* in diameter, are seen, occasionally budding, and either free or intracellular. Cultivation has succeeded only on one occasion, when it was found that it produced a white growth on agar and other media. Action on gelatine and other sugars have not been investigated. *Cryptococcus plimmeri*, according to some authors, has been applied to cellular changes.

Cryptococcus degenerans Vuillemin, 1896.

Synonym.—*Blastomyces vitro-simile degenerans* Roncali, 1896.

Found by Roncali and others in malignant tumours, sarcomata, and carcinomata. Easily grown; on potatoes it attains a much larger size than on any other medium; on gelatine growth greyish yellow. Sugar reactions scarcely known. Does not ferment saccharose, but nothing definite known about other sugars. Pathogenic for guinea-pigs.

Cryptococcus corsellii Neveu-Lemaire, 1908.

Found by Corselli and Frisco in a sarcoma of the mesenteric glands. The fungus appeared in the tumours under the shape of black masses. It was easily cultivated, and found pathogenic to guinea-pigs, rabbits, and dogs. Sugar reactions unknown.

Cryptococcus hessleri Rettger, 1904.

Synonym.—*Blastomyces hessleri* Rettger, 1904.

Isolated by Hessler from a small tumour which developed on a patient after a razor-cut. Easily cultivated, especially on alkaline media. Pathogenic for the rabbit and guinea-pig. Sugar reactions unknown.

Cryptococcus breweri Verdun, 1912.

Synonym. *Atelosaccharomyces breweri* Verdun, 1912.
Found by Brewer and Wood in an abscess of the vertebral column.

Cryptococcus tonkini Legendre, 1911.

Synonym.—*Blastomyces tonkini* Legendre, 1911.
Found by Legendre in two cases of blastomycosis in Indo-China. Pinoy considers that the characters given are not sufficient to create a new species for it.

Cryptococcus sulfureus Beauverie and Lesieur, 1912.

Found by Beauverie and Lesieur in certain pharyngeal lesions of a case of typhoid. Ferments slightly dextrose, saccharose, and lactose.

Cryptococcus lesieuri Beauverie and Lesieur, 1912.

Found in a case of stomatitis. Ferments dextrose only.

Cryptococcus salmoneus Sartory, 1911.

Described by Sartory. Found in human gastric juice. Growth on usual media of a pinkish or reddish colour. Does not ferment any sugar. Slowly coagulates milk.

Cryptococcus guillermondi Beauverie and Lesieur, 1912.

Found by Guillermond and Lesieur in cases of stomatitis.
Cellular elements *in situ* spherical, 10-25 microns, surrounded by large mucilaginous capsule. Growth on agar white or slightly yellowish. On potato scanty growth, white. Gelatine not liquefied. Does not ferment any sugar.

Cryptococcus harteri de Beurmann and Gougerot, 1913.

Synonym.—*Atelosaccharomyces harteri* de Beurmann and Gougerot, 1913.
Cells oval, 4-6 and 3-5 microns. Growth on sugar media and gelatine, which is not liquefied white. Does not ferment any sugar. Found by Harter in a case of systemic blastomycosis.

Cryptococcus hudelo de Beurmann and Gougerot, 1914.

Cellular elements *in situ* mostly spherical, 2-20 microns; at times oval, easily grown. Colonies white; gelatine not liquefied. Growth on potato at first white, later yellow, and finally reddish or blackish. Found by Hudelo, Duval, and Loederich in a case of periostitis.

Cryptococcus membranogenes Steinhouse, 1916.

Cellular elements roundish, 7-8 microns in diameter, with very distinct double contour. Surrounded by a thick capsule. Easily grown on all the usual culture media. Colonies white. Gelatine not liquefied. Ferments with gas production glucose but not maltose, lactose, or saccharose. Action on other sugars not known. Very pathogenic for rabbits.
Found by Steinhouse in 1916 in a case of scarlet fever showing symptoms of tracheal obstruction.

Cryptococcus epidermidis Castellani, 1914.

Found by Castellani in saccharomycosis epidermica. Cells of very variable size. Has not yet been cultivated.

Cryptococcus niger Vuillemin.

Found by Maffucci and Sirleo, in 1895, in a pulmonary myxoma of a guinea-pig. Cells *in situ* round or ovoid, with thick mucilaginous membrane. White on most media; on potato brown or black. Gelatine not liquefied. Said to ferment maltose. Nothing known about other sugars.

Cryptococcus lithogenes San Felice

Synonym. *Saccharomyces lithogenes* San Felice.

Found by San Felice in the lymphatic glands of an ox. Roundish cells with a membrane which is at times calcified. Growths whitish on most media, dark brownish after a time on potato. Gelatine not liquefied.

Cryptococcus granulomatogenes (San Felice).

Synonym.- *Saccharomyces granulomatogenes* San Felice.

Isolated from the lung of a hog by San Felice. It grows easily on ordinary laboratory media producing white colonies. It does not liquefy gelatine, but it produces slight rose-red pigment on slices of pear and on honey.

Cryptococcus farciminosus (Rivolta and Micellone, 1883).

Synonyms.- *Cryptococcus tokishigei* Vuillemin; *Lymphosporidium equi* Gasperini, 1908; *Leucocytozoön piroplasmoides* Ducloux, 1908.

Definition.- Vegetative cells *in situ*, oval or roundish, with well-marked double contour.

Remarks.—It is often included in hypertrophied endothelial cells and in leucocytes in the lesions in horses suffering from lymphangitis epizoötica in Europe, Africa, Asia, and America.

Cultivation.- It is of difficult cultivation. Nègre and Boquet have used with success a medium made of agar and dried horse-dung. Sugar reactions are unknown.

Cryptococcus capsulatus (Darling, 1906).

Synonym.- *Histoplasma capsulatum* Darling, 1906.

Definition.- In the affected tissue the parasite appears in round or oval form, measuring 1-4 microns in diameter, and enclosed in an achromatic refractile capsule. Cultivation so far negative.

Remarks.- It was found by Darling in the endothelial cells of capillaries and small bloodvessels in the lungs, spleen, liver, intestines, and lymph glands, as well as in the leucocytes. It was considered by Darling and others to be a protozoön, and for it the genus *Histoplasma* was created. At present there is a consensus of opinion that it is a *Cryptococcus*.

Pathogenicity. It is pathogenic for man, causing disseminated, hyaline, pseudogranulomata in the lungs, splenomegaly, necrotic areas in the liver, and ulceration of the small and large intestines.

Cryptococcus ruber Demme, 1889.

Synonym.- *Saccharomyces ruber* Demme, 1889.

This organism was found in the stools of children suffering from enteritis and also in certain specimens of milk.

It grows easily on ordinary laboratory media, producing red colonies. According to Casagrandi, it does not ferment any sugar.

Cryptococcus myrmeciæ Chalmers and Christopherson, 1914.

Cryptococcus measuring 1·4-2·1 microns in diameter, found in a case of murmekiasmosis amphilaphes in the Anglo-Egyptian Sudan. All attempts at cultivation on a large series of media under aerobic and anaerobic conditions at 20°, 37°, and 40° C. failed, as did inoculations into monkeys and dogs. It was named because of its association with the peculiar disease called murmekiasmosis, but evidence was wanting that it was the causal organism, although its association was intimate.

Genus Pityrosporum Sabouraud, 1895.

Synonym.—*Dermatophyton* Dodd, 1910.

Definition.—Cryptococcaceæ without well developed double contour.

Type Species.—*Pityrosporum ovale* (Bizzozzero, 1882).

Remarks and Classification.—This genus, which is difficult to classify, is allied in appearance in some forms, to a budding yeast, and as such comes close to Cryptococcus. No species has so far been cultivated (Dodd claims to have cultivated *P. malassezi*), but two are known—viz.: *P. ovale* Bizzozzero, 1882 (synonyms, *Saccharomyces capillitii* Oudemans and Pekelharing, 1885; *S. sphæricus* Bizzozzero, 1884; *S. ovalis* Bizzozzero, 1889; *Pityrosporum malassezi* Sabouraud, 1895, often called the bottle bacillus of Malassez, in cases of pityriasis simplex capitis and pityriasis alba in Europe) and *P. cantliei* (Castellani, 1908) in cases of seborrhœa capitis in children in Ceylon.

They may be distinguished as follows:—

A. Flask-shaped or oval, 3 to 15 microns, but usually small—*Ovale*.
B. Generally roundish, 5 to 16 microns, but usually large—*Cantliei*.

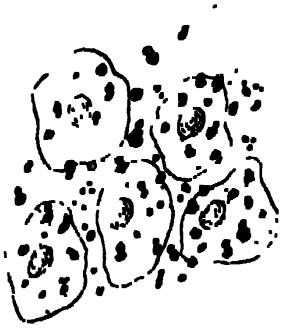

FIG. 500.—*Pityrosporum ovale* BIZZOZZERO.

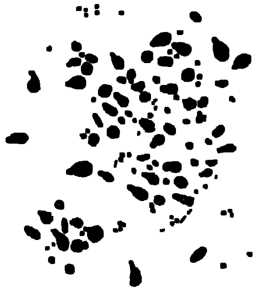

FIG. 501.—*Pityrosporum ovale* BIZZOZZERO.

(After Sabouraud.)

Pityrosporum ovale (Bizzozzero, 1882).

Synonyms.—*Saccharomyces ovalis* Bizzozzero, 1882; *Pityrosporum malassezi* Sabouraud, 1895. Usual term: bottle bacillus of Malassez.

This organism was first described by Bizzozzero, who considered it to be a *Saccharomyces*. Malassez and Sabouraud associated this organism with the ætiology of pityriasis simplex capitis and pityriasis alba.

Its shape somewhat resembles a budding yeast or a flask. The size varies greatly; the maximum diameter of some individuals may be as much as 10 to 15 μ, but much smaller forms (3 to 5 μ) are found.

Pityrosporum cantliei (Castellani, 1908).

Synonym.—*Saccharomyces cantliei* Castellani, 1908.

Somewhat similar to *Pityrosporum ovale*, but the cells are generally roundish and on the average larger (5 to 16 μ). Probably the cause of a variety of seborrhœa of the scalp occasionally met with in children in the tropics.

FAMILY 2: OÖSPORACEÆ Saccardo, 1886.

Definition.—Blastosporineæ in which the hyphæ may be long or little different from the spores, which are typically in chains.

Classification.—This family is divided into several genera—*e.g.* *Oospora* Wallroth, 1833; *Monilia* Persoon, 1797; and *Oidium* Link, 1809, which may be distinguished as follows:—

A. Hyphæ thin, short, simple, or nearly simple, terminating in chains of spores—*Oöspora*.

B. Hyphæ not thin, often long and branched:—

   I. Sporophores simple or subsimple, typically with disjunction apparatus. Glucose completely fermented, gas being produced. Numerous budding forms in cultures—*Monilia*.

   II. Sporophores simple, septate often with disjunction apparatus. Glucose not completely fermented, gas not being produced. Budding forms rare in cultures—*Oidium*.

These genera may now be briefly described.

Genus Oöspora Wallroth, 1833.

Definition.—Oösporaceæ with a lax or compact mycelium in which the hyphæ are slender, septate, and marked by differentiated nuclei. The fertile hyphæ are short, slender, and nearly simple. The conidia, which are globose or ovoidal, hyaline or brightly coloured, are arranged regularly in chains.

Remarks.—Saccardo in his 'Sylloge Fungorum' recognizes a large number of species as belonging to this genus, and these are grouped into sections by the varying colour of the conidia.

The only species known to cause disease in animals referable to this genus is *Oöspora canina* Sabrazès, 1893, which causes favus in dogs, and which can produce an eruption resembling ringworm when inoculated into man. According to Sabouraud, however, it has never been known to cause disease in man spontaneously (*i.e.*, without experimental inoculation), and is therefore of little importance at present.

Vuillemin considers that *Achorion schoenleini* Lebert, 1845, the fungus of favus of human origin, belongs to this genus.

Genus Monilia Persoon, 1797.

Definition.—Vague.

Original Definition.—*Stipitata aut effusa byssoidea, Fila moniliformis articulata.*

Botanical Definition.—Sporophores simple or subsimple, producing by constriction at their extremities a chain of large lemon-shaped conidia, often provided with a disjunction apparatus.

Usual Definition.—Oösporaceæ possessing *in situ* budding forms and mycelial threads, which latter are often long and branched; *in cultures* mostly budding forms, but sometimes filaments, in which thallospores of the blastospore type are formed. Glucose and often other carbohydrate media fermented with the production of gas.

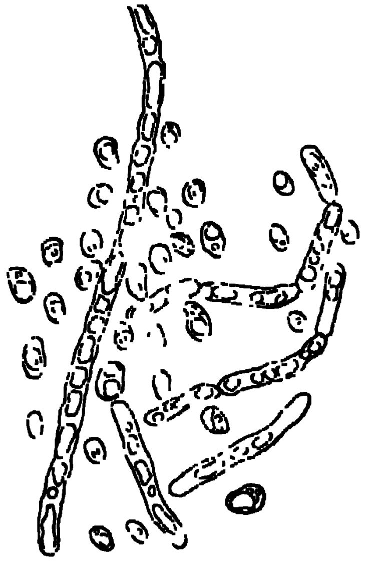

FIG. 502.—*Monilia tropicalis* CASTELLANI. FRESH PREPARATION FROM SPUTUM.

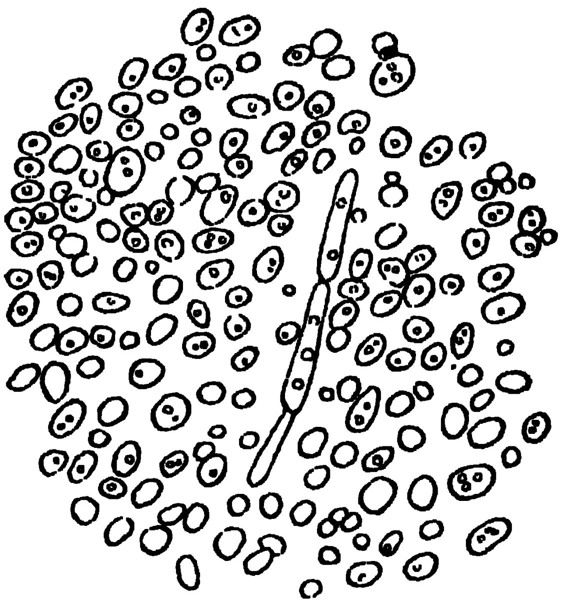

FIG. 503.—*Monilia intestinalis* CASTELLANI PREPARATION FROM GLUCOSE AGAR CULTURE.

Nomenclature.—A few words are necessary with regard to the nomenclature and the synonyms, as the greatest confusion has existed with regard to this genus. The first description of the genus Monilia, as we understand it, was given by Persoon as '*Stipitata, aut effusa byssoidea, Fila moniliformias articulata,*' and the first date given by Saccardo 1797, though the earliest we have found is in his book of 1801. The name is derived from *monile*, a necklace. Link's description in Gmelin's thirteenth edition (really the fourteenth edition) of Linnæus's 'Systema Naturæ,' 1791, refers, it is true, to *Monilia aurea* (Link, 1791), but it was described as *Oidium aureum* Link, 1791. The other synonyms do not require explanation.

We have not included the genus *Zymonema* de Beurmann and Gougerot, 1909, in the synonyms because *Z. gilchristi*, the cause of American blastomycosis, more usually called *Cryptococcus gilchristi*, is said to have lateral as well as terminal conidia, and is classified here as a cryptococcus.

The genus '*Parasaccharomyces*' de Beurmann and Gougerot, 1909, with its species *Parasaccharomyces harteri* Verdun, 1912, found in a case of enteritis with hepatic, bronchial, and cutaneous lesions, has not merely yeast-like forms, but septate hyphæ, but it is not known whether it develops terminal conidia in chains, and therefore it may, at present, correctly be placed in the genus Cryptococcus until more is known about it; and the same remarks apply, we think, to *Parendomyces* Querat and Laroche, 1909.

Fig. 564.

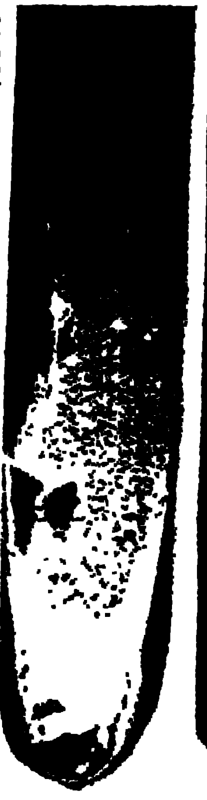

Fig. 565.

Fig. 566.

FIG. 564. *Monilia zeylanica* CASTELLANI. GLUCOSE AGAR CULTURE.
FIG. 565. —*Monilia bronchialis* CASTELLANI. GLUCOSE AGAR CULTURE.
FIG. 566. —*Monilia nivea* CASTELLANI. GLUCOSE AGAR CULTURE.

Remarks. —A number of species belonging to this genus are known to exist in nature growing on decomposing wood, dead leaves, and fruits.

The number of species known to infect man has been considerably extended during recent years by Castellani. The Monilias are of importance in that they are considered to be the ætiological agents of thrush, bronchomycosis (*pro parte*), some dermatomycoses, and, according to certain authors, of sprue.

Type Species.—It is difficult to know which is really the type species of this genus, but probably it is *Monilia aurea* (Link, 1791).

Geographical Distribution.—Possibly world-wide.

Biological Characters.—Some species clot milk, others have no action on this medium; some species liquefy gelatine and serum. Certain fungi of this genus, when growing on serum, produce a peculiar zone of brownish or black discoloration of the medium all round the growth using the serum of *Bos indicus*. The biochemical properties and sugar reactions vary from species to species. Rabbits can be immunized for these fungi, and attempts to use the immunization and agglutination reactions in the differentiation of the various species have been made with only partial success, as there is a large production of co-agglutinins in addition to the specific ones for very different fungi—*e.g.*, fungi of the genus *Sporotrichum*.

Pathogenicity.—Fungi of this genus are the ætiological agents of thrush, some types of bronchomycoses, and some dermatomycoses.

Classification.—There has been and there is still a great deal of confusion in the classification of such fungi. Many of the species of this genus can hardly be distinguished by purely morphological and botanical characters. We are of opinion that the classification should be based, not only on morphological data, but also on biochemical characters and immunization phenomena. Among the biochemical properties, the most important are the actions on milk, gelatine, serum, and on sugar broths. A large number of sugars should be used in the same manner as is done in the classification of the various species of intestinal bacteria. It is to be noted that the reactions with certain sugars are constant, while with others (for instance, mannite) these may vary; and the fermentative power on certain sugars—*e.g.*, galactose—may be rapidly lost. Hence species should be compared only in strains recently isolated. It is to be noted also that in analogy to intestinal bacteria, a species may be trained to ferment certain sugars on which it did not act when recently isolated.

While taking all this into account, we believe the investigation of the various biochemical reactions to be of great value for classifying these fungi, and for this purpose give the table on pp. 1082, 1083.

Determination of Species.—By means of the sugar reactions it is possible to divide the species of Monilia into groups by the use of the following carbohydrates—viz., glucose, levulose, maltose, galactose, saccharose, inulin, and dextrin. When the Monilia is classified into its group it is easy, by means of the table on pp. 1082, 1083, to make the specific determination:—

A. Gas produced in *glucose only*—Group I., *Balcanica* group:—*M. balcanica*, *M. parabalcanica*.

B. Gas produced in *glucose* and *levulose*—Group II., *Krusei* group:—*M. krusei*, *M. parakrusei*.

C. Gas produced in *glucose*, *levulose*, and *maltose*—Group III., *Pinoyi* group.—*M. pinoyi*, *M. nabarroi*.

D. Gas produced in *glucose*, *levulose*, *maltose*, and *galactose*—Group IV., *Metalondinensis* group—*M. metalondinensis*, *M. pseudometalondinensis*.

TABLE SHOWING PRINCIPAL BIOCHEMICAL AND CULTURAL REACTIONS OF THE FUNGI IN ALPHABETICAL ORDER:

O = negative result—viz., neither acid nor clot in milk; neither acid nor gas in sugar media; non-production of indol; non-liquefaction of gelatine or serum, as the case may be.

+ = positive result, liquefaction of medium.

E. Gas produced in ***glucose***, ***levulose***, ***maltose***, ***galactose***, and ***saccharose***—Group V., *Tropicalis* group:—***M. tropicalis***, ***M. paratropicalis***, ***M. pulmonalis***, ***M. nivea***, ***M. insolita***, ***M. enterica***.

F. Gas produced in ***glucose***, ***levulose***, and ***saccharose***—Group VI., *Guillermondi* group:—***M. guillermondi***, ***M. pseudoguillermondi***.

H. Gas produced in ***glucose***, ***levulose***, ***galactose***, ***saccharose***, and ***inulin***—Group VII., *Chalmersi* group:—***M. chalmersi***, ***M. parachalmersi***, ***M. macedoniensis***.

I. Gas produced in ***lactose and other carbohydrates***—Group VIII., *Pseudotropicalis* group:—***M. pseudotropicalis***.

K. Gas produced in ***dextrin*** in addition to other sugars—Group IX., *Pseudolondinensis* group:—***M. pseudolondinensis***.

A. *Species believed to be ætiological factors of disease in man*:—

- I. *Species found in thrush and allied infections*:—
  1. M. albicans (Robin, 1853).
  2. M. alba (Castellani, 1911).
  3. M. londinensis (Castellani, 1910).
  4. M. metalondinensis (Castellani, 1916).
  5. M. tropicalis (Castellani, 1910), and most of those found in bronchomycosis.
- II. *Species found in bronchomycosis*:
  6. M. tropicalis (Castellani, 1909).
- III. *Species found in otomycosis*:
  7. M. rhoi (Castellani, 1909).
- IV. *Species found in pinta*:
  8. M. montoyai Castellani, 1907.
- V. *Species found in cases of generalized moniliomycoses*:—
  9. M. rosea (Zenoni, 1912).

B. *Species associated with a disease in man*:

- I. *Associated with bronchomycosis*:—
  - (a) *By their presence in the sputum of cases of bronchomycosis (in alphabetical order)*:—
    1. M. guillermondi (Castellani, 1910).
    2. M. krusei (Castellani, 1909).
    3. M. negrii (Castellani, 1910).
    4. M. nitida (Castellani, 1910).
    5. M. parakrusei (Castellani, 1910).
    6. M. paratropicalis (Castellani, 1912).
    7. M. pinoyi (Castellani, 1910).
    8. M. pseudotropicalis (Castellani, 1910).
  - (b) *By their presence in bronchitis*:—
    1. M. chalmersi (Castellani, 1912).
    2. M. parachalmersi (Castellani, 1910).
    3. M. bethaliensis (Pijper, 1918).
  - (c) *By their presence in human sputum*:—
    1. M. balcanica (Castellani, 1910).
    2. M. bronchialis (Castellani, 1910).
    3. M. nabarroi Castellani, 1917.
    4. M. nivea (Castellani, 1910).
    5. M. parabalcanica (Castellani, 1916).
    6. M. pseudoguillermondi (Castellani, 1916).
    7. M. pseudolondinensis (Castellani, 1910).
    8. M. pulmonalis (Castellani, 1911).
    9. M. zeylanica (Castellani, 1910).
  - (d) ***By their presence in tea-dust***:—
    1. M. blanchardi (Castellani, 1912).
    2. M. lustigi (Castellani, 1912).
    3. M. perryi (Castellani, 1912).

II. *Associated with sprue :—*
1. M. decolorans Castellani and Low, 1913.
2. M. enterica Castellani, 1911.
3. M. fæcalis Castellani, 1911.
4. M. insolita Castellani, 1911.
5. M. intestinalis Castellani, 1911.

C. *Species found in vaginal discharge in the tropics and in Europe :—*
1. M. balanica (Castellani, 1910).
2. M. metalondinensis (Castellani, 1910).
3. M. naborroi (Castellani, 1917).
4. M. parabalcanica (Castellani, 1910).
5. M. pinoyi (Castellani, 1910).
6. M. tropicalis (Castellani, 1910).

D. *Species found in man, but not classified :—*
1. M. lactea Castellani, 1913.
2. M. lacticolor Castellani, 1913.

A brief description of these species may be given.

Monilia albicans Robin, 1853.

Synonyms. *Oidium albicans* Robin, 1853; *Syringospora robini* Quinquaud, 1868; *Saccharomyces albicans* Rees, 1877; *Monilia albicans* Zopf, 1890; *Endomyces albicans* Vuillemin, 1898.

One of the fungi giving rise to thrush. Widely different descriptions have been given of the so-called thrush-fungus. Some authorities (Hewett) state that the organism liquefies gelatine; others affirm the reverse. Several writers give it as clotting milk, others as having no action on this medium. Castellani has demonstrated that man can be affected by numerous different species of *Monilia*, and that the term thrush-fungus (*Oidium albicans*, *Endomyces albicans*, *Monilia albicans*) has been in the past used to cover a number of different species, in the same manner that the term *B. coli* was for years applied to a multitude of different intestinal bacteria, when a few fermentation tests only were carried out. As the species *M. albicans* has to be split into many species, we keep the term *M. albicans* for the species which we are now describing, and which clots milk and liquefies gelatine.

FIG. 567 *Monilia albicans* ROBIN.

Parasitic Life.—This fungus forms white patches on the tongue and oral mucosa. The patches are easily detached. A particle of the patch examined microscopically shows septate mycelial threads, occasionally ramified, with segments straight or somewhat bent, and easily dissociated. Each segment is about 20 μ in length and 3 to 5 μ in breadth. At the terminal end of each mycelial thread three or four shorter ovoid elements are found, which reproduce by budding. Some similar ovoid or roundish globular refringent cells may be observed originating laterally at the septations of the mycelium. These globular elements (conidia) become detached, and reproduce by budding.

Cultures.—The fungus grows best of all on slightly acid Sabouraud's maltose agar or on glucose agar, but grows fairly well also on all alkaline media. In cultures the fungus appears under two forms—a globular form morphologically similar to a typical yeast, and reproducing by budding; a filamentous form, showing mycelial threads, simple or ramified. *Asci* and *internal spores*, as in the genus *Endomyces*, are absent. On Sabouraud's and glucose agar the growth is abundant, smooth, of a creamy-white colour; on ordinary agar the growth is less abundant. Gelatine and serum are very slowly liquefied. Milk is rendered acid, and after a time it clots. The sugar reactions are given in the table.

Pathogenicity.—*M. albicans* is one of the fungi which gives rise to *thrush*. This condition may be due to several different fungi—*M. albicans*, *Endomyces vuillemini*, *M. tropicalis*, etc. (p. 1741). *Thrush* is generally restricted to the oral mucosa, but in certain cases it may spread to the œsophagus, stomach, intestine. *M. albicans* has been found also in a few cases of bronchomycosis.

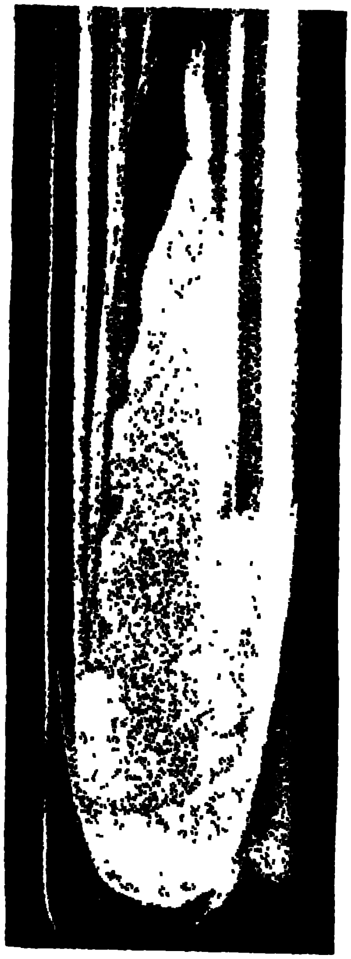

FIG. 568.—*Monilia tropicalis*—CASTELLANI

Monilia tropicalis (Castellani, 1909).

Synonym.—*Endomyces tropicalis* Castellani, 1909.

Found by Castellani in Ceylon in many cases of bronchomycosis. In the expectoration round or oval shape yeast-like cells are seen, and at times segments of mycelium. Cultures are easily obtained on Sabouraud's or glucose agar, and even on ordinary agar. It grows more abundantly on slightly acid than on alkaline media. On Sabouraud's and glucose agar the growth is abundant, creamy white, with a smooth surface when young; often slightly crinkled when old. The growth is composed practically of only globular yeast-like cells, while in the water of condensation globular cells and mycelium may be found together. A little mycelium may be found, however, occasionally in the growth on the slope. Ascus formations are absent. Gelatine and serum are not liquefied; there is no brownish discoloration of the serum, as is the case with some other species of *Monilia* (*M. insolita*, etc.). Litmus milk is generally rendered acid, but is not clotted. The sugar reactions will be found in the table on pp. 1082, 1083. It produces acid and gas in glucose, levulose, maltose, and also, in less amount, in galactose and saccharose. After some transplantations it often loses its fermentative power on galactose and saccharose.

Pathogenicity.—Is the commonest cause of a type of bronchomycosis (see Bronchomoniliasis, p. 1886). In Ceylon it has been found by Castellani also in a few cases of *thrush*, and in a case of *pseudo-diphtheria* which terminated fatally. This case was a little native girl, who developed white patches on the tonsils, uvula, and soft palate. The microscopical examination revealed absence of *B. diphtheriæ* and presence of *M. tropicalis*. Symptoms of broncho-pneumonia soon developed, and the child died. At the autopsy the fungus was found in enormous amount in the bronchi; it was pathogenic for guinea-pigs.

Monilia paratropicalis (Castellani, 1909).

Synonym.—*Endomyces paratropicalis* Castellani, 1910.

Found in some cases of bronchomycosis by Castellani. Microscopically and on Sabouraud's and glucose agars identical with *M. tropicalis*. Does not coagulate milk. Differs from the typical *M. tropicalis* by producing acid and gas in very large amount in saccharose and in rendering dextrin acid (see table).

The same fungus, or a very similar one, was found in two cases of blastomycosis of the skin in Ceylon.

Monilia pseudo-tropicalis (Castellani, 1910).

Synonym. —*Endomyces pseudo-tropicalis* Castellani, 1910.

Found by Castellani in a few cases of bronchomycosis. Differs from *M. tropicalis* and *M. paratropicalis* by clotting milk and fermenting lactose with the production of gas. For the sugar reactions see table.

Monilia metatropicalis Castellani, 1916.

Differs from *M. tropicalis* in clotting milk

Monilia bronchialis (Castellani, 1910).

Synonym.—*Endomyces bronchialis* Castellani, 1910.

Found in sputum. Colonies white. Has no action on milk, gelatine, serum. Sugar reactions are found in the table.

Monilia chalmersi Castellani, 1912.

Found by Castellani in a case of bronchitis. Colonies of white colour. Renders the milk first slightly acid, then alkaline. Does not liquefy either gelatine or serum. Sugar reactions are collected in the table.

Monilia parachalmersi (Castellani, 1917).

Differs from *M. chalmersi* in slowly liquefying gelatine and in other minor characters. Found in sputum.

Monilia macedoniensis Castellani, 1917.

Found in sputum. Clots milk. Belongs to the Chalmersi group.

Monilia guillermondi (Castellani, 1910).

Synonym.—*Endomyces guillermondi* Castellani, 1910.

Observed in sputum once by Castellani. Milk is rendered alkaline. Serum and gelatine are not liquefied. For sugar reactions see table.

Monilia pseudo-guillermondi Castellani, 1916.

Clots milk.

Monilia nivea (Castellani, 1910).

Synonym.—*Endomyces niveus* Castellani.

Found in a sample of sputum which had not been collected in a sterile vessel. Of doubtful pathogenicity. For cultural and biochemical characters see table.

Monilia nitida (Castellani, 1910).

Synonym.—*Endomyces nitidus* Castellani, 1910.

Observed in a sample of sputum by Castellani. Of doubtful pathogenicity. Milk is rendered first acid, then decolourized and clotted. Other cultural characters are found in the table.

Monilia zeylanica (Castellani, 1910).

Synonym.—*Endomyces zeylanicus* Castellani, 1910.

Found in sputum by Castellani. Growth on glucose agar of a yellowish colour. Milk is rendered very acid and is slowly clotted. Gelatine and serum are not liquefied. Does not produce gas in any carbohydrate, with the doubtful exception of raffinose.

Monilia krusei (Castellani, 1909).

Synonyms.—*Saccharomyces krusei* Castellani, *Endomyces krusei* Castellani.

Found in sputum by Castellani. In sputum it appeared as a saccharomyces, and in cultures had all the characters of a saccharomyces at first, except that no asci were observed; after several generations a little mycelium was present on Sabouraud's agar. The sugar reactions are found in the table. It produces acid and gas in glucose and levulose. Its reactions remain constant after ten years.

Monilia pinoyi (Castellani, 1910).

Synonym.—*Endomyces pinoyi* Castellani, 1910.

Found in sputum. Grows well on Sabouraud's and glucose agar, and other sugar media; also on ordinary agar, though less abundantly. Does not clot milk; does not liquefy either gelatine or serum. Produces acid and gas in glucose, levulose, maltose.

Monilia enterica (Castellani, 1911).

Synonyms.—*Endomyces entericus* Castellani: *Monilia psilosis* Ashford: *Parasaccharomyces ashfordi* Anderson, 1916.

Found in stools by Castellani. Milk is rendered alkaline. Gelatine and serum are not liquefied. For sugar reactions see table.

Monilia fæcalis (Castellani, 1911).

Synonym.—*Endomyces fæcalis* Castellani, 1911.

Found in intestinal contents by Castellani. Milk is rendered first acid, then decolourized, and, later, slightly peptonized. Gelatine is not liquefied; serum is not liquefied, but a brownish pigmentation develops on the medium all round the growth. For sugar reactions see the table (p. 1082).

Monilia insolita (Castellani, 1911).

Synonym.—*Endomyces insolitus* Castellani, 1911.

Found in stools and in the saliva. The milk is rendered first slightly acid, then alkaline. On serum a zone of dark pigmentation develops on the surface of the medium round the growth. The medium is not liquefied. For other cultural characters see the table.

Monilia intestinalis (Castellani, 1911).

Synonym.—*Endomyces intestinalis* Castellani, 1911.

Found in stools and saliva by Castellani. Colonies on solid media white. Milk first rendered acid, then slowly decolourized. The growth on serum is not surrounded by a zone of dark pigmentation. Further cultural characters are found in the table (p. 1082).

Monilia alba (Castellani, 1911).

Clots milk. Produces acid and gas in glucose, levulose, maltose, galactose, and acid only in saccharose. Does not liquefy gelatine or serum.

Monilia rhoi (Castellani, 1909).

Synonym.—*Endomyces rhoi* Castellani, 1909.

Found by Castellani in Ceylon in several cases of otomycosis, and once in a sample of tea. In the ear the fungus forms a whitish

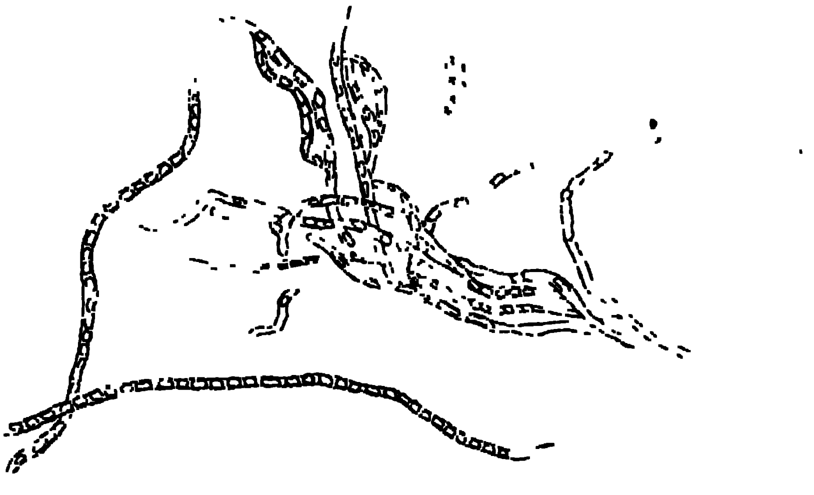

FIG. 569.—*Monilia rhoi* CASTELLANI.

(From a fresh preparation. The free spores are not shown.)

mass (generally embedded in wax), in which numerous long, septate mycelial threads, 2 to 3·5 μ in breadth, and numerous roundish free spores, 3·5 to 5 μ in diameter, are seen. On laboratory media it generally grows, showing a yeast-like type. Does not clot milk; does not liquefy gelatine and serum. The sugar reactions are quoted in the table (p. 1082).

In the cases of otomycosis the mycelium was abundant, the mycelial threads being very long and septate, 3 to 4 μ in breadth; very numerous free, round spores, 4 to 5 μ in diameter, were present For cultural characters see table.

Monilia burgessi (Castellani, 1912).

Synonym.—*Endomyces burgessi* Castellani, 1911.

Isolated from the air Grows abundantly on the usual sugar media, the growth being of a white creamy appearance. Does not render acid or coagulate milk. Does not liquefy serum or gelatine. On serum it produces a zone of peculiar brownish or black discoloration in the medium all round the growth. The sugar reactions are found in the table.

Monilia pulmonalis Castellani, 1911

Found by Castellani in sputum and also in samples of tea. For cultural characters see table (p. 1082).

Monilia lustigi Castellani, 1912

Found in samples of tea. Grows well on all sugar media and also on ordinary agar, the growth being of a snow white colour. Renders litmus milk slightly acid, and then decolourizes it completely. Does not liquefy serum or gelatine. On serum it induces a narrow zone of black discoloration all round the growth. The sugar reactions are found in the table (p. 1082).

Monilia balcanica Castellani, 1916.

Found in sputum and also in a case of dermatitis, of which it was not the cause. Produces gas in glucose only. Levulose often rendered acid (see table).

Monilia parabalcanica Castellani, 1916.

Differs from *M. balcanica* in clotting milk.

Monilia perryi Castellani, 1912.

Found by Castellani in samples of tea-dust. The cultural characters and chemical properties are seen in the table.

Monilia nabarroi Castellani, 1917.

Clots milk and produces gas in glucose, levulose, and maltose. Found in sputum. An identical or very similar variety has been found in vaginal mucus by Castellani and Taylor.

Monilia blanchardi (Castellani, 1912).

Synonym.—*Endomyces blanchardi* Castellani, 1912.

Isolated from tea-dust by Castellani. Grows abundantly on maltose, glucose, and other sugar media; also on ordinary agar, though less vigorously. The growth is of a white colour and smooth surface. Milk rendered at first very slightly acid, and then alkaline. No liquefaction of gelatine or serum. Does not produce gas in any sugar except, in small quantity, in glucose.

Monilia bethaliensis Pijper, 1918.

Found by Pijper in a case of bronchitis. Ferments glucose and maltose with production of gas. Action on levulose not known. Gelatine not liquefied, milk not clotted

Monilia rosea (Zenoni, 1912).

Synonym.—*Oidium roseum non liquefaciens* Zenoni, 1912.

The cultures on Sabouraud's and other sugar media are of a pinkish colour. Neither serum nor gelatine are liquefied

Pathogenicity.—Was isolated by Zenoni in a peculiar case of hepatitis with fever and jaundice which ended fatally. Microscopically conidia and mycelial filaments could be seen very abundant in and about the smaller hepatic bloodvessels and the bile-ducts. The fungus is pathogenic to rabbits, guinea-pigs, and white rats

Monilia subtilis (Blanchard, 1895)

Synonyms.—*Oidium subtile cutis* Babès, 1895; *Mycoderma subtile* Verdun, 1912.

Found by Babès in some ulcers on which the fungus produced white membranes. The mycelial threads were thinner than in most species of *Monilia* There was dichotomous branching, and at the extremities of the mycelial threads ovoid conidia were present. Biochemical properties of the fungus not known Pathogenic for the rabbit.

The same, or a very similar, fungus was later found by Clozel, de Boyer and d'Antin in a peculiar pustular affection observed in cachectic children

Monilia pulmonea (Bennett, 1842).

Synonyms.—*Oidium pulmoneum* Bennett, 1842; *Oöspora pulmonea* Saccardo, 1886; *Mycoderma pulmoneum* Vuillemin, 1891.

The organism was found in a case of pneumothorax by Bennett in 1842, it was observed again by Vuillemin in the sputum of a tubercular patient in 1891, and in an ulcerative dermatitis by Balzer, Burnier, and Gougerot in 1910. It grows under two types—a saccharomyces-like and a filamentous type. Colonies on glucose agar white. Biochemical reactions not given.

Monilia candida (Bonorden, 1851).

Synonym.—*M. bonordeni* Vuillemin.

Commonly found vegetating in decomposing vegetable matter; occasionally seen parasitic in Mammalia, giving rise to white patches on the tongue and buccal mucosa, somewhat similar to human *thrush*. Once found in a child in some white patches present on the tongue. Mycelium elements easily dissociated. Yeast-like conidial elements. Pellicles in fluid sugar media. Ferments glucose and saccharose, and, according to Bau, dextrin. Its action on other carbohydrates and gelatine has not been recorded. Mycelial tubes thinner than in most *Monilias* (1 to 1½ μ in breadth); conidia roundish, smooth, 7 to 8 μ in diameter. Biochemical actions of the fungus have not yet been investigated completely. Found in cow-dung, on which it forms white membranes.

Monilia kochi (von Wettstein, 1885).

Synonym.—*Rhodomyces erubescens* Aster, 1900.

Morphologically similar to *M. candida*; grows well on sugar media, where it produces pinkish colonies; was observed by Wettstein in a case of chronic acid dyspepsia. Biochemical properties not studied.

Monilia montoyai (Castellani, 1907).

Synonym.—*Monilia pictor* Neveu-Lemaire, 1908.

Discovered by Montoya in cases of white pinta. Some fertile hyphæ are much thicker than others; the spores are large, globular (5 to 7 μ), and contain a large nucleus. Grows well on sugar media, giving rise to white creamy colonies which rapidly fuse together. Biochemical properties of the fungus not known.

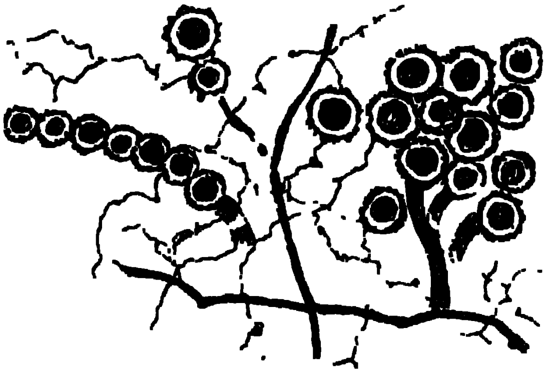

FIG. 570. *Monilia montoyai* (After Montoya y Florez.)

Monilia cutanea (de Beurmann, Gougerot, and Vaucher, 1909).

Synonyms.—*Oidium cutaneum* de Beurmann, Gougerot, and Vaucher, 1909; *Mycoderma cutaneum* Verdun.

Isolated by de Beurmann, Gougerot, and Vaucher from a case showing a peculiar gummatous condition clinically resembling sporotrichosis or syphilis. The fungus, on certain media (glycerine agar), vegetates as a saccharomyces and ferments glucose; on other media (agar) mycelium and yeast-like cells are present, and the fungus does not ferment glucose any longer. On glucose agar the growth is white-yellowish, mammillary, with a radiating aureola. The fungus, unless injected in massive doses, is not very pathogenic to the rabbit, guinea-pig, and rat. Intraperitoneal injections of rather large doses induce in these animals a nodular peritonitis.

Monilia caoi Verdun, 1912.

Found by Cao in the sputum of a tubercular patient in association with the tubercular bacillus. Yellowish colonies on ordinary agar. Pathogenic to rabbits. Biochemical reactions not given.

Monilia harteri Verdun, 1912.

Synonym. *Parasaccharomyces* sp. (?) de Beurmann and Gougerot.

Found by Harter in a case of enteritis which later developed hepatic, bronchial, and cutaneous lesions, due to the same fungus. On maltose agar and carrots the colonies are cream-white, and yeast-like cells only are generally found. In Raulin's liquid mycelial threads are present, septated, 2 μ in breadth. The fungus does not liquefy gelatine, does not coagulate milk; produces slight acidity, but not gas, in saccharose.

Monilia perieri Matruchot and Antoine, 1917.

Synonym.—*Oöspora perieri* Matruchot and Antoine.

Found in a case of thrush of a wound. Biochemical reactions not given.

Monilia parakrusei Castellani, 1912.

Differs from *M. krusei* in clotting milk. Found by Castellani in sputum.

Genus Oidium Link, 1809, *emendavit* Pinoy.

Definition.—Oösporaceæ with hyphæ terminating in chains of spores. Hyphæ long and branched. Sporophores simple, septate, often without disjunction apparatus. Do not produce gas in carbohydrates.

Type Species.—*Oidium lactis* Link, 1809.

Remarks.—Pinoy has adjusted this genus, so that now it contains human parasites, which are:—

Oidium lactis Link, 1809.
Oidium rotundatum Castellani, 1911.
Oidium asteroides Castellani, 1914.
Oidium matalense Castellani, 1915.

These fungi may be differentiated as follows:—

A. Only produces slight acidity, and only at times, in glucose; cultures white—*Lactis*

B. Produce acidity in several carbohydrates:—
  I. No acidity in glucose, culture white and hairy—*Matalense*
  II. Acidity in glucose:—
    (*a*) No acidity in mannitol:—
      Mycelial spores, roundish or oval. Typical colonies convoluted—*Rotundatum*.
    (*b*) Acidity in mannitol:—
      Mycelial spores, quadrangular. Typical colonies asteroid—*Asteroides*.

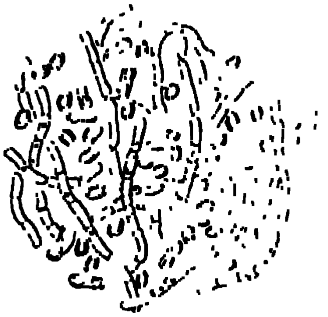

FIG. 571.—*Oidium rotundatum* CASTELLANI. FRESH PREPARATION.

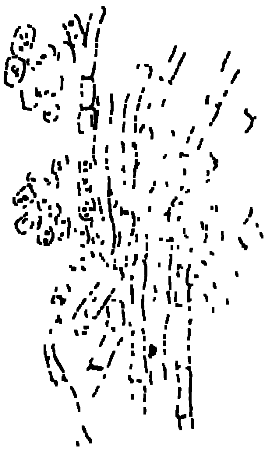

FIG. 572.—*Oidium asteroides* CASTELLANI. FRESH PREPARATION.

Oidium lactis Link, 1809.

Definition.—Oidium found in milk, in which it produces acid and clot. Grows easily on ordinary culture media, producing white colonies. It does not form gas in carbohydrate media, and only slight acidity at times in glucose.

Name of Fungus	*Litmus Milk.*	*Glucose.*	*Levulose*	*Maltose*	*Galactose*	*Saccharose*	*Lactose*	*Mannite*	*Dulcite*	*Dextrin*	*Colour of Growth.*	*Remarks.*
Oidium asteroides Cast., 1914 ..	AC	A	A	A	A	A	A	O or Avs	O	O	Whitish yellowish and amber colour	Isolated colonies have often a radiating appearance. Liquefaction of gelatine may be extremely slow.
Oidium lactis Link, 1809 ..	AC	O or As	O	O	O	O	O	O	O	O	White	—
Oidium matalense Cast., 1915	O or As	O or A	O or A	As	O or Avs	O or As	O	O	O or As		White	--
Oidium rotundatum Cast., 1911	A or AC	As	A	O or As	As	O	O or Avs	O or As	O		Yellowish	Surface of cultures often has a crinkled appearance. Liquefaction of gelatine may be extremely slow.

Name of Fungus	*Raffinose*	*Arabinose.*	*Adonite.*	*Inulin.*	*Sorbite.*	*Indol.*	*Gram*	*Gelatin.*	*Serum*	*Colour of Growth.*	*Remarks*
Oidium asteroides Cast., 1914	O or Avs	O or As	O	O		O	-	—	O	Whitish-yellowish and amber colour	Isolated colonies have often a radiating appearance. Liquefaction of gelatine may be extremely slow.
Oidium lactis Link 1809 ..	O	O	O	O	-	O	+	O	O	White	—
Oidium matalense Cast., 1915	O	O or A	O or As	O or Avs	-	O	—	O	O	White	--
Oidium rotundatum Cast., 1911	O	O or A	--	O	---	O	+	+	O	Yellowish	Surface of cultures often has a crinkled appearance. Liquefaction of gelatine may be extremely slow or absent.

Abbreviations used in the Tables.—A = acid; G = gas; C = clot (in milk); [illegible] P = [illegible] pellicle present. D = decolourized. P = peptonized (milk); p = pellicle (broth). Alk = alkaline. $\frac{A}{Alk}$ = acid, then alkaline. s = slight; vs = very slight. O = negative result—viz., neither acid nor clot in milk; neither acid nor gas in sugar media; non-production of indol; non-liquefaction of gelatine or serum as the case may be. + = positive result, liquefaction of medium. f = fine.

Remarks.—It was found by Link in milk and recently by Linossier in cases of bronchitis. The latter was considered to be slightly different and to form a pathogenic race, *Oidium lactis* var. A.

Oidium rotundatum Castellani, 1911.

Definition.—Oidium growing on glucose agar and producing crinkled or vermiform yellowish growths. It gives rise to acidity in milk, and after a variable time may form a clot. Gelatine is liquefied, but liquefaction may be extremely slow or absent with certain strains. For the sugar reactions see the table (p. 1094). It forms acid in glucose, levulose, galactose, maltose, and lactose.

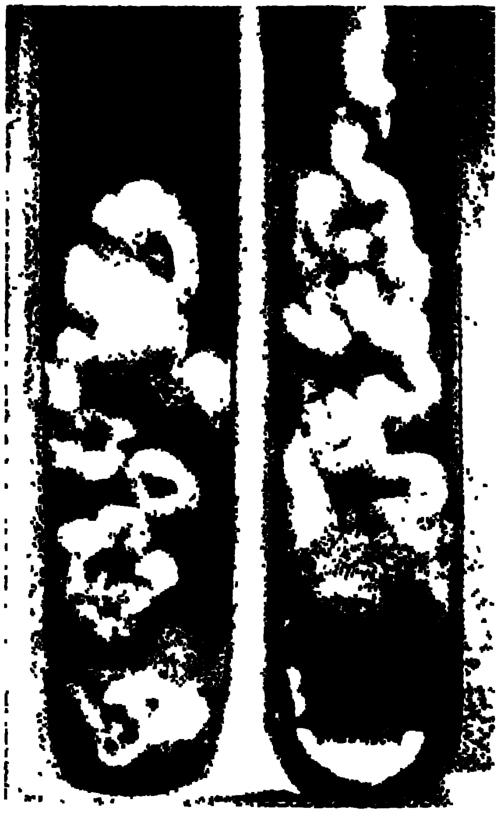

Fig 573 Fig. 574.

Figs. 573 and 574.—*Oidium rotundatum* Castellani. Culture.

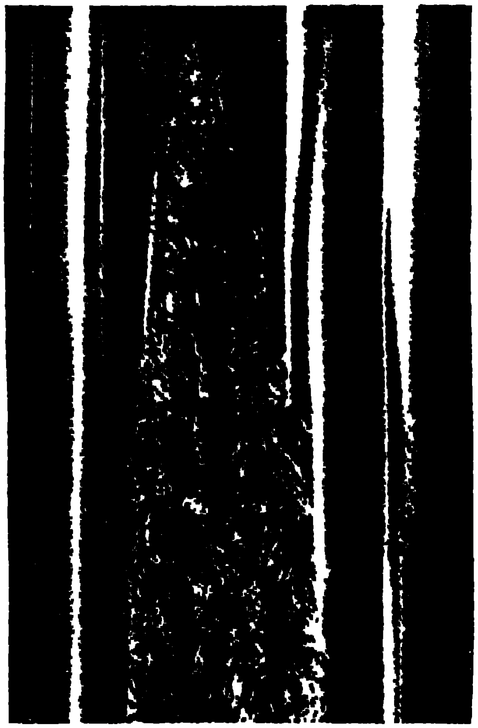

Fig. 575.—*Oidium asteroides* Castellani. Culture.

Remarks.—Found in cases of bronchitis and a very similar or identical form in the fæces of cases of sprue and of enteritis.

Oidium asteroides Castellani, 1914.

Definition.—Oidium producing colonies with a characteristic radiating appearance on glucose agar, from which it derives its name. It grows badly or not at all upon inspissated blood serum, which it does not liquefy. It turns milk acid and clots it in a variable time. No gas is formed in any carbohydrate medium.

Remarks.—This fungus was isolated from stools in cases of sprue and from the sputum in cases of chronic bronchitis.

FIG. 576.—*Oidium matalense* CASTELLANI. CULTURE.

Oidium matalense Castellani, 1915.

Definition.—Oidium producing a white growth on glucose agar. It turns milk sometimes slightly acid, without the formation of a clot, or it may have no effect. Gelatine is not liquefied, nor is any gas produced in carbohydrate media.

FAMILY 3: ENANTIOTHAMNACEÆ Chalmers and Archibald, 1915.

Definition.—Blastosporineæ with a thallus composed of ramifying hyphæ, with regular septa, which easily disappear, thus dissociating the segments, which are 2-2·5 microns broad. The conidia are arranged verticillately around the septa.

Remarks.—This family contains only one genus, *Enantiothamnus* Pinoy, 1911. The name is derived from ἐναντίος, 'opposite,' and θάμνος, 'a shrub.'

Genus Enantiothamnus Pinoy, 1911.

Definition.—Enantiothamnaceæ with the characters of the family.

Remarks.—There is only one species so far known, *Enantiothamnus braulti* Pinoy, 1911.

Enantiothamnus braulti Pinoy, 1911.

Definition.—Enantiothamnus with oval conidia 2-2·5 by 1-1·5 microns.

Habitat.—Parasitic in man.

Remarks.—This fungus was discovered by Brault in umbilicated tumours containing pus, in the gluteal region of an Arab in Algiers.

On Sabouraud's agar the colonies are white, with a yellowish central portion.

Pathogenicity.—Produces tumours and pus in man, and is pathogenic for guinea-pigs.

FIG. 577.—*Enantiothamnus braulti* PINOY. (After Brault and Pinoy.)

FAMILY 4: HAPLOGRAPHIACEÆ Saccardo, 1896.

Definition.—Blastosporineæ with hyphæ manifest and distinct from the conidia, which are usually arranged in chains, or, in parasitic condition in man, in grape-like masses.

Remarks.—This family contains the genera *Hormodendrum* Bonorden, 1851, and *Malassezia* Baillon, 1889, which are recognizable as follows:—

All sterile hyphæ creeping. Conidia all alike and produced on the hyphæ. Conidiophores not spirally twisted; hyphæ dendroid:—

A. Conidia in cultures in chains, in parasitic form in masses—Genus *Hormodendrum* Bonorden, 1851.

B. Conidia in parasitic form in masses. Cultural form unknown—Genus *Malassezia* Baillon, 1889.

Genus Hormodendrum Bonorden, 1851.

Definition.—Haplographiaceæ with creeping dendroid sterile hyphæ and branched conidiophores, bearing conidia all of one kind.

Remarks.—The genus Hormodendrum contains about ten species, which are generally parasitic on plants or saprophytic, but one is known to occur in man—viz., *H. fontoynonti*.

Type Species.—*Hormodendrum olivaceum* (Corda, 1838). The name is derived from *ὅρμος*, 'a chain,' and *δένδρος* (or *δένδρον*), 'a

Hormodendrum fontoynonti Langeron, 1913.

Definition.—Hormodendrum in cultures with sterile hyphæ 3 to 8 microns in diameter, greenish brown in colour, septate with thick walls. Sporophores well defined, not swollen at the extremity, carrying chains of very caducous spores. In man mycelium broken in segments, long and undulating; spores, which are capable of budding, arranged in masses.

Remarks.—Found by Fontoynont and Carougeau in the scales of a dermatosis, called 'hodi-potsy' in Madagascar, which is comparable to that termed 'tinea flava' in other tropical countries. It is doubtful whether the fungus is the ætiological agent of the condition.

Genus Malassezia Baillon, 1889.

Definition.—In man mycelium broken into septate segments, with T-shaped or budding extremities. The hyphæ carry round or oval conidia, which may be solitary or in grape-like masses, and may be smooth or with longitudinal, radial, or spiral marks. In culture unknown.

Remarks.—This genus is only known to contain parasites of man The two species may be recognized as follows:—

I. Causing a brown eruption on the white skin—*i.e.*, tinea versicolor. Lesions very superficial—Species *Malassezia furfur* Charles Robin, 1853.

II. Causing a red eruption on the white skin and a yellow eruption on the dark skin—*i.e.*, tinea flava. Deeper lesions—Species *Malassezia tropica* (Castellani, 1905).

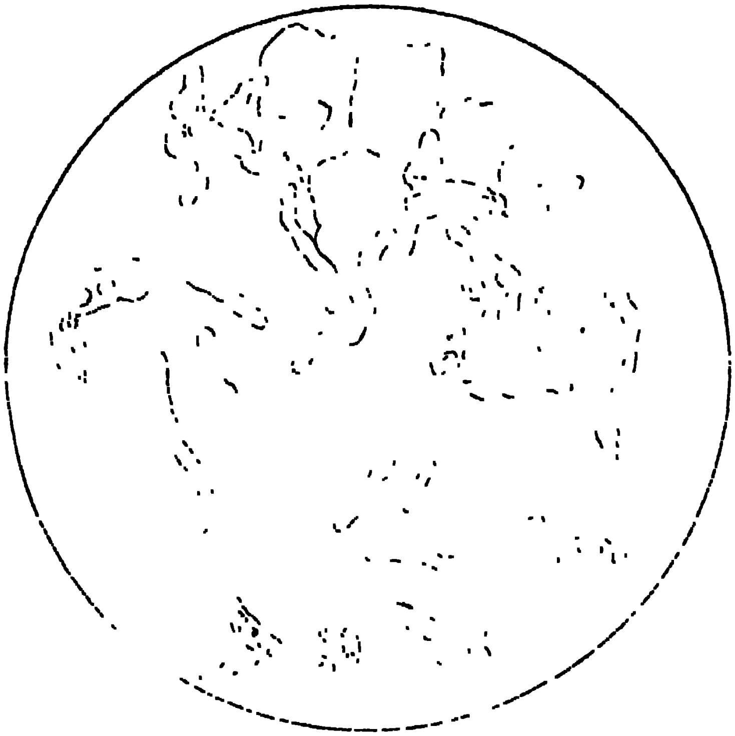

FIG. 578.—*Malassezia tropica* CASTELLANI.

From a fresh preparation in liquor potassæ. Old case.)

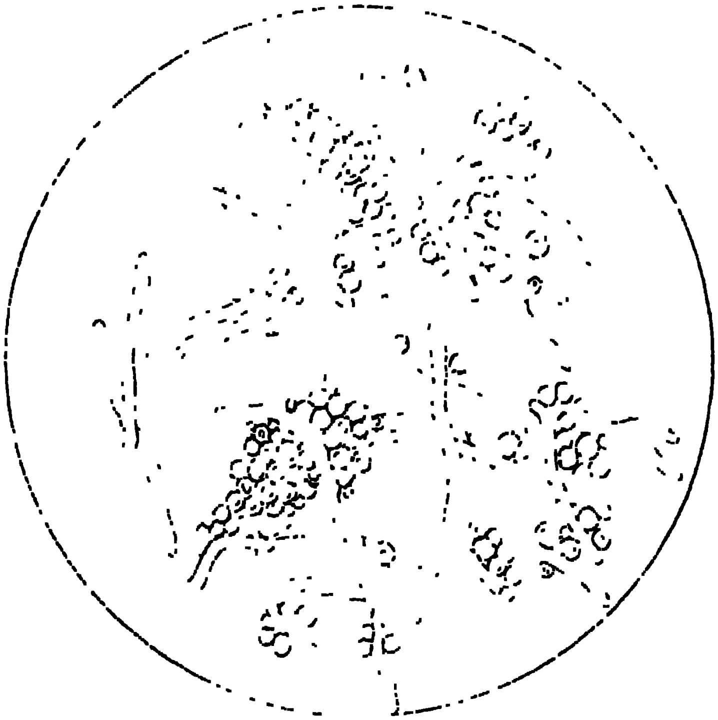

FIG. 579.—*Cladosporium mansoni* CASTELLANI.

(From a fresh preparation in liquor potassæ. The mycelial tubes are in reality not so regular in outline as in this drawing.)

Malassezia furfur Ch. Robin, 1853.

Synonyms.—*Microsporon furfur* Ch. Robin, 1853; *Sporotrichum furfur* Saccardo, 1886; *Malassezia furfur* Baillon, 1889; *Oidium furfur* Zopf, 1890; *O. subtile* Kotliar, 1892.

Mycelium abundant, septate, non-ramified; some mycelial threads are much larger than others; the breadth varies between 3 and 4 μ. The spores are roundish (3 to 5 μ in diameter), and run into clusters. Attempts at cultivation have failed. It is the cause of pityriasis versicolor.

Malassezia tropica Castellani, 1905.

Synonym. *Microsporon tropicum* Castellani, 1905.

Mycelial threads generally thick (3 to 5 μ wide), with numerous swellings, constrictions, and other irregularities of shape; spores roundish (4 to 5 μ), with a double contour; are often collected in clusters. The fungus does not grow on artificial media. It is the cause of tinea flava or pityriasis flava of tropical climates.

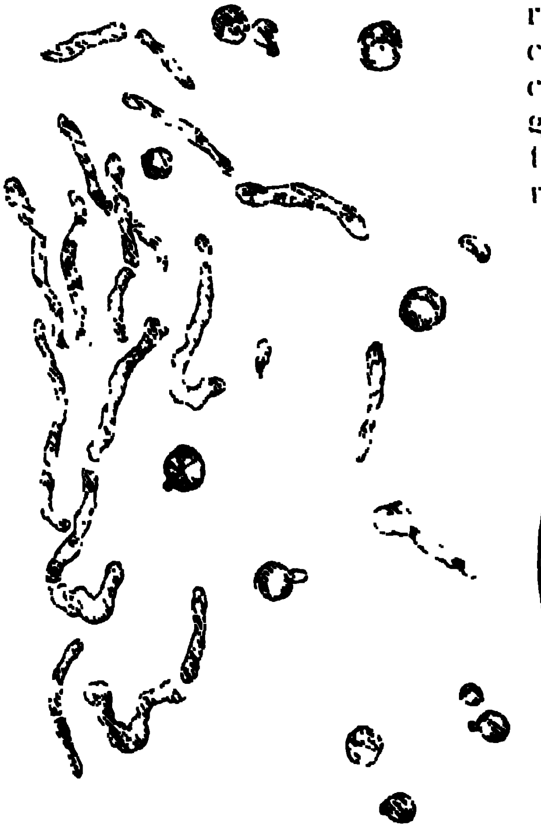

FIG. 580.—*Cladosporium mansoni* CASTELLANI.

(From a preparation stained by fuchsin.)

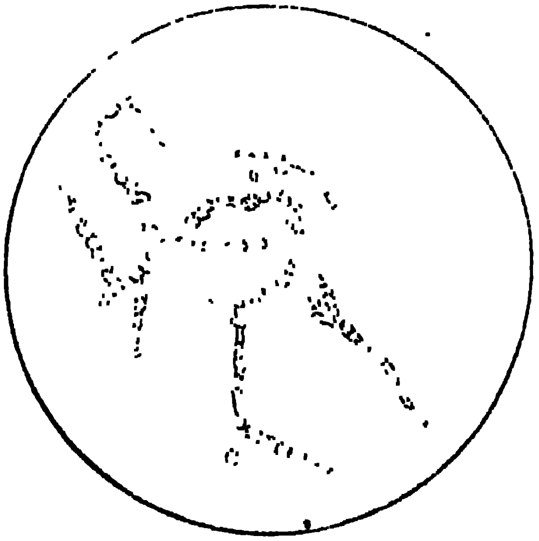

FIG. 581.—*Cladosporium mansoni* CASTELLANI. HANGING-DROP CULTURE.

FAMILY 5: CLADOSPORIACEÆ Saccardo, 1886.

Definition.—Blastosporales with hyphæ manifest and distinct from the conidia, which are either solitary or arranged in short chains.

Remarks.—We are only concerned with the type genus *Cladosporium* Link, which may be recognized as follows:—

Conidia smooth, not capitate, more or less in chains at first. Hyphæ and conidia uniform. Hyphæ not inflated, but decumbent; conidia in short chains and finally solitary—Genus *Cladosporium* Link, 1809.

Genus Cladosporium Link, 1816.

Definition.—Cladosporiaceæ with decumbent hyphæ. Conidiophores bearing smooth, uniform conidia arranged in short chains or solitary.

Etymology.—The name is derived from κλάδος, 'a young shoot.'

Remarks.—The type species is *Cladosporium herbarium* Persoon, 1801, and there are a very large number of species scattered all over the world, and commonly found on plants in tropical gardens, from whence the spores can easily be conveyed to the human skin, and either grow there, causing a lesion, or simply remain sheltered among the scales of other lesions, from which they may be grown in pure culture, thus giving rise to the impression that they may be causal organisms, but they do not agglutinate with the patient's serum.

They may also grow as contaminations of laboratory media, so commonly may their spores be found in the air. The two species known in man may be recognized as follows:-

Habitat, tinea nigra—Species *Cladosporium mansoni* (Castellani, 1908).

Habitat, ulcerating nodules—Species *Cladosporium penicilloides* Gueguen, 1911.

Fig. 582.—*Cladosporium mansoni* Castellani. Young Agar Culture.

Cladosporium mansoni Castellani, 1905.

Synonyms.—*Microsporon mansoni* Castellani, 1905; *Foxia mansoni* Castellani, 1908; *Cladosporium mansoni* Pinoy, 1912.

The fungus is found very abundantly in the lesions of tinea nigra; the mycelial articles are rather short—18 to 20 μ in length and 2½ to 3½ μ in breadth; non-ramified. Sometimes they may be irregular in outline, bent, banana-shaped. The spores are globular, and most of them very large—5 to 10 μ. They are frequently arranged in clusters.

The fungus is easily cultivated by inoculating scrapings of the affected patches on maltose agar. After two to four days roundish hemispheric colonies appear, which are black, but at first have usually a greenish tinge, and may present at the periphery some radiating, delicate, pale greenish hyphæ. These colonies may remain separate or more often gradually coalesce into a jet-black knobby mass, deeply rooted into the medium. The fungus grows well, though less abundantly, on the other sugar agars, and also on ordinary agar. In *broth* and *peptone-water* the growth is very slow, and takes place at the botton of the tubes, with formation of a black or greenish-black sediment. Gelatine is very slowly liquefied.

The *optimum temperature* for the growth of the fungus is between 30° C. and 32° C.; above 35° C. and under 25° C. the growth is much slower, and may be nil under 20° C.

This fungus is the cause of tinea nigra (p. 2078).

Cladosporium penicilloides Gueguen, 1911.

Synonym.—*C. Madagascariense* Verdun, 1913.

Found by Fontoynont in a patient with some ulcerated nodules of the leg in Madagascar. The fungus grows easily on Sabouraud's and other media, giving rise to black cerebriform colonies. In hanging-drop cultures shows the typical features of the genus.

Cladosporium herbarium Persoon has been demonstrated by Nassee to be the cause of the black spots so often found on imported frozen meat.

SUBORDER 2. ARTHROSPORINEÆ VUILLEMIN, 1910.

Definition.—Thallosporales with yeast-like forms, associated in cultures with hyphæ and other forms with longer hyphæ. Reproduction by means of arthrospores parasitic on man.

Remarks.—Vuillemin includes in this suborder the genera Trichophyton, Microsporon, Achorion, and their allies, although it is more usual to consider these to be allied to the Gymnoascaceæ, because *Ctenomyces serrata* Eidam, 1880, when injected into animals, develops a trichophyton-like mycelium and eruption, which classification has recently been supported by the work of Marshall and one of us on *T. currii*. However, for the present, we propose to leave these genera and their allies out of consideration.

Classification.—This suborder contains the following genera:—

A. Producing *Piedra* on hairs—Genus *Trichosporum* Behrend, 1890.

B. Producing *Black Maduromycosis*—Genus *Madurella* Brumpt, 1905.

C. Producing *White Maduromycosis*—Genus *Indiella* Brumpt, 1906.

Genus Trichosporum Behrend, 1890.

Definition.—Arthrosporales living parasitically on the hairs of man in the form of large, oval, or roundish bodies embedded in a ground substance. In cultures elongated hyphæ and spores are formed.

Remarks.—Care must be taken not to confuse *Trichosporum* Behrend, 1890, with *Trichosporium* Fries, 1849, a very different genus with over forty species, mostly saprophytic.

The species of this genus give rise to nodosities on hairs. They are:—

T. giganteum Behrend, 1890, the cause of piedra in Columbia, in hairs of the head.

T. beigeli (Rabenhorst, 1867), the cause of piedra in Europe, in hairs of the beard.

T. ovoides (Behrend, 1890), the cause of piedra, in hairs of the moustache.

T. ovale Unna, 1896, on the hairs of the moustache in Europe.
T. glycophile du Bois, 1910, on the pubic hairs of a diabetic.
The various species may be differentiated as follows:-

A. *Bodies around hair polyhedral* :—
  I. Diameter of bodies 12-15 microns—*Giganteum*
  II. Diameter of bodies 3-4 microns—*Beigeli*.

B. *Bodies around hair oval and small, 3-4 microns by* 1·5-2·5 *microns*:—
  I. In cultures hyphæ often twisted like a corkscrew—*Ovale*.
  II. In cultures hyphæ not so twisted—*Ovoides*.

C. *Bodies around hair roundish*, 3-4 *microns in diameter* :—
  Fungus associated with a coccus, with which it grows well on sugar media—*Glycophile*.

These fungi live parasitic on the surface of the hairs, but do not penetrate into their interior g their parasitic life they vegetate in the shape of large oval or roundish elements, embedded in an amorphous substance. Saprophytically (cultures) they vegetate, forming mycelial threads and spores.

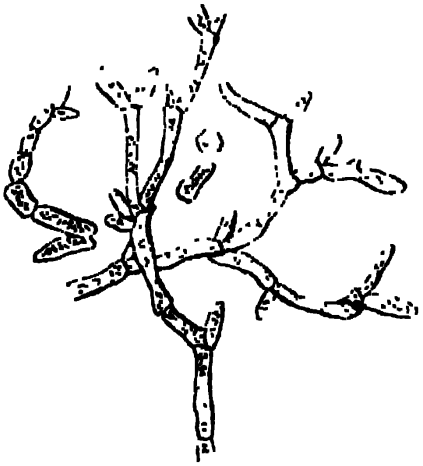

FIG. 583.—TRICHOSPORUM (After Vuillemin

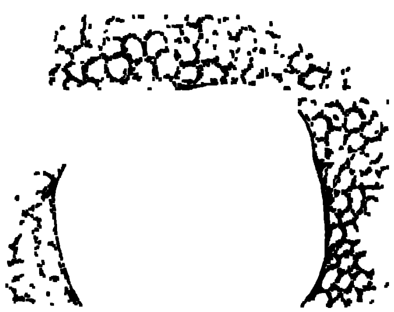

FIG. — TRANSVERSE SECTION OF A PIEDRA NODULE.

Trichosporum giganteum Behrend, 1890.

This is the cause of *piedra* of Columbia; develops on the surface of the hair in the shape of large polyhedric cells 12 to 15 μ in diameter. Masses of the fungus form hard nodules along the hair. The fungus is easily grown on various media. In cultures the mycelial threads are septated, cylindrical, between 1 and 4 μ wide. The spores are of various dimensions, between 2 and 12 μ. The colour of the colonies is light brownish. Horta describes in the nodules of a variety of piedra certain large cyst-like bodies containing generally eight fusiform bodies. When the membrane bursts, these bodies escape, being provided with one flagellum at each end. Pinoy is inclined to consider these formations to be asci containing ciliated ascospores.

Trichosporum beigeli Rabenhorst, 1867.

Synonyms.—*Pleurococcus beigeli* Rabenhorst, 1867; *Sclerotium beigelianum* Hallier, 1868; *Hyalococcus beigeli* Schroeter, 1886; *Chlamydotomus beigeli* Trevisan, 1889; *Micrococcus beigeli* Migula, 1900; *Trichosporum beigeli* Vuillemin, 1901.

This fungus has been found in Europe several times in nodosities of the hairs of the moustache. It lives parasitically under the form of ovoid or polyhedral elements massed together on the surface of the hair. These ovoid or polyhedral elements are much smaller than those of the preceding species, their maximum diameter varying between 3 and 4 μ. It is easily cultivated on ordinary media. In cultures mycelial threads are found, septate, slender (1·57 to 2 μ). In old cultures chlamydospores can be seen.

Trichosporum ovoides Behrend, 1890

Found by Behrend in the nodosities present on the moustache of a European patient; vegetates parasitically on the surface of the hair under the form of ovoid elements; 3 to 4 μ long and $1\frac{1}{2}$ to $2\frac{1}{2}$ μ wide. Grows easily on culture media; on potatoes the colonies are white, while the medium takes a brownish-black colour.

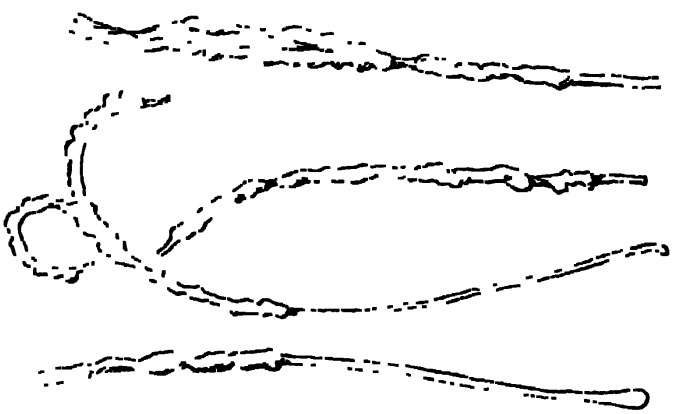

Fig. 585.—Hair affected with Trichosporosis. (After Vuillemin.)

Trichosporum ovale Unna, 1890.

Found by Unna in the nodosities present on the moustache of a European patient. Very similar to *T. ovoides*; in cultures, however, the mycelial threads are often corkscrew-like, and the spores have thick walls.

On potatoes the colonies are white-yellowish, and the substratum takes a brownish-black colour.

Trichosporum glycophile du Bois, 1910.

Found by du Bois in a nodular affection of the pubic hairs in a diabetic patient. In the nodules roundish elements, 3 to 4 μ, were present, together with a coccus. The fungus was easily cultivated in symbiosis with the coccus on sugar media.

Genus Madurella Brumpt, 1905, *emendavit* Pinoy, 1912.

Definition.—Arthrosporineæ with sterile septate hyphæ, reproducing the thallus by fragmentation and secreting a black pigment The spores are produced secondarily by binary division of the articles. Found in black maduromycosis and grow well at 37° C.

Type Species.—*Madurella mycetomi* (Laveran, 1902).

Historical.—In 1901, Brumpt, Bouffard, and Chabaneix wrote an account of a case of black mycetoma which they observed at Djibouti. In the following year the organism found in this case was studied by Laveran, who gave it the name *Streptothrix mycetomi* Laveran, 1902. Brumpt also found the same organism in a maduromycosis in the centre of Somaliland, and also in an amputated foot sent from Madagascar.

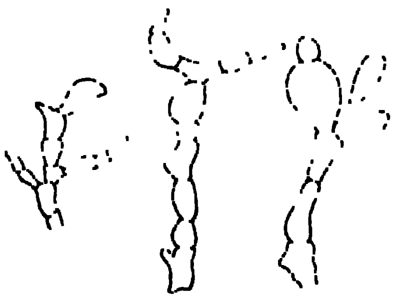

FIG. 586.—*Madurella mycetomi* LAVERAN.

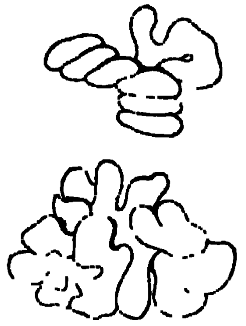

FIG. 587.—GRAINS OF *Indiella reynieri* BRUMPT

(After Brumpt)

Bouffard, in 1905, reported the presence of the same disease in Senegal and in the French Sudan.

In this variety the grains are black or deep brownish red, and always hard and generally small, from 1-2 millimetres in diameter, when single, and not in accumulated masses. The surface is irregular, with projecting points. On clearing with Eau de Javelle, the fungal elements can be clearly seen.

Brumpt (1905) formed a new genus, '*Madurella,*' for this fungus, defining it as follows:—

> 'Mucedine with white thallus, living parasitically in various animal tissues (bone, muscle, connective tissue), possessing during its vegetative life filaments with a diameter greater than 1 micron, and even reaching to 8-10 microns. These filaments are septate and branch from time to time; they secrete a brown substance. When old, these filaments form a sclerote, and their walls sometimes become impregnated with a brown pigment. In this sclerote there are a number of rounded corpuscles, from 8-30 microns in diameter (chlamydospores).'

The type species is the organism called *Streptothrix mycetomi* by Laveran, in 1902, which therefore becomes *Madurella mycetomi* (Laveran, 1902), first cultivated by Brault (1911) in material from Algerian cases.

This form of mycetoma was reported by Balfour (1911) to be present in the Anglo-Egyptian Sudan.

It is generally assumed that this and the Asian, together with the American type, are one and the same disease, but this still requires proof.

In 1908, Nicolle and Pinoy described a maduromycosis which they found in Southern Tunisia, near the Oasis of Tozeur, with hard dark brown grains about the size of a pin's head, in which segmented and ramified hyphæ about 1-4 microns in diameter were seen, as were rounded bodies arranged in chains and resembling the mycelial spores of a trichophyton, the whole being embedded in a brownish cement substance. Cultures were obtained at 35° C., and the growths were identical on maltose agar, glycerine agar, potato, and carrot, and all the media became pigmented black, due to a tyrosinase produced by the fungus, while the colonies which developed in twenty-four hours at 37° C. were white. Microscopically the growths showed the 'favic nails' so commonly met with in cultures of *A. schoenleini*. The authors looked upon the organism as belonging to the genus *Oöspora* Wallroth, 1833, with which Vuillemin considers *Achorion schoenleini* Lebert, 1845, should be classified. Its name, therefore, became *Oöspora tozeuri* (Nicolle and Pinoy, 1908).

Inoculation experiments were unsuccessful in the rabbit, the guinea-pig, and the monkey, but two successful infections were obtained in pigeons.

Brumpt, however, considers the fungus to be a *Madurella*, and therefore its name becomes *Madurella tozeuri* (Nicolle and Pinoy, 1908).

Brault (1911 and 1912) cultivated the fungi *Madurella mycetomi* and *M. tozeuri*.

The former grew at 20° C. and 37° C. on broth, various agars, potato, carrot, and some vegetal liquid media.

In the liquid media the growth appeared as a whitish grey puff-ball, which later became yellowish or brownish, while the medium remained clear and the growth fell to the bottom of the tube.

On solid media it formed a greyish-white, duvet-covered growth, which possessed a central button, surrounded by a radiation, and later, when the culture was drier, the medium became coloured.

Glycerine agar was best, as the growth thereon was luxurious, and when old became yellowish in colour, while the medium showed a caramel tinge in its entirety.

Glucose glycerine agar produced a growth of the colour of touchwood. This culture is thrown into black wrinkles, producing an appearance seen on some seashores.

When the growths of *M. tozeuri* were compared with those of *M. mycetomi* a number of differences were observed.

The cultures of *M. tozeuri* grew more quickly, were more luxuriant, and were white, resembling powdered flour. Those of *M. mycetomi* were more discrete, grey, *duveteuse*, radiated, and sometimes showed concentric circles, and disassociated more easily than the preceding.

Old cultures on glucose agar or on glycerinated glucose agar were quite different in the two species.

On carrot *M. tozeuri* attained a deeper brownish-yellow colour, while in old cultures on this medium it produced spores in a manner resembling an Oöspora.

Pinoy, in his remarks upon the mycology of these two species, says that Brault's *M. mycetomi* very closely resembles that isolated by Nicolle under the name of *Oöspora tozeuri*. Its filaments are 2-8 microns in diameter, and do not possess apparatus for fructification, reproducing by a breaking up of the hyphæ of the thallus into articles 5-10 microns in length, which divide into two spores. These spores are of the same diameter as the hyphæ from which they arise, varying from 2-5 microns, while the membrane becomes yellowish with age. In addition, chlamydospores can be observed forming at the end of the filaments, more or less like favic nails. The spores of *M. tozeuri* are smaller, but are formed in the same manner.

On Sabouraud's gelatine *M. mycetomi* gives rise to black sclerotes in the depth of the medium. These are very numerous, measure ½-1 millimetre in diameter, and are composed of hyphal segments, more or less cylindrical. Sometimes the sphere attains a diameter of 10 microns, and usually contains only one nucleus; but, though studied for a long time, these sclerotes were never observed to have any higher form of fructification. In *M. tozeuri* it is very rare to see the formation of sclerotes, which takes place on the surface of the medium.

On the bases of the researches on *M. mycetomi* and *M. tozeuri*, Pinoy classifies the genus Madurella as follows:—

A. Sclerotes 0·5-1 millimetre in diameter, formed in the depths of medium in cultures—*Mycetomi*.

B. Sclerotes rarely produced, and then on the surface of the medium—*Tozeuri*.

Madurella mycetomi (Laveran, 1902).

Synonym.—*Streptothrix mycetomi* Laveran, 1902.

Mycelium greyish white; when old, yellowish and darkening the media in sugar cultures. Spores varying in dimension from 2-5 microns. Sclerotes black and sterile, with a diameter from 0·5-1 millimetre, formed in the depths of the medium in cultures. Can invade the skin, bone, muscles, and connective tissue of man, giving rise to black grains, which are small, hard, round, and more or less warty, and which morphologically resemble the sclerotes formed in the cultures. Up to the present the inoculation into animals is negative. Very widely spread in Africa. Isolated by Brault from a mycetoma with black grains in Algeria.

Madurella tozeuri (Nicolle and Pinoy, 1908).

Synonym.—*Oöspora tozeuri* Nicolle and Pinoy, 1908.

Mycelium white, becoming yellowish with age and darkening the medium in sugar cultures. Spores generally small, 2 microns or sometimes even 5 microns in diameter. Sclerotes are only rarely produced, and then they appear on the surface of the medium. Occasionally it gives rise to a mycetoma in man, in which it forms black amorphous grains, which are often made up of mycelial rings, enclosing some degenerate cellular elements, which are impregnated with the pigment of the fungus, and also of small diffuse masses, formed solely by the filaments of the fungus, which have a yellow membrane. Inoculation into pigeons positive. Isolated by Nicolle from a mycetoma at Tozeur.

Genus **Indiella** Brumpt, 1906.

Definition.—Arthrosporineæ with septate, ramified hyphæ, without black pigment, and hence sclerotia white or yellowish.

Type Species.—*Indiella mansoni* Brumpt, 1906.

Remarks.—White thallus, living parasitic in various animal tissues—connective tissue, muscles, and bones. Mycelial threads 1-8 or 10 μ, septate, ramified, never secreting—in contrast to the fungi of genus *Madurella*—any black pigment. Masses of mycelial threads form sclerotia-like bodies or grains of various shape containing chlamydospores.

Classification.—The species may be recognized as follows:—

A. Sclerotia hard and bean-shaped —*Mansoni*.
B. Sclerotia soft and in coiled masses—*Reynieri*.

Indiella mansoni Brumpt, 1906.

Mycelial threads are septated, white, thin, 1·5-2 μ when young, larger (3-5 μ) and of irregular shape when old. Numerous spherical chlamydospores, generally terminal, 5-12 μ in diameter. Grains (sclerotia) very small, of $\frac{1}{3}$-$\frac{1}{2}$ millimetre, white, lenticular or reniform, very hard, do not soften by keeping in caustic potash. The fungus has not been grown.

Pathogenicity.—It is the cause of Manson's white mycetoma, of which only one case is known.

Indiella reynieri Brumpt, 1906.

White thallus. Most mycelial filaments are very thin, 1-1½ μ, septated; some—those at the periphery—are of irregular shape, much broader (4-5 μ), moniliform. Nearly every mycelial thread has at the peripheral extremity a terminal chlamydospore, 5-20 μ, often septate in two or three cells. Grains or sclerotia are small, less than 1 millimetre in diameter, coiled up like the excrementa of earth-worms.

Pathogenicity.—This fungus causes a variety of mycetoma with white grains (Reynier's white mycetoma), of which there is only one case on record—a European patient who had never left France. The case was observed and reported on by Reynier.

ORDER III. HEMISPORALES Vuillemin, 1910.

Definition.—Hyphales with the mycelium composed of abundant hyphæ, thin, but more than 1 micron in diameter, septate and branched conidiophores ramified basally, each branch terminating in a protoconidium, preceded by an annular construction produced by a brown, rigid thickening of the wall. The protoconidium is transformed completely or partially into deuteroconidia, but occasionally it elongates, forming a new conidiophore, or puts out branches which are capable of becoming conidiophores.

Classification.—There is only one genus, *Hemispora* Vuillemin, 1906.

Genus Hemispora Vuillemin, 1906.

Definition.—Mycelial filaments, thin, hyaline, septated, ramified. Each conidiophore terminates into an ampulliform structure (protoconidium), which later divides into several spore-like segments (deuteroconidia).

Hemispora stellata Vuillemin, 1906.

Definition.—Hemispora composed of white, sessile discs covered with conidiophores, arranged like brown stars in relief on the surface. Deuteroconidia subspherical, measuring 2·6-3·5 microns, with a dark coloured granular membrane except at the point of attachment, sometimes elongated and barrel-shaped. Habitat, parasitic on man and fungi.

Remarks.—This species was first found in 1904 by Vuillemin, growing on *Aspergillus repens* (De Bary, 1870). In 1909 Gougerot and Caraven first found it parasitic in man, and this has since been confirmed by other cases described by Auvray, De Beurmann, Clair and Gougerot, and by Thiry. So far it has not been found in the tropics.

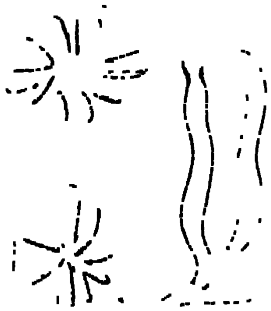

FIG. 588.—*Hemispora stellata* VUILLEMIN. (After Vuillemin.)

Pathogenicity.—It is the cause of hemisporosis, characterized by bony lesions and cold abscesses simulating tertian syphilis, tuberculosis, or sarcomata.

Biology.—It grows well on sugar media at the temperature of the room, and when separated in pure culture can be tested by sero agglutination and complement fixation. Typical colonies asteroid.

Treatment.—Iodide of potassium gives good result.

Hemispora rugosa Castellani, 1910.

Synonym.—*Monilia rugosa* Castellani, 1910.

Definition.—Hemispora growing on all ordinary media, with a crinkled surface without asteroid colonies.

Remarks.—Isolated from cases of bronchitis and a case of tonsillitis by Castellani, and recently from a case of thrush by Pijper.

Abbreviations used in the Tables.—A = acid; C = clot; G = gas; S = slight; vs = very slight; O = negative result—viz., non-production of acid or gas in sugar media, non-production of indol, non-liquefaction of gelatine or serum, as the case may be; + = positive result.

The growth on glucose agar is abundant, crinkled, or at times somewhat cerebriform; and in colour is amber, yellow, or brownish. Grows well on gelatine, which it liquefies very slowly, so much so that at first it was believed to be a non-liquefier. Gram-positive. Milk is not changed as a rule, but occasionally it undergoes a certain degree of peptonization, with a very small coagulum at the bottom of the tube. For sugar reactions see the table.

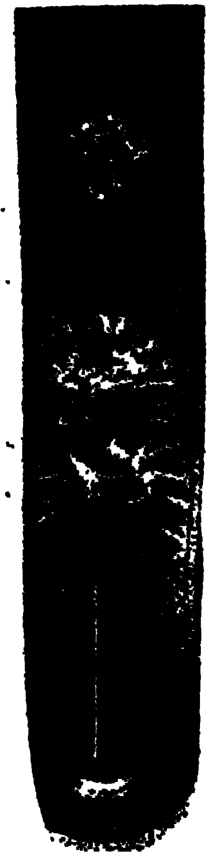

FIG. 591.—*Hemispora rugosa*: GLUCOSE AGAR CULTURE.

ORDER IV. CONIDIOSPORALES Vuillemin, 1910.

Definition.—Hyphales with the mycelium composed of abundant hyphæ, more than 1 micron in diameter, septate and branched, with or without true conidiophores, and with reproduction by means of true conidia.

Remarks.—The reasons for the formation of this order, which contains a large number of families, have already been given, as well as its advantage over the more fully worked out system of Saccardo (p. 1037).

Classification.—The order Conidiosporales is divided into five suborders, which may be recognized as follows:—

A. *Conidium imperfect:* Aleuriospore.
  Suborder 1: *Aleuriosporineæ* Vuillemin, 1911.
B. *Conidium perfect:* Conidium verum.
  I. True Conidiophores absent:—
    Suborder 2: *Sporotrichineæ* Vuillemin, 1910.
  II. True Conidiophores present:—
    (*a*) Conidia borne on sporophores.
    Suborder 3: *Sporophoralineæ* Vuillemin, 1910.
    (*b*) Conidia borne on phialides.
      1. Prophialides absent.
    Suborder 4: *Phialidineæ* Vuillemin, 1910.
      2. Prophialides present.
    Suborder 5: *Prophialidineæ* Vuillemin, 1910.

The fourth suborder, Phialidineæ, contains species of the genera *Aspergillus* Micheli, 1729; *Penicillium* Link, 1809; and *Sterigmatocystis* Cramer, 1859, in which asci are unknown; but though logically correct to include these species in the Fungi Imperfecti, it is more convenient to consider them under the heading Ascomycetes, though the genus Scopulariopsis may be placed here.

The last suborder, Prophialidales, does not contain any genera with species parasitic in man.

SUBORDER 1: ALEURIOSPORINEÆ VUILLEMIN, 1911.

Definition.—Conidiosporales in which reproduction takes place by aleuriospores.

Classification.—The suborder contains two families, which can be distinguished as follows:—

A. Conidiophores absent—*Aleurismaceæ.*
B. Conidiophores present—*Monotosporaceæ.*

FAMILY ALEURISMACEÆ Vuillemin, 1911.

Definition.—*Aleuriosporineæ* without conidiophores.

Classification.—The family is divided into two tribes:—

A. Spores simple or appendiculate—*Aleurismeæ.*
B. Spores bi- or multi-cellular—*Blastotricheæ.*

Only the first tribe is of interest to us.

TRIBE ALEURISMEÆ.

This tribe may be classified as follows:—

A. *Hyphæ pale:*—
  I. Hyphæ very short; sporogenous. Apparatus but little differentiated from the mycelium—*Myceliophthora* Costantin, 1894.
  II. Hyphæ elongate, sporogenous apparatus but little differentiated from the mycelium—*Acladium* Link, 1809.
  III. Hyphæ elongate, sporogenous apparatus well differentiated from the mycelium:—

- (*a*) ***Aleuriospore***, smooth, small, acro-pleurogenous:—
    - 1. Aleuriospores coloured—***Aleurisma*** Link, 1809.
    - 2. Aleuriospores pale—***Corethropsis*** Corda, 1839.
- (*b*) ***Aleuriospore***, large, spiny, acrogenous:—
    - 1. Aleuriospore appendiculate—***Mycogone*** Link, 1809.
    - 2. Aleuriospore non-appendiculate—***Sepedonium*** Link, 1809.

B. *Hyphæ dark*:—

- I. Hyphæ pale and dark. Aleuriospores become dark and acro-pleurogenous on light or dark hyphæ, small, generally 6×4, rarely 11×5 microns—*Glenospora* Berkeley and Curtis, 1876.
- II. Hyphæ very dark. Aleuriospores remain hyaline, situate acrogenously on hyaline hyphæ at the base of sterile dark hyphæ, large 11-14 microns—*Botryotrichum* Saccardo and Marchal, 1885.

Genus Acladium Link, 1809.

Definition.—Aleurismeæ with pale elongate hyphæ and with sporogenous apparatus, but little differentiated from the mycelium. Sporophores unbranched. Conidia pleurogenous.

Type Species.—*Acladium conspersum* Link, 1809.

Remarks.—There is only one species which concerns us—viz., *A. castellanii*.

Acladium castellanii Pinoy, 1916.

Definition.—Acladium with small chains of acrogenously placed chlamydospores. The aleuriospores are acropleurogenous.

Remarks.—The parasite was found by Castellani in cases of ulcerative dermatitis, with gumma-like nodules, in Ceylon, the Federated Malay States, and Macedonia, and fully described by Pinoy.

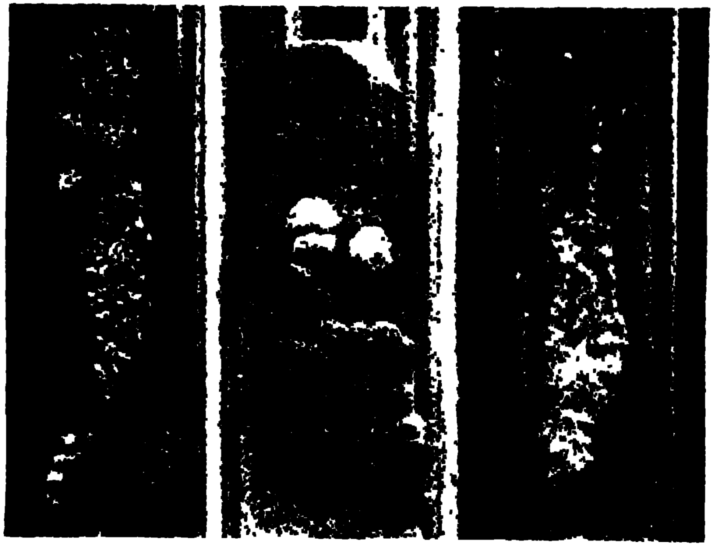

Fig. 592. Fig. 593. Fig. 594.

FIGS 592-594.—*Acladium castellanii* PINOY: CULTURES ON GLUCOSE AGAR POTATO AND CARROT.

The growth on artificial media (such as carrot, potato, glucose agar) consists of many small roundish masses, which later on may coalesce. They are covered by spiculated formations, giving them a prickly appearance, and consisting of erect, straight filaments, parallel to each other, or at times interlacing. These filaments are approximately 2 microns in diameter, and carry laterally pseudoconidia of variable shape, cylindriform, pyriform, or spherical, attenuated in size at their points of insertion. Most of these pseudoconidia are 4 microns in length, with a breadth of 3 microns. This type of fructification recalls the type Acladium decribed by Bodin in certain species of the genus Trichophyton (Malmsten, 1848).

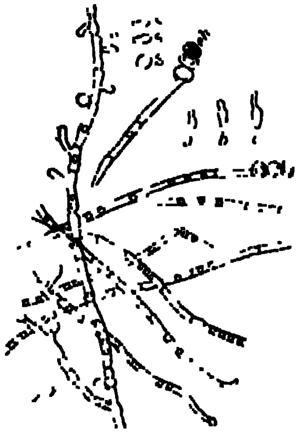

Fig. 595.—Microscopical Appearance of *Acladium castellanii* Pinoy in Hanging-Drop Culture, Five Days Old.

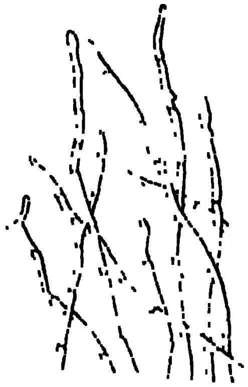

Fig. 596.—Microscopical Appearance of the Fungus in Hanging-Drop Culture, Twenty-Four Hours Old.

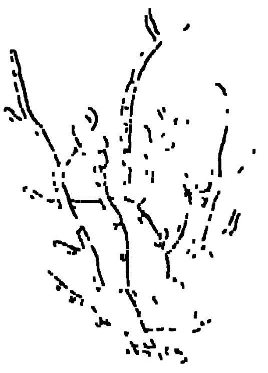

Fig. 597.—Microscopical Appearance of the Fungus in Hanging-Drop Culture, Three Days Old.

S, pseudoconidia; *a*, *b*, *c*, development of mycelial filaments from pseudoconidia; *ch*, chlamydospores.

These pseudoconidia become detached and then develop by sprouting, and mycelial filaments are formed. Certain filaments produce spherical chlamydospores arranged in small strings, as found in certain fungi of the genus Fusarium. These small chains of chlamydospores are very frequently terminal, the dimensions being variable—8 to 10 microns (Figs. 595-597).

In cultures on carrot and potato the colonies are white, on glucose agar often amber colour. Old cultures may show a certain amount of pigmentation, brown or black, especially on potato.

Genus Glenospora Berkeley and Curtis, 1876.

Definition.—Aleurismeæ with pale and dark hyphæ. Aleuriospores become dark, and are situate acropleurogenous on light or dark hyphæ, but are small in size, being generally 6 x 4 microns in diameter and rarely 11 x 5 microns.

Type Species.—*Glenospora curtisii* Berkeley and Desmond.

Classification.—Besides the type, *G. ramorum* (Schweinitz, 1822) and the pathological species are known. The latter are:—

G. graphii (Siebenmann, 1889), found in cases of otomycosis and keratomycosis.

G. sacchari Spegazzini, 1896, in the Argentine.

G. microspora Spegazzini, 1891, in Brazil.

G. khartoumensis Chalmers and Archibald, 1916, found in black maduromycosis.

G. semoni Chalmers and Archibald, 1917.

The various species may be recognized as follows:—

Fig. 598.

Fig. 599.

FIG. 598 AND 599.—*Glenospora khartoumensis* CHALMERS AND ARCHIBALD ALEURIOSPORES.

A. Aleuriospores large, usually measuring 10 or more microns in diameter:—
   Parasitic on plants—(1) *Curtisii*, (2) *Ramorum*.

B. Aleuriospores medium, measuring 6-8-9-11 microns—(3) *Sacchari*.
   Parasitic on plants—(4) *Microspora*.

C. Aleuriospores small, usually measuring 5 or less microns in diameter:—
   - I. Parasitic in man, causing otomycosis and keratomycosis—(5) *Graphii*.
   - II. Parasitic in man, causing black maduromycosis:—
     - (*a*) Growth on clear maltose agar twelve days, uncapped tube at 30° C. Central black rounded mass surrounded by an abundant white fringe—(6) *Semoni* (in India).
     - (*b*) Growth in exactly same conditions as in (*a*). Central series of small elevations from which radiate furrows cutting in black plateau. Fringe very slightly marked—(7) *Khartoumensis* (in Africa).

Glenospora graphii Siebenmann, 1889.

Synonyms.—*Graphium penicillioides* Hallier, 1869; *Stemphylium polymorphum* Hallier, 1869; *Verticillium graphii* Siebenmann, 1889; *Glenospora praphii* Vuillemin, 1912.

Definition.—Glenospora with aleuriospores large, 10 or more microns in diameter.

Mycelium at first white, later dark brownish. The filaments are septated, 2 to 3 μ in breadth, ramified. Fertile hyphæ are erected, often dichotomous or trichotomous, with terminal conidia, which are ovoid with a smooth surface, and of a greyish-brownish colour. It is easily grown on the usual laboratory media; gelatine is not liquefied. This fungus has been found in cases of otomycosis by Hassestein, Bezold, Siebenmann, etc., and in a case of keratomycosis by Morax and Pinoy.

Fig. 603 and 604.—*Glenospora semoni* Chalmers and Archibald: Culture on Clear Maltose Agar.

A, Twelve days; B, fourteen days.

Glenospora khartoumensis Chalmers and Archibald, 1916.

Definition.—Glenospora with aleuriospores small, 5 or less microns in diameter; parasitic in man, causing black maduromycosis, and differing from *G. semoni* in cultural characters.

History.—Found by Chalmers and Archibald in a case of black maduromycosis in Khartoum, Anglo-Egyptian Sudan. It occurred in the sole of the foot of a native boy.

Morphology.—All cultures show septate branched hyphæ, varying in diameter from 2·8-1·4 microns, and increasing in very old cultures, when all the hyphæ are dark, to 2·4 microns. At first the hyphæ are pale, but when older they become dark, being of a greenish-black tinge. Thick walled, clear, or dark coloured. Chlamydospores (14 × 11·3 microns) are present, and are especially marked in the black masses on the surface of potato infusions and nutrient gelatine. Aleuriospores are to be found acropleurogenously situated in the surface growth of old potato infusions.

Cultures.—The fungus grows well aerobically in glucose peptone at 30° C., which is the optimum temperature. It also grows well on maltose agar, on glycerine agar, glucose agar, and agar agar. It does not liquefy inspissated blood serum or gelatine. It grows on potato and carrot, but not on cheese or lard. It grew well on litmus milk, but formed neither acid nor clot, though it produced a flaky precipitate. On maltose agar the typical growth was in colour, Ridgway's Standard Colour 'Dusky Drab,' and had a central elevation surrounded by a depression, which separated it from a grooved raised plateau which had a slight fringe.

Habitat.—So far it is only known in man, and all experiments with grains or with cultures failed to infect monkeys, rabbits, or pigeons intraperitoneally, subcutaneously, intramuscularly (with or without a thorn), or into the anterior chamber of the eye. Attempts to find a similar fungus on plants have so far failed.

Pathogenicity.—It causes a variety of *African black maduromycosis.*

Glenospora semoni Chalmers and Archibald, 1917.

Definition.—Glenospora closely resembling *G. khartoumensis*, but differing markedly in cultural characters on maltose agar when grown under exactly similar conditions.

Remarks.—This fungus was isolated by Semon from a case of black maduromycosis occurring in a native Indian soldier serving in France.

It is very like *G. khartoumensis*, but differs markedly in cultural appearances, as may be judged by a comparison of Figs. 601 and 602 with Figs. 603 and 604.

Pathogenicity.—It causes a variety of *Asian black maduromycosis.*

Genus Trichothecium Link, 1824.

Fertile hyphæ are erect, grouped together, each terminating in an oval, pear-shaped, or globular conidium. The only species so far observed in man is *Trichothecium roseum.*

Type.—*Trichothecium roseum* (Persoon, 1801), *emendavit* Link, 1824.

Trichotheclum roseum Persoon, 1801.

Synonyms.—*Trichoderma roseum* Persoon, 1801; *Sporocephalum roseum* Persoon, 1801; *Puccinia rosea* Corda, 1837.

This species vegetates on decaying vegetable matter; the colour is at first white, then pinkish. Each fertile hypha terminates in a pear-shaped conidium, 10 to 20 μ in length and 8 to 12 μ in breadth.

This fungus has been found in cases of otomycosis by Stendener, who did not succeed in cultivating it. Some authorities believe it to be identical to *Glenospora graphii*.

SUBORDER 2 SPOROTRICHINEÆ VUILLEMIN, 1910.

Definition.—Conidiosporales in which reproduction takes place by means of true conidia, but in which true conidiophores are absent.

Type Genus.—*Sporotrichum* Link, 1809, which has a very large number of species scattered over the world, of which 100 are described in Saccardo's 'Sylloge Fungorum,' vol. iv.

Genus Sporotrichum Link, 1809, *emendavit* Saccardo, 1882.

Synonyms.—*Miainomyces* Corda; *Chromelsporium* Corda.

Definition.—Sporotrichales with the characters of the suborder.

Type Species.—Possibly *Sporotrichum obducens* Link, 1809.

Human Species.—There has been considerable discussion as to whether the human species belonged to this or another genus—*e.g.*, Oöspora, Botrytis, Trichosporum, Rhinocladium or Torula—but Smith, de Beurmann, and Gougerot's belief that Sporotrichum is the correct genus has been supported by Matruchot, Vuillemin, and Pinoy, and may be considered as settled as far as our present knowledge goes.

The first species ever associated in any way with man was:—

Sporotrichum inquinatum (Link, 1809), which was found growing on dry human fæces. This was probably a saprophyte. The first ever found in diseased men was *Sporotrichum bronchiale* Montagne, 1844. It was discovered by Gubler in the bronchi of sick persons.

Species Parasitic in Man.—It is customary at the present time to give the following species as parasitic in man, and it may be noted that they do not correspond to any known species living saprophytically or parasitically on plants:—

1. *S. schenki* (Hektoen and Perkins, 1900).
2. *S. beurmanni* (Matruchot and Ramond, 1905).
3. *S. dori* de Beurmann and Gougerot, 1906.
4. *S. indicum* Castellani, 1908.
5. *S. asteroides* Splendore, 1908.
6. *S. gougeroti* Matruchot, 1910.
7. *S. jeanselmi* Brumpt and Langeron, 1910.
8. *S. lesnei* (Vuillemin, 1910).
9. *S. councilmani* Wolbach, Sisson and Meier, 1917.

And one may add:—

10. *S. bronchiale* Montagne, 1844.

There is, however, some difference of opinion with regard to some of these species; thus de Beurmann and Gougerot consider that the fourth and fifth are only varieties of the second.

4. *S. beurmanni* Matruchot and Ramond, 1905, var. *indicum* Castellani, 1908.

5. *S. beurmanni* Matruchot and Ramond, 1905, var. *asteroides* Splendore, 1908.

Considering them all provisionally as separate species, they may be recognized as follows:—

- A. Conidia large (4-11 microns in greatest diameter), with well-developed pedicle and presence of lateral spore clusters:—
  - Mycetomas in Madagascar—*Lesnei*.
  - Conidia large with absence of lateral spore clusters:—
  - Traumatic arthritis in America—*Councilmani*.
- B. Conidia usually small with very short pedicle, which may be absent:—
  - I. With radiating bodies. Conidia very polymorphic, round, oval, or bacilliform, varying from 4-8 microns in greatest diameter—*Asteroides*
  - II. Without radiating bodies:—
    - (*a*) Conidia not numerous. Ferments lactose, not saccharose—*Schenki*.
    - (*b*) Conidia numerous:—
      - 1. Hyphæ 2 or more microns in diameter:—
        - (A) Cultivated:—
          - (i.) Colonies dark from the first—*Gougeroti*.
          - (ii.) Colonies whitish at first:—
            - (1) Colonies finally black. Ferments saccharose, not lactose—*Beurmanni*.
            - (2) Colonies lightish brown—*Dori*.
            - (3) Colonies whitish grey to black. Hyphæ wide, 3 to 4 microns—*Indicum*.
        - (B) Not cultivated. Hyphæ 5 to 7 microns in diameter—*Bronchiale*.
      - 2. Hyphæ less than 2 microns in diameter. Hyphæ 0·5 to 1 micron in diameter—*Jeanselmi*.

Pathogenicity.—They usually give rise to lesions in the skin and deeper tissues, resembling those of tertiary syphilis (gummata, etc.) or tuberculosis, but *S. lesnei* produces a disease like mycetoma.

Treatment.—As a rule the diseases are amenable to iodide of potassium.

Sporotrichum schenki Hektoen and Perkins, 1900.

Synonyms.—*Sporothrix schenki* Hektoen and Perkins, 1900; *Rhinocladium beurmanni* Verdun, 1913.

Discovered by Schenk in a case of gummatous lymphangitis in 1896 in North America. Easily grown on glucose, maltose, and other sugar media. Optimum temperature 30° to 38° C. Growth with an irregular surface, generally of white colour, but old cultures may present some brownish or black pigmentation. Glucose gelatine is slowly liquefied. Mycelial threads as a rule not very straight, rather bent, curved, or undulating; they are about 2 μ in diameter. Conidia present in small numbers, oval, supported by a short sterigmata. Ferments lactose, producing acidity but no gas; has no action on saccharose.

Pathogenicity.—It is the cause of Schenk's sporotrichosis, found in North America. According to de Beurmann, this fungus is very little or non-pathogenic to rats and mice.

Sporotrichum beurmanni Matruchot and Ramond, 1905.

Synonym.—*Rhinocladium beurmanni* Verdun, 1913.

Discovered by de Beurmann in France, and completely investigated by himself and Ramond, Gougerot, Dor, Sicard, Pinoy, etc., in that country; by Adamson in England; by Lutz and Splendore in South America; by Carougeau in Madagascar, etc.

Parasitic Life.—In the tissues oval, yeast-like, or short bacillary forms are seen, 3 to 5 μ in length and 2 to 3 μ in breadth, free or engulfed by phagocytes. Pinoy has described some minute oval forms the shape and size of piroplasmata inside the macrophages. In a case of general infection he has made the important observation that typical fructifications may be seen in the blood capillaries.

Cultures.—The best media are Sabouraud's maltose agar and glucose agar. The growth begins to appear between the fourth and the twelfth day. Optimum temperature 22° C. The growth may be whitish at first, but soon becomes completely black or of a brownish chocolate-like colour. The surface is cerebriform. Glucose gelatine is slowly liquefied. Mycelial threads about 2 μ in diameter, rather straight. Conidia oval, 5 to 6 μ in length and 3 μ in breadth, supported by short sterigmata. In contrast to *Sp. schenki*, the conidia are extremely numerous.

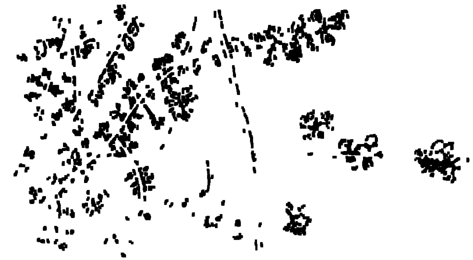

FIG. 605. *Sporotrichum beurmanni* MATRUCHOT AND RAMOND.
(After Gougerot.)

Ferments saccharose, producing acidity, but no gas; has no action on lactose.

Pathogenicity.—Is the cause of by far the greatest number of cases of sporotrichosis in Europe (see p. 2086). Is very pathogenic to rats and mice.

Sporotrichum dori de Beurmann and Gougerot, 1908.

Found by Dor in a case of gummatous sporotrichosis. In contrast to the typical *Sp. beurmanni*, the growth on maltose and glucose agars is slower; the colonies do not coalesce into a large mass, but remain separate and small, not exceeding 1½ millimetres in diameter. The colour is light brownish; never becomes black. Does not grow on gelatine. The mycelial filaments are very thin (0·5 to 1 μ), with short mycelial segments occasionally dichotomous.

The fungus is not pathogenic, or very slightly so, for rats and mice.

Sporotrichum gougeroti Matruchot, 1910.

Synonym.—*Rhinocladium gougeroti* Verdun, 1913.

Differs from the typical *Sp. beurmanni* only in small details, the principal ones of which are the black pigmentation of the colonies from the very beginning, and the extremely abundant sporulation.

Sporotrichum indicum Castellani, 1908.

Found by Castellani in Ceylon. It is doubtful whether it is a separate species, or merely a variety of *Sp. beurmanni*. The mycelial threads are often somewhat larger (2 to 3 μ wide); conidia roundish (3 to 5 μ) or oval (4 to 5 μ long and 3 to 4 μ in breadth). The colonies on maltose and glucose agars may be of various colour —white-greyish, light brownish, dark brownish, black.

Sporotrichum jeanselmei Brumpt and Langeron, 1910.

Was isolated by Jeanselme and P. Chevalier from a case of gummatous sporotrichosis, and was studied botanically by Brumpt and Langeron. It differs from *Sp. beurmanni* by the mycelial filaments being thinner. These are septate, ramified with short lateral branches supporting clusters of spores. The spores are oval or roundish, 2·5 to 3·5 μ.

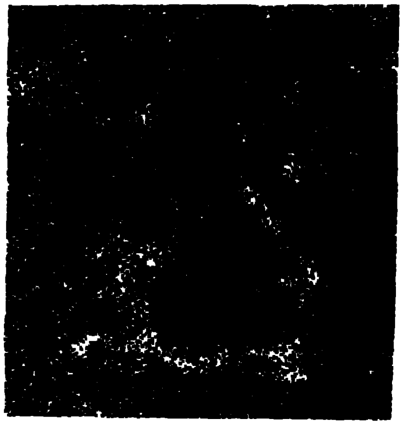

FIG. 606.—*Sporotrichum asteroides* SPLENDORE IN THE TISSUES.
Note radiate body.

FIG. 607.—*Sporotrichum asteroides* SPLENDORE.
Young culture.

(From photographs by Dr. Splendore.)

Sporotrichum asteroides Splendore, 1908.

Synonym.—*Rhinocladium asteroides* Verdun, 1913.

Discovered by Splendore in South America. Is characterized by the presence in the infected tissues of spherical bodies, 4 to 12 μ in diameter, from which some bacillary-like formations radiate. The fungus grows well on maltose and glucose agars, the colonies being first white and later black. Pathogenic to man, rats, and mice.

Sporotrichum lesnei (Vuillemin, 1910).

Synonym.—*Rhinocladium lesnei* Vuillemin, 1910.

Differs from all the other species of *Sporotrichum* by the elongated shape and large dimensions of the conidia, which are 4 to 11 μ in length and 2·5 to 4 μ in breadth. Old cultures are of a dark sooty hue, and black chlamydospores may be present.

Sporotrichum councilmani Wolbach, Sisson and Meier, 1917.

Found by Wolbach, Sisson and Meier in a case of acute arthritis of the knee following injury, in America. This species is characterized by the large size of the spores with absence of lateral spore clusters and by the occurrence in the lesions of septate branching filaments.

SUBORDER 3. SPOROPHORINEÆ VUILLEMIN, 1910.

Definition.—Conidiosporales reproducing by true conidia borne on conidiophores.

Remarks.—A number of families and a large number of genera are included in this suborder, but we are only concerned with four, which may be separated from one another as follows:—

A. Conidiophores unbranched:—
    I. Single hyaline or lightly coloured terminal spore—*Acremonium* Link, 1809.
B. Conidiophores branched:—
    I. Conidiophores erect—*Monosporium* Bonorden, 1851.
    II. Conidiophores decumbent—*Scedosporium* Saccardo, 1911.

Monosporium is only mentioned because *Scedosporium apiospermum* used to be *Monosporium apiospermum*.

Genus Acremonium Link, 1809.

Definition.—Sporophorineæ with creeping sterile hyphæ but little branched, and carrying laterally simple unbranched conidiophores, broad in the middle and gradually reduced towards the distal extremity, terminating in a single hyaline or lightly coloured spore.

Type Species.—*Acremonium alternatum* Link, 1809.

Remarks.—A small number of species are known, which mostly live, saprophytically, on decaying wood, leaves, etc. Two species only are known in man.

Acremonium potroni Vuillemin, 1911.

Found by Potron and Noisette in a case of subcutaneous gummata with fever, somewhat resembling typhoid before the gummata appeared. Easily grown on Sabouraud's agar; colonies white, then pinkish, and, later, orange-yellow. Serum is liquefied. In cultures the mycelial filaments are septated; numerous conidiophores are present of a peculiar elongated type, 15 to 20 µ in length. Conidia ovoid, with a smooth surface, 4 to 5 µ in length and 2 to 2·2 µ in breadth; of *pinkish colour*. This fungus is pathogenic to guinea-pigs.

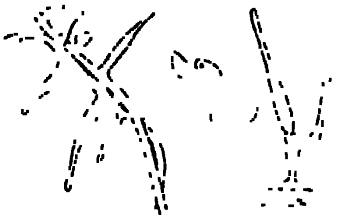

FIG. 608.—*Acremonium potroni* VUILLEMIN.
(After Vuillemin.)

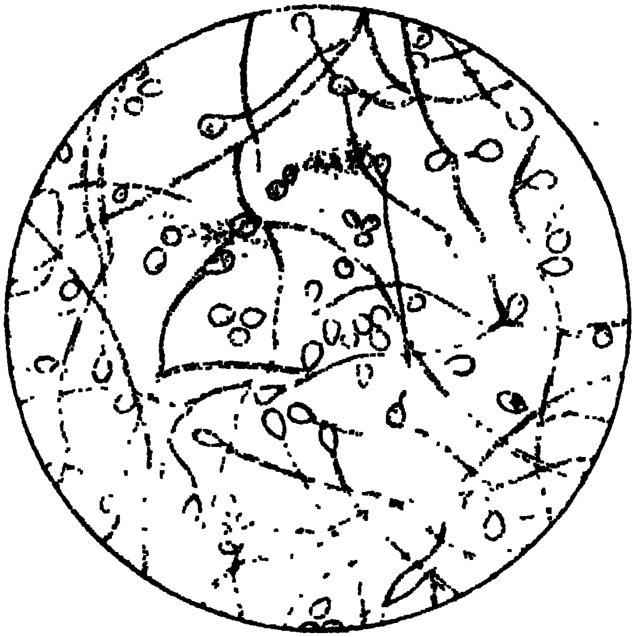

FIG. 609.—*Scedosporium apiospermum* SACCARDO.
(After Radaeli.)

Acremonium niveum Boucher, 1918.

Very similar to *A. potroni*, but colonies are generally white.

Genus Scedosporium Saccardo, 1911.

Definition.—Sporophorineæ with unbranched decumbent conidiophores.

Type Species.—*Scedosporium apiospermum* (Saccardo, 1911).

Remarks.—The other known species are *Scedosporium acremonioides* Harvey, which does not concern us, and *S. sclerotiale*.

Scedosporium apiospermum (Saccardo, 1911).

Definition.—Scedosporium with mycelium at first white and later slightly brown; bundles 3-5 mm. broad in cultures. Mycelial hyphæ creeping, filiform. Conidiophores decumbent, very slightly branched, hyaline, 2·5-3 microns, with one spore oblong, 14 × 5·6-11 × 5·7, rarely subround; at first hyaline, later dilute, dirty rose yellow. Scedosporium, causing white maduromycosis.

Remarks.—Easily grown, the cultures are whitish and covered with duvet; may become brownish when old.

Mycelial tubes septated and of various size; may reach 4 to 5 µ in breadth. Each conidiophore supports a terminal spore, which is either ovoid, 12 to 14 μ in length, and 5 to 6 μ in breadth, or roundish, 6 to 7 μ in diameter. No other kind of fructification is seen.

Pathogenicity.—This fungus has been found in Italy, in cases of mycosis of the foot resembling madura foot, by Tarozzi and Radaeli. Tarozzi considered the fungus to be a *Nocardia*, while Saccardo and Radaeli described it as a new species of the genus *Monosporium*. Saccardo placed it later in the genus Scedosporium. Radaeli made a complete pathological and clinical investigation of the condition.

Scedosporium sclerotiale (Pepere, 1914).

Synonym.—*Monosporium sclerotiale seu nigricans* Pepere, 1914.

Definition.—Scedosporium causing black maduromycosis.

Remarks.—This fungus resembles *S. apiospermum*, with the exception that it produces black pigment. It was ably investigated by Pepere, who grew it on various media, studied it mycologically, studied complement fixation with it, and finally obtained successful inoculations in the anterior chamber of the eye in guinea-pigs.

Pathogenicity.—It was found in a case of black maduromycosis in a peasant, aged thirty-three years, living at Domusnovas, in the province of Cagliari, in Sardinia.

SUBORDER 4. PHIALIDINEÆ VUILLEMIN, 1910.

Definition.—Conidiosporales with conidia borne on phialides.

Remarks.—As already stated, the species of *Aspergillus*, *Sterigmatocystis*, and *Penicillium* in which asci are unknown could be classified, here but we will only consider Scopulariopsis, which is closely related to Penicillium.

Genus Scopulariopsis Bainier, 1907.

Synonym.—*Penicillium pro parte.*

Definition. — Phialidalineæ resembling Penicillium, with unbranched erect conidiophores, bearing phialides, which carry a chain of large ovoid or roundish spores.

Type Species.—*Scopulariopsis brevicaulis* Saccardo, *emendavit* Bainier, 1907.

Remarks.—In addition to those found in man, *S. rubellus* Bainier, 1907, *S. rufulus* Bainier, 1907, *S. repens* Bainier, and *S. communis* Bainier, are known.

Species found in Man.—Two species are found in man, which may be differentiated as follows:—

A. With white creamy formation in old cultures—*Blochi*.

B. Without such formations in old cultures—*Koningii*.

Scopulariopsis blochi Matruchot, 1911.

Synonyms.- *Mastigocladium blochi* Matruchot, 1911; *Scopulariopsis blochi* Vuillemin, 1911.

Found by Bruno Bloch in a case of gummatous lymphangitis, clinically very similar to an ordinary case of sporotrichosis. In cultures the mycelial threads are slender (0·5 to 1·5 μ in breadth), colourless, septated, very little ramified. Conidiophores, 20 to 30 μ in length, are tapering, and from the pointed ends chains of conidia take origin. Conidia elongated, ovoid, 3 to 4 μ in length and 1·5 to 2 μ in breadth. In old cultures white-creamy formations may be seen, which may possibly be undeveloped perithecia.

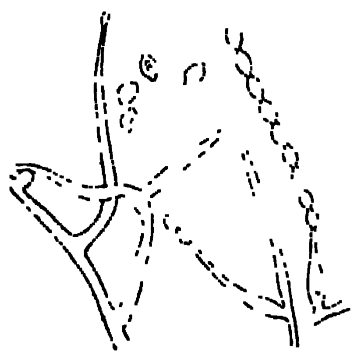

Fig. 610.- *Scopulariopsis blochi* MATRUCHOT. (After Vuillemin.)

Scopulariopsis koningii Oudemans.

Synonyms.—*Monilia koningii* Oudemans; *Scopulariopsis rufulus* Bainier; *S. koningii* Vuillemin, 1912.

A scopulariopsis isolated by Yanin in a case of subcutaneous gummata has been identified by Vuillemin as *S. koningii* Oudemans. The cultural characters are very similar to those of the previous species, but the peculiar white-creamy formations as observed in old cultures of *S. blochi* are not seen. Boucher in cases of gumma-like swellings in Madagascar has isolated a species which he calls *S. ivorensis.*

CHAPTER XL

THE MALARIAL FEVERS

General account—Quartan fevers—Tertian fevers—Subtertian fevers—Pernicious malaria—Chronic malaria—Relapses—Reinfections—Complications—Sequelæ—Diagnosis—Prognosis—Treatment—Prophylaxis—References.

I. GENERAL ACCOUNT.

Definition.—The *malarial fevers* are a group of *specific fevers of protozoal causation*, being due to infections with the parasites *Plasmodium malariæ* (Laveran, 1881), which produces the quartan fevers, *Plasmodium vivax* (Grassi and Feletti, 1890), the agent of the tertian fevers, and *Laverania malariæ* (Laveran, 1890), the exciting cause of the subtertian fevers, which are carried from man to man by the agency of many species of anopheline mosquitoes.

Nomenclature.—The name '*malaria*' is derived from two Italian words, *mal aria*, meaning 'bad air,' and was intended originally to signify that the bad air arising from marshes was the cause of the fevers.

Synonyms.—*English Names:* Ague, paludism, marsh fever, remittent fever, intermittent fever, climatic fever, jungle fever, coast fever.

French Names: Fièvre palustre, paludisme, fièvres paludiennes, fièvres des marais, impaludisme, fièvres malariques, fièvres telluriques.

Italian Names: Paludismo, malaria, febbre intermittente, febbre palustre, febbri malariche, febbri di stagione, febbri d'aria, infezione malarica.

German Names: Wechselfieber, Kaltes Fieber, Intermittens, Sumpffieber, Klimafieber. Marschfieber, Kaltes Fieber.

Local Names.—In all countries local names have been applied to the malarial fevers—for example, Roman fever, Sierra fever, fever of Batavia, Kurunegala fever (Ceylon), Dambul fever (Ceylon), Kamerun fever.

Seasonal Names.—As malarial fevers are more abundant in spring than in winter, and still more so in summer and autumn than in spring, it is natural that seasonal names should be applied to them—*e.g.*, spring fevers, summer to autumn fevers, autumn fevers.

Remarks.—The malarial fevers cover such a wide field of clinical symptoms and pathological phenomena that it is necessary first of all to give a general account, which will comprise such subjects as ætiology, climatology, pathology, chemical pathology, and morbid anatomy, and then to consider the type of fever caused by each of the three parasites mentioned above—viz., the *quartan fevers*, the *tertian fevers*, and the *subtertian fevers*—in their typical and atypical acute phases. Having completed this, we have still to consider the subject of chronic malaria, and we are then in a position to review the complications, sequelæ, diagnosis, and prognosis. Finally, the important matters of treatment and prophylaxis must be discussed.

It may be thought that it would be better to write three separate chapters detailing what is known, considering the three types of fever separately; and though scientifically this would be more accurate, still, clinically it would not benefit, because it is in its atypical forms that malaria is mostly seen by the physician of to-day, and therefore clinically it is better to treat the malarial fevers together and not separately.

It is, however, necessary to preface the account of the disease with a very short note on the history, in order that the reader may understand the salient features of the evolution of knowledge with regard to it.

History.—It is suggested that the references in the 'Charaka-Samhitā' to fevers spread by mosquitoes refer to malaria, and that this fever was recognized at the time of Homer.

In any case, Hippocrates clearly distinguished intermittent from continuous fevers, while among the former he noted the tertian and quartan types, and observed their frequency in summer and autumn and their occurrence near stagnant water and after rains. In 116 B.C. Varro drew attention to the relationship between malaria and marshes, a fact so well realized in the Middle Ages that illustrations are given of mosquito-nets as the only way to live near these collections of water.

We thus see that very early in the history of medicine mosquitoes were associated with fever, which was also associated with stagnant water, and that fevers were divided into the intermittent and the continuous. The introduction of cinchona bark into medicine, as noted in Chapter I., made a distinction as to those fevers which are and those which are not curable by that drug, and this was emphasized by the cure of 'Le Grand Dauphin' in the days of Louis XIV. The medicine used in this celebrated case appears to have been cinchona bark soaked in Rhine wine and presumably strained, and having a small quantity of tincture of opium added thereto.

The pernicious fevers were brought into special prominence by Torti, in 1712, in his celebrated 'Theraputice Specialis Mutinæ.'

As to the actual cause of the disease, it was believed to be minute forms of animal life arising in the exhalations from decaying vegetal matters in marshes. This is the *miasm* theory of malaria, which was fully accepted until modern times, but in 1847 Meckel noticed black pigment (hæmozoin) in the organs of people dying from malaria. There was much discussion as to the origin of this pigment, till, in 1881, Laveran discovered the parasite of malarial fever, and thus laid one of the principal foundations of modern tropical medicine. Golgi in 1886 demonstrated its life-cycle in man, showing the relationship between the attacks of fever and the sporulation of the parasite, as well as the origin of the hæmozoin. Golgi's researches firmly established the parasites of quartan and tertian malaria—*i e.*, *Plasmodium malariæ* and *P. vivax*—while Marchiafava and Bignami in 1891 demonstrated the existence of *Laverania malariæ* and its relationship to subtertian malaria.

During these researches the presence of the peculiar crescent bodies in cases of subtertian infection became known, and caused much speculation; and it was now that King, in 1883, suggested anew that mosquitoes might be the carrier of malaria, a suggestion which we have already noted to be present at the dawn of written medicine. In 1884 Laveran pointed out that Manson's researches on filariasis opened a possibility that malaria might be conveyed in the same way, but these suggestions did not lead to anything, and it was not till Manson, in 1894, emphasized the importance of this possibility that any serious notice was taken of the problem involved. In 1898 Ross, working on Manson's hypothesis, discovered the important fact that the malarial parasite could grow in the stomach of a mosquito, and eventually traced out the whole cycle of the parasite of bird malaria in that insect, and this was subsequently completed as regards the human parasite by Grassi, and confirmed by Marchiafava and Bignami with regard to the infection in man.

Experimental proof of the truth of this carriage was effected by Manson producing typical attacks of malaria, in persons who had never left England, by anopheline mosquitoes infected with the parasites in Italy, and by Low and Sambon living during the malarial season in the Roman Campagna, with no other protection except good anti-mosquito measures, and failing to become infected with the disease.

We therefore have reached this stage of knowing the parasitic cause and its life-cycle in man and the mosquito, but there are some things which we do not know, and these are the reason of the persistence of the infection, in spite of quinine therapy, in some people, while others are without doubt cured, and the reason why the disease appears at times as epidemics. There can be no doubt that the realization of a reservoir for the disease is most important, and there is equally no doubt that this reservoir is man, especially native races, and perhaps more especially the children of native races.

The following additional points appear to us to require further study:—

1. The form in which the malarial parasite lies dormant in the human body (with special reference to the parthenogenesis of the macrogametocyte).

The question of parthenogenesis is still much debated. Neeb has investigated it in *L. malariæ*, and has contrasted it with the schizont stage of the same parasite as follows:—

Character.	*Segmenting Macrogametocyte.*	*Schizont.*
Size	Almost fills the erythrocyte.	Fills about two-thirds of the erythrocyte.
Shape	Oval, not quite centrally situated.	Circular, and centrally situated.
Chromosomes ..	Large, coarse, purplish-brown in red-violet basis, which runs in a band-like curve along periphery.	Small, fine, separate, purple, arranged in a circle around the hæmozoin.
Cytoplasm ..	Resembles that of a typical macrogametocyte.	Resembles that of the trophozoite.
Hæmozoin ..	Coarse yellowish-brown granules excentrically placed.	Fine, dark brown or black granules, usually concentrated into one centrally placed clump.

Thompson believes that Schaudinn probably mistook for parthenogenesis a double infection of a corpuscle with a gametocyte and a schizont.

Ross believes that the ordinary asexual forms persist in the blood in small numbers, and undergoing schizogony, are sufficient to account for the indefinite persistence of the infection. Karrewij has found parthenogenesis to occur in *P. vivax* at the height of the febrile attack.

2. Whether Schaudinn is correct in believing that the eggs of the mosquito can become infected, and, if so, whether that infection is capable of being spread by the next generation of mosquitoes.

With regard to this point the tendency at present is to believe that Schaudinn's observations will not be confirmed.

3. Whether any mosquito other than the Anophelinæ carry the parasites. So far, no evidence in favour of this has been brought forward.

4. Whether there is any animal other than man in which the parasites live in nature.

The investigations of Fermi and Lumbau in 1912 are steps in answering this question negatively, but many more observations in different countries are necessary before a final answer can be given. Mesnil has succeeded in infecting an orang-utan with simple tertian malaria. The attacks of fever in this animal were mild, but for several weeks typical parasites were found.

5. Whether there are any malarial parasites of man which have so far not been recognized.

Thus Stephens has insisted upon *Plasmodium tenue*, which does not appear to us to be specifically distinct, and Oswaldo Cruz has invited attention to a peculiar quartan type of parasite found in the valley of the Amazon and associated with *œdema of the legs* as a pronounced symptom. Laloir's parasite is mentioned in the next chapter, and several other observers have described new varieties of the malarial parasites which require confirmation.

6. Usually it is believed that all fevers regularly recurring every third or fourth day are malarial, but this, while correct as a general rule, is open to doubt in certain instances, and in any case requires careful watch.

Ætiology.—The ætiology may be divided into:—

I. The Exciting Causes.
II. The Predisposing Causes (p. 1142).

I. EXCITING CAUSES.—Malarial fevers are produced by the parasites *Plasmodium malariæ* Laveran, 1881, *P. vivax* Grassi and Feletti, 1890, and *Laverania malariæ* Grassi and Feletti, 1890, because they are always found in the blood or organs of persons suffering from the disease, and can be injected into healthy persons, producing in them typical fevers, the different stages of which correspond to the stages of the life-cycle of the parasite. These parasites can be spread from human being to human being by mosquitoes, in whose bodies they undergo development as already described. Infected mosquitoes can convey the parasites to healthy persons, living in either non-malarial or malarial climates, by their bites, producing attacks of fever typical for the type of parasite with which the mosquito was infected. The classical experiment is the infection of Sir Patrick Manson's son with tertian malaria by means of infected anophelines sent from Rome to London.

There are, therefore, three factors necessary for the production of malarial fever: (1) the blood parasite; (2) the mosquito; (3) man.

1. **The Blood Parasite.**—We have drawn attention to three parasites in connection with malaria, and we believe these to be the only three at present known to cause the fevers, but it is necessary to say that this view is by no means universal. Some authorities believe in a quotidian form of fever due to a species of *Laverania*, or to two separate species of the same genus. These parasites, however, if they exist as distinct species, which we believe to be very doubtful, have not come within our observation, and we therefore agree with those writers who only acknowledge the three types mentioned above.

The descriptions of the structure and life-histories of these parasites have been given in Chapter XXI. (p. 504), and need not be referred to here.

Infection.—The parasites are introduced into the human body as sporozoites, which pass from the salivary glands down the hypopharyngeal canal of the mosquito's proboscis into the blood when a human being is bitten by an infected anopheline.

Incubation.—Once in the blood, three possibilities confront the parasites: they may either be killed and no infection result, or they may remain dormant in some form in the spleen, and not develop until predisposing causes, by lowering the vitality, give them opportunity, or they may at once proceed to develop and give rise to fever.

In this latter event, there is usually an interval between the period of the bite and the attack of fever, for it is evident that in order to influence the metabolism of the body so profoundly as to produce a rise of temperature a certain amount of toxin must be generated. This requires a definite number of parasites, and hence the ***incubation period*** may be short if many parasites are simultaneously inoculated by the mosquitoes, or long if but few. As a rule it may be said that some ***nine to twelve days*** are required for the development of a sufficient number of parasites to produce fever. Acton gives the following table of the length of the incubation period:—

Parasite.	*Maximum in Days.*	*Minimum in Days.*	*Average in Days.*
Quartan	18	11	14
Tertian	21	6	11
Subtertian	14	2	6

During the incubation period, however, there may be slight symptoms of lassitude, or pains in various parts of the body coming on at regular intervals, and often not much regarded, as they may pass off quickly. We are inclined to consider these as being due to parasites as yet not numerous enough to produce fever, and we think these symptoms of importance, as an attack of fever may be prevented by the prompt administration of quinine. This subject will, however, be further discussed under the Pathology of Latent Malaria.

The Fever.—The life-history of the parasite has a definite relationship to the disease, as can be noted by studying the diagrams. The rise of body temperature is always associated with the sporulation of the parasite and the liberation of pyrogenetic toxins, the apyretic interval with the growth and maturation of the parasites in the red corpuscle. This point has been recently carefully studied by Ross and Thomson by their enumerative methods, and they find that there is a distinct correlation between the number of the asexual forms found in the peripheral blood and the fever, and that no fever exists unless these forms exceed some hundreds per cubic centimetre of blood. These forms persist through the apyretic interval before a relapse, but in small numbers, which increase for some days before the relapse takes place. The pigmentation of the cells and organs is due to the hæmozoin liberated by the disruption of the infected red cell. The liberated spores attack new erythrocytes, and so the numbers of the parasites may increase, until in certain pernicious cases it appears as though the majority of the red cells were infected with parasites, and, indeed, two or more may be noted in one cell. Such a condition must, of course, lead to death.

But this does not by any means always happen: for it is well known that a malarial, especially a quartan fever may wear itself out, the attacks becoming less and less severe until they cease.

This would appear to be due to acquired immunity, which no doubt explains the known fact that the European in West Africa on first arrival generally suffers from repeated attacks of fever, but he gradually becomes partially immune, and can then live there, with care, for years. Further, it would certainly explain, in part, the relative immunity of the native races in that region who are infected from earliest childhood, and no doubt this is the true cause of the racial immunity which some allege to exist. It is now known that the merozoites can, although very rarely, penetrate the placenta, and infect the fœtus, giving rise to congenital malaria.

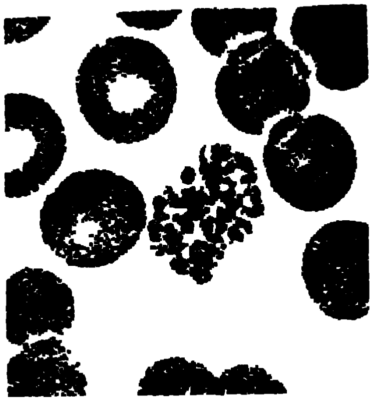

FIG. 611.—*Plasmodium vivax.* (× 1,000 DIAMETERS.)

Schizont or sporulation stage is shown enclosed in a red blood-corpuscle, which will presently rupture and liberate the pyrogenetic toxins, which will cause the fever. At the same time the merozoites and hæmozoin will be liberated.

(From a photomicrograph by Norman.)

The three parasites produce very different results, apparently due to their habitats. Thus *Plasmodium malariæ* and *P. vivax* as a rule live mainly in the circulating blood, in which the former sporulates, while the latter develops in the spleen; their toxins will therefore produce general symptoms. *Laverania malariæ,* on the other hand, seems to affect the red corpuscles so profoundly that they are liable to adhere to the walls of the capillaries of the organs in which the parasite sporulates. Hence this parasite may produce severe local symptoms, due to the mechanical blocking of capillaries or to the more intense local action of the toxin, or to both of these causes, and therefore it is associated with what are called the pernicious fevers—that is to say, the fevers which produce severe effects on one or more organs—*e.g.*, on the brain, causing coma or paralysis; or on the pancreas, causing hæmorrhagic pancreatitis.

At the onset, all three types of fever are apt to be irregular, because the parasites are of different ages, due to the different times of inoculation, but they settle down to a regular type, possibly because the amount of antitoxin generated is able to kill off those parasites which do not conform to the age-period of the majority. Sometimes, however, two distinct broods may exist, producing double fevers, or three distinct broods, causing triple fevers.

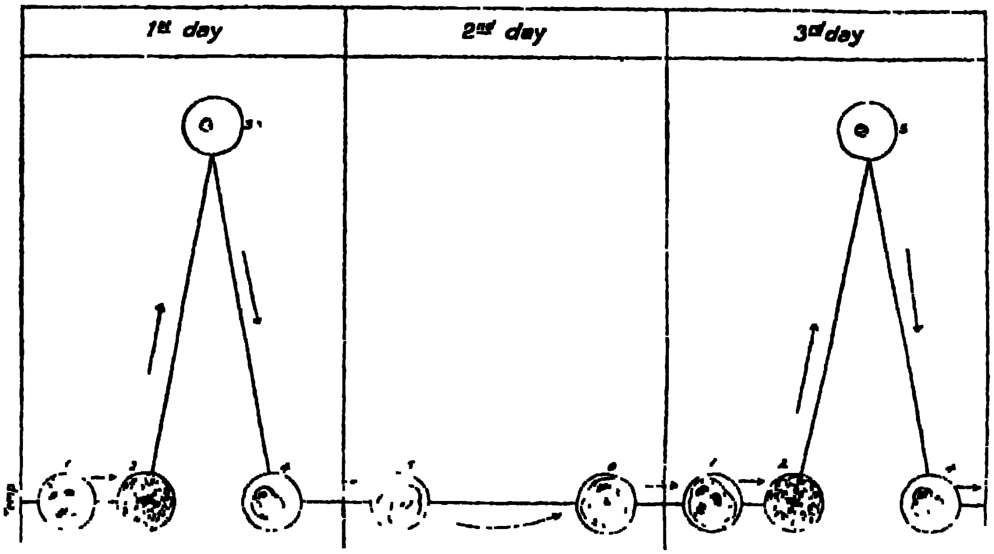

FIG. 612.—DIAGRAM OF A TEMPERATURE CHART IN SIMPLE TERTIAN MALARIAL FEVER.

1, Schizont, with commencing sporulation; 2, sporulating schizont; 3, young trophozoite; 4, 5, trophozoites; 6, schizont.

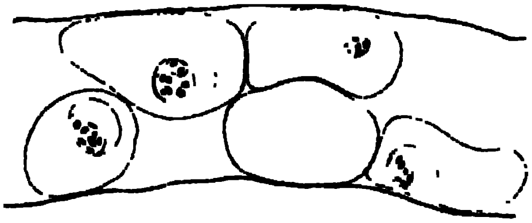

FIG. 613.—*Laverania malariæ.*

Diagram showing parasites in red corpuscles blocking a brain capillary in the cerebral type of pernicious malaria.

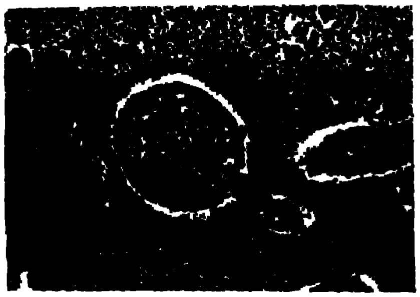

FIG. 614.—*Laverania malariæ.* (× 250 DIAMETERS.)

Photomicrograph showing parasites *in situ* in red blood cells blocking capillaries of the brain.

(After Norman.)

The malarial parasite acts not merely by destroying the corpuscle in which it lives and by altering the metabolism of the body by the pyretic toxin of Rosenau and his collaborators, but it also has a hæmolytic toxin, first described by Casagrandi and De Blasi, which destroys the red corpuscles, thus throwing more work on to the liver and leading to excessive formation of bile, with, as a result, diarrhœa and urobilin in the urine. If the blood-destruction is excessive, the liver is unable to convert the whole of the hæmoglobin liberated into bile, with the result that some may be left unaltered, and may produce hæmoglobinuria.

It appears, however, that an antitoxin is quickly formed, of the nature of an anti-auto-complement, which neutralizes this hæmolysin, and it further appears, from the experiments of Casagrandi on pigeons infected with *Hæmoproteus* (*Halteridium*), that the antitoxin may be a cause of the natural disappearance of the parasites and the cure of the disease. Of course, this antitoxin is produced by the cells of the body, and anything which lessens its formation, such as starvation, gives the parasite a chance to grow and cause disease. Thus Casagrandi found that out of twenty-one birds infected in 1904, ten were still infected in 1905. On semi-starving two of these, he produced relapses, while two others treated with antitoxin obtained from guinea-pigs inoculated with pigeon's blood did not relapse.

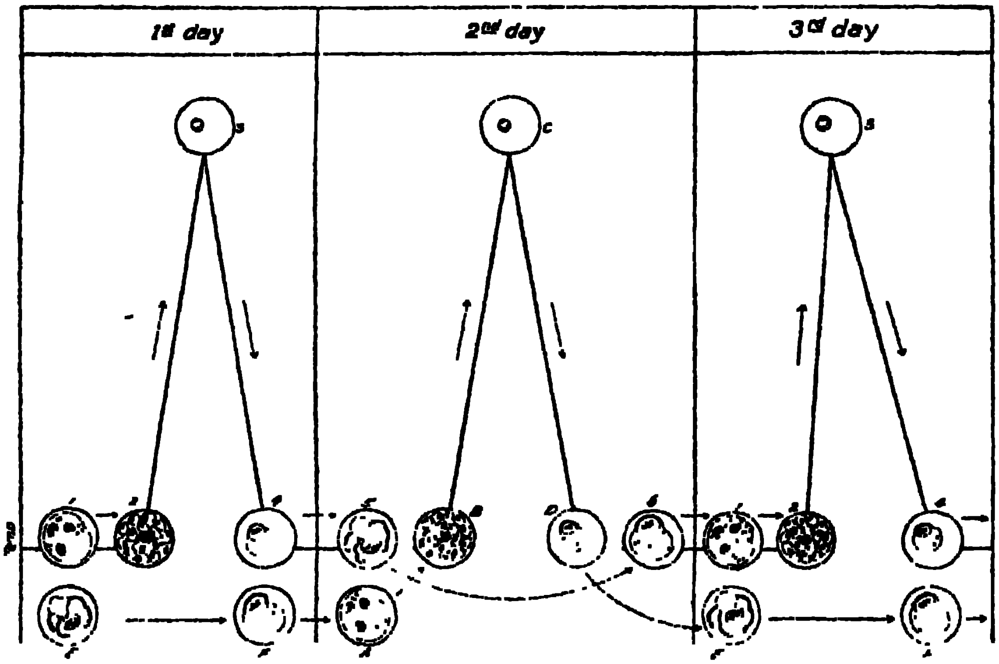

FIG. 615.—DIAGRAM OF A TEMPERATURE CHART IN DOUBLE TERTIAN MALARIAL FEVER.

The fever of the first and third days is due to one brood of parasites, and that of the second day to another brood.

1, Schizont of first brood; 2, sporulating schizont of first brood; 3-5, trophozoites of first brood; 6, schizont of first brood; *A*, schizont of second brood; *B*, sporulating schizont of second brood; *C-E*, trophozoites of second brood; *F*, schizont of second brood.

It will thus be seen that a relapse may be due entirely to predisposing causes which lower the vitality of the body and prevent the production of sufficient quantities of the antitoxin.

Besides the difference pointed out above as to the place of sporulation, there is also a great difference in the time occupied by the cycle of schizogony. *Plasmodium malariæ* requires seventy-two hours to complete its schizogony, or, in other words, it will liberate its toxins and cause an attack of fever in its human victim every seventy-two hours, while in an infection with only one brood of parasites the intervening period will be without fever. This intermission is so marked that it was noted by the ancients, and formed one of their types of intermittent fever, and as the attack of fever occurred on the fourth day, after an interval of seventy-two hours, it was called a 'quartan,' or fourth-day fever, and as such is clearly described by Hippocrates. *Plasmodium vivax* requires forty-eight hours to complete its schizogony, and in single infections produces fever every forty-eight hours—*i.e.*, on the third day—and therefore this type of fever is called 'tertian.'

Laverania malariæ, on the other hand, does not appear to be so regular in the time of its schizogony, and may require from thirty-six to forty-eight hours for the purpose; but though typically producing a tertian fever, the effects due to its sporulation in the organs are much more severe and protracted than those produced by *P. vivax*. Clinically, therefore, there are two types of tertian malarial fever—a benign and a malignant. The former, caused by *P. vivax*, is generally called 'tertian malarial fever,' while the latter, caused by *L. malariæ*, is called 'subtertian malarial fever,' or malignant tertian.

In addition to these clearly defined parasites, others have been described by various authors, and have been named *Hæmamœba præcox* and *H. immaculata* by Grassi and Feletti. The former was said to be pigmented, and the latter to be unpigmented. These parasites require only twenty-four hours for the completion of the cycle of schizogony; consequently they cause fever every twenty-four hours, which is therefore of the nature of a 'quotidian malarial fever.' Many authorities, with whom we agree, consider these parasites to be only stages in the development of *Laverania malariæ*. Quotidian fever can be produced by three broods of *P. malariæ*, or two of *P. vivax* or *L. malariæ*, and does not require a special quotidian parasite. *Plasmodium tenue* Stephens, 1913, appears in part to be related to *P. vivax* and in part to *L. malariæ*, while *P. vivax minutum* of Emin, *P. falciparum quotidianum* of Craig and Oswaldo Cruz's parasite require confirmation.

Therefore, there are only three parasites and three classes of fever to be considered—viz.: (1) *Plasmodium malariæ*, causing quartan malarial fever; (2) *P. vivax*, causing tertian malarial fever; (3) *Laverania malariæ*, causing subtertian malarial fever.

2. **The Mosquito.**—With regard to the Anophelinæ, we know positively that some can carry the germ, while others cannot (see p. 883). Further, it appears quite evident that *Culex* and *Stegomyia* are not carriers of malaria. Daniels, as we have already stated, is inclined to suspect the Ædinæ as being possible disseminators of malaria in jungles, but there is no complete proof of this. Therefore we have at present only the Anophelinæ to consider.

For the various species of the Anophelinæ which are more or less definitely known to carry malaria see Chapter XXXV., p. 883.

The presence of Anophelinæ, however, does not indicate that there must be malaria in the locality, an important point to which Celli was the first to call attention.

England, for example, though it possesses three species of the Anophelinæ—viz., *Anopheles maculipennis* Meigen, 1818; *A. bifurcatus* Linnæus, 1758; and *A. nigripes* St., of which the two former certainly can carry malaria—is practically free from the disease. Nuttall, Cobbett, and Strangeways-Pigg believe that this condition has been arrived at by the reduction of the numbers of the mosquitoes by drainage.

Since the war, however, a certain number of indigenous cases of benign tertian malaria have been reported.

On the other hand, there is no evidence of the existence of malaria without some of the Anophelinæ. On the contrary, there is evidence that where there are no Anophelinæ there is no malaria (Barbados, for example, as first noted by Low). Further, it is highly probable that the endemic malaria of Mauritius and Réunion is due to the introduction of *Pyretophorus costalis* Loew, 1866, as has been pointed out by Ross. There is also the evidence that in places where successful anti-anopheline measures have been carried out, as in Ismailia, malarial fever has ceased to exist.

In order that there may be plenty of these insects, there must be a certain degree of warmth; for as a rule they hibernate in the winter of the temperate zone, coming out in the spring, and increasing in numbers, to reach a maximum in the warm days of autumn. In the tropics, of course, the heat is present all the year round. Heat alone, however, will not suffice for the mosquito, for there must be water for the development of the larvæ and pupæ. Hence, in the dry season in the tropics, there may be few mosquitoes visible, while their numbers will increase remarkably after the rains. In the dry season the mosquitoes and their larvæ æstivate, and wait for more suitable conditions.

There is, however, a third factor to be considered, and that is the effect of the temperature upon the parasite in the mosquito. For ages it has been noted that the fevers due to *P. malariæ* and *P. vivax* occur in the temperate zone in the earlier period of the year—*i.e.*, in the spring—while the worst fevers, due to *L. malariæ*, do not occur until the summer or autumn. This point has been carefully studied by Grassi, Jancsó, Holländer, and others, and the result of their experiments tends to show that temperature has most effect upon the oökinete before it pierces the wall of the stomach of the mosquito and becomes encysted. It would appear that if the temperature is below 15° to 16° C., no further development of the oöcyst will take place in any form of parasite. Further, *P. malariæ* will develop at a lower temperature than the other two, while *P. vivax* will also develop at a low temperature, but *L. malariæ* requires a distinctly higher one.

This may be the reason of the scarcity of *L. malariæ* in the temperate zone, except in the summer and autumn, and its common occurrence in the tropics, and, possibly, this is also the reason of the rarity of *P. malariæ* in the low country of the tropics, while its presence in the hills is common.

Here may also lie the explanation of the universal distribution of *P. vivax* in both the tropics and temperate zone; for Jancsó's researches show that it can develop through a wide range of temperatures.

But these are not the only factors concerning the Anophelinæ and malaria, for Schaudinn showed that the mosquito eggs may possibly be infected by the malarial parasites, and this at once raises the question whether they cannot be carried via eggs, larvæ, and pupæ into a second generation of mosquitoes. If so, this would explain some outbreaks of malaria, but so far Schaudinn's work has not been confirmed.

Another point of importance is the fact that when new lands are opened, it is asserted that people suffer more severely from malaria than can be explained by any theory brought forward at present. For example, it is stated that if a zone of forest on a steep hillside be burnt in the dry season, and then cleared by coolies, who return every night to the quarters where the other estate coolies also sleep, these clearing coolies will suffer severely from malaria, while their fellows working on other portions of the estate will be but little affected. The explanation of this is not that emanations have arisen from the soil and invaded the bodies of the coolies— indeed, after the description of the life-history of the malarial parasite already given, this would be a *reductio ad absurdum*—but merely that the exposure to the sun or the harder work has lowered the vitality of these coolies, and has given the germs already in their system a chance to develop.

It has also long been thought that the mechanical opening of new ground by digging produced the disease, but Ross has pointed out that in Mauritius the digging of earth for years caused no malaria, until some new factor was introduced which occurred in the sixties of last century: this factor we now know to have been the introduction of *Pyretophorus costalis* into the island.

When an attack of malarial fever occurs in a person living in a place where there are no Anophelinæ, it is the result of infection obtained in some other place where these mosquitoes are to be found.

It may safely be concluded that, as far as our present knowledge goes, certain of the Anophelinæ are the only carriers of malaria, and upon this public prophylaxis must be based.

A female mosquito, apparently, can live for at least a month (Ross), if not longer. This does not include such dormant periods of its life as the hibernation in the cold or æstivation in dry seasons, when it may live for a long time in damp places.

The eggs of the Anophelinæ are laid only in natural collections of water supplied with water-plants, such as the back eddies of streams, close under the banks, which are especially good breeding-places. The young imagines, apparently, do not usually travel, but remain near the place where they are developed. Occasionally they can be carried long distances by ships, trains, coaches, carts, etc., but this is the exception, and not the rule. Winds do not appear to carry them far, as they generally take shelter from a high wind. The natural enemies of the Anophelinæ are numerous, including all insectivorous animals, such as bats and birds, together with fish, which eat the larvæ.

The anopheline not merely carries the germ, but because of its length of life, a single individual may be capable of infecting several human beings; for it must be remembered that there is no proof that the mosquito is in any way deleteriously affected by the malarial parasite, and in this way it forms a reservoir of infection.

3. **Man.**—The female anopheline requires blood for the purpose of providing its eggs with sufficient nourishment, and will, therefore, bite any vertebrate it may come across in order to obtain the same.

The malarial parasites have, so far, only been found in man, and hence, until they are found in some other vertebrate, we are not justified in assuming that the anophelines can obtain them from any other source. In the tropics the native population is undoubtedly the great source of the gametocytes by which the infection of the mosquito is brought about, because the majority of them do not protect themselves against mosquito-bites. Of the native population, the children are the greatest source of infection, because, as has already been explained, the adults obtain a partial immunity. But in considering the native as a source of infection, care must be taken not to forget the European, whose blood is sometimes swarming with gametocytes.

Ross has pointed out that, in considering the amount of malaria in a particular locality, imported cases must be distinguished from indigenous cases, and that the latter should be further classified according to the month in which they are infected. He has also attempted, by mathematical formulæ, to investigate the infection-rate of the disease, which method he terms 'pathometry'; but it is very difficult to obtain the necessary data for these calculations. He points out that the number of infections in a given locality during a given period depend upon—

1. The number of persons with gametocytes in the blood.
2. The number of anophelines which have bitten these people and become infected.
3. The number of infected Anophelines which live long enough to transmit the infection—*i.e.*, at least a week.
4. The number of these surviving infected Anophelines which get the chance of biting man again.

It is by no means easy to determine, even approximately, in a district the number of Anophelines capable of carrying malaria; but an attempt might be made to follow Ross, and determine the output from one or two of the more important breeding-places by enclosing a given area with mosquito-netting, and counting daily the numbers of Anophelines which hatch out. A calculation of the areas of the breeding-places, together with the numbers hatching per diem, will give a rough estimate of the increase during that time. Associated with this, a census may be taken of the Anophelines found inside damaged mosquito-curtains very early in the morning. This is a method we have used in Tropical Africa and found of service, for it supplies not merely the number of the Anophelines, but also the percentage which are infected, though of course the error is likely to be considerable. Ross proceeds to show

mathematically that the increase or diminution of the malaria really depends upon the ratio to the population of Anophelines capable of carrying the parasite; and also how an epidemic gradually increases, and how it diminishes when the Anophelines are reduced; and proves that, in order that there may be a reduction of the malaria in man, there need only be a reduction in the numbers, and not an extermination of the Anophelines, which is what would appear to have happened in England, and to be the cause of the disappearance of malaria therein.

Investigation of an Endemic Region.—In investigating malaria in an endemic region, it is necessary to find out—

1. The specific diagnosis of the parasite or parasites causing the malaria.
2. The population of the area.
3. The average number of infected persons.
4. The average number of infected persons carrying the gametocytes in their blood.
5. The species of Anophelinæ in the district, and their breeding-grounds.
6. The species which carry the parasite.
7. The species in which the parasite is found in nature.
8. The number of Anophelines in the affected area.

No remarks need be offered with regard to 1, 2, 4, 5, 6, and 7.

With regard to 8, the method suggested by Ross should be adopted; and as regards 3, the quickest and the best method is to estimate the spleen-rate, but it must be remembered that the spleen is palpable in 1·07 to 2 per cent. of non-malarial children living in London.

Ross suggests that the term 'endemic index,' which was introduced by Stephens and Christophers to denote the percentage of persons carrying parasites in their blood, should be extended to include not merely that factor, but also the proportion of people with spleens enlarged by malaria.

He therefore proposes that the endemic index should be made up of a parasite-rate and a spleen-rate, of which the latter is the more convenient, and if applied to children under fifteen years of age, is useful, provided that kala-azar does not occur in the locality investigated. Children are chosen because the adults have acquired a partial immunity, as already explained.

But the endemic index as defined by Ross is sure to be higher than the mere spleen-rate, and therefore the blood must be examined in the children whose spleens are not enlarged, and the parasite-rate must be added to the spleen-rate to obtain the true endemic index.

In all calculations such as the above the statistical error must be borne in mind, and Poisson's formula, or the modification by Pearson which Ross recommends, must be applied.

Let N=total number of children under fifteen years of age in a locality.
n=number examined for spleen-rate.
x=number with enlarged spleen.
$\frac{x}{n}$ 100=spleen-rate.
e%=percentage of error.

Then by the Poisson-Pearson formula the percentage error will be :—

$$e\% = \frac{200}{n}\sqrt{\frac{2x(n-x)}{n}}\sqrt{1-\frac{n-1}{N-1}}.$$

Latent Malaria.—This term is employed to denote cases in which, without any sign of illness, malarial parasites can be found in the blood in small numbers. These cases form a reservoir of transmission to the anopheline. Craig states that out of 1,267 cases in which malarial parasites were demonstrated in the blood, 21 per cent. were latent, and the majority of these were found to be caused by the subtertian parasite.

Congenital Infection.—The question of congenital malaria has been much debated, but Dumolard and Viallet have recorded a case in which a woman suffering from malaria gave birth to a child, in which blood from the umbilical cord during life and from the heart after death contained malarial parasites identical with those in the maternal blood and placenta. A similar case has been recently reported by Léger.

II. PREDISPOSING CAUSES.—These may be classified into:—

1. Those which promote infection with the parasite.

2. Those which promote the increase of the parasite in man after its inoculation.

1. THOSE WHICH PROMOTE INFECTION WITH THE PARASITE.—The first of these is residence in an area which contains not merely persons with gametocytes in their blood, but also mosquitoes capable of carrying the disease, associated with an atmospheric temperature suitable for the development of the parasite in the mosquito.

The second is any cause which produces large numbers of mosquitoes capable of spreading the disease. This will be not merely a suitable air-temperature, but also moisture. Hence low-lying, marshy places, and the wet season, are important predisposing causes.

The third is occupation, for this may compel people to live in malarial countries, to reside in the low-lying marshy portions of the same, to work in rice fields covered with water, etc. Age is a predisposing factor, as mosquitoes have more opportunity of biting a young child than an adult. Sex has no influence.

2. THOSE WHICH PROMOTE THE INCREASE OF THE PARASITE AFTER ITS INOCULATION.—These predisposing causes are subdivisible into: (*a*) racial; (*b*) personal; (*c*) meteorological.

(*a*) *Racial.*—There is no doubt that the native races suffer less than an immigrant race in a tropical country, where there is always malaria present, and this we believe to be mainly due to the acquired partial immunity of the native races, as already explained.

(*b*) *Personal.*—It will be obvious from the above remarks that the parasite cannot produce the markedly deleterious effects which we term malarial fever, unless there be a sufficiently large number present. Further, there appears to be a tendency on the part of the body to manufacture protective substances, which keep the growth of the parasite in check. Anything, therefore, which interferes with the production of these checking materials will enable the parasite to grow and multiply, and will thus become a predisposing cause of the disease. Such conditions are: (1) chills; (2) starvation or overfeeding; (3) the onset of another acute disease; (4) the presence of some chronic ailment, which may often be but slight.

(c) *Meteorological.*—We have already drawn attention to the relationship between the temperature of the external air and the development of the parasites in the mosquito. It now remains to point out that a similar relationship exists between that condition and the development of the parasite in the human being.

Ross is of the opinion, not merely from observations upon man infected with malaria, but also upon birds infected with *Halteridium*, that high air-temperatures are favourable to the increase of the malarial parasites in man. High air-temperatures are therefore a cause of the relapses met with so frequently in the hot dry season of the tropics.

The reverse is also true; hence the benefit of sanatoria at high altitudes in the tropics, and also of sending a fever-stricken patient to cooler climates, provided the change from the hot to the cold climate be not sudden, but gradual.

Climatology.—The geographical distribution of malaria is determined by a combination of the conditions suitable for the production of large numbers of mosquitoes capable of carrying the germ, and of those suitable for the development of the parasites in the mosquitoes, together with the presence of human beings with numbers of gametocytes in their blood.

The virulence in one region more than in another may depend upon the type of parasite. Thus, *Laverania malariæ*, which is a more virulent parasite than *Plasmodium malariæ* or *P. vivax*, being very common on the West Coast of Africa, renders that area peculiarly dangerous.

Generally speaking, malaria is most prevalent in the region of the Equator, and diminishes gradually north and south till the Arctic and probably Antarctic Circles are reached. The malarial area lies between 63° north latitude (mean summer isotherm of 15° to 16° C.) and 35° south latitude. Its geography may alter considerably in the course of years. Thus regions in England, Holland, France, Germany, and Austria-Hungary are much less malarial than they formerly were. On the other hand, it has been known to affect countries which at one time were immune. Thus Ross says that he believes that Mauritius was infected in the early sixties of last century by the introduction of a mosquito capable of spreading the disease, and hence the epidemic which occurred in that island. Réunion is another example. Barbados is said to have no malaria and no anophelines. Therefore the geography to be described is that known to exist at present.

AFRICA.—The worst malarial region in the world is probably the West Coast of Africa, from Senegal to the Congo, but the whole of Africa, except portions of Cape Colony, is malarial.

ASIA.—Malaria is widespread throughout Asia, being very marked in certain districts of India, especially the swampy land at the foot of the Himalayas, in Ceylon, and Borneo; while Arabia, Syria, the Straits, Siam, and China are also malarial. Little is known about Siberia.

AUSTRALASIA AND POLYNESIA.—Malaria occurs in the north of Western Australia, the Northern Territory, North Queensland, Torres Straits Islands, New Guinea, Finschafen, the Solomon Islands, and the Bismarck Archipelago.

AMERICA.—Malaria exists in Central America, the West Indies, with the exception of Barbados, the coast of the Mexican Gulf, the north of South America, including British Guiana, and the north of Brazil as far as Rio de Janeiro. Paraguay and Bolivia are infected, as are Peru and Chili, but the south part of South America is less infected. Many places in the United States are malarial, but Canada is not markedly infected, except about the northern shore of Lake Ontario, while Greenland is supposed to be free.

EUROPE.—Great Britain and Norway are practically free, but most of the other countries have endemic foci, particularly Russia, Italy, Serbia, Greece, Turkey, and Austria-Hungary.

In France malaria exists in the south and west; in Switzerland in the canton of Tessin; in Germany along the course of the Rhine, and in the lowlands watered by the tributaries of the Danube. Sweden has also some endemic spots.

Apart, however, from mere geographical distribution, it will be obvious that the necessary conditions for malarial propagation are best supplied in the tropics, especially near the Equator, where there is generally a considerable amount of atmospheric moisture and rain as well as heat.

The wet season has also a great influence, supplying the necessary moisture which at other times may be lacking. The effect of altitude has already been mentioned.

Pathology.—In malaria the body is invaded by protozoal parasites, which grow and increase at the expense of the red cells of the blood, and in doing so manufacture toxins, of which we know two—viz., a pyrogenetic toxin and a hæmolysin.

Red blood cells are found in the whole of the circulatory organs, but are generally contained in arteries, veins, and capillaries. In two places, however—viz., the spleen and bone-marrow—they come intimately into relationship with the parenchyma cells. Whatever function the spleen may in future be found to possess as regards the malarial parasites, it probably acts as a purifier to the blood which passes through it. Perhaps the bone-marrow assists in such a function.

Parasites contained in red cells should, therefore, be able to pass all over the body, and should be found equally distributed, no matter what organ is examined. This would be so if the parasite did not seriously damage the red cell, and, by its toxins, the endothelium of the vessels, especially that of the capillaries, in which the blood-flow is slowest. It would appear as though the damage done to the red cell by the quartan parasites is not severe enough to cause them to be caught in the capillaries. Therefore the whole life-history of the quartan is spent in the circulation, and sporulating forms can be readily seen in finger-blood.

Tertian parasites, on the other hand, seriously affect the red cells, causing swelling, degeneration, and decolorization. The trophozoite and schizont stages are easily seen in the peripheral circulation. Still, the sporulating forms are more common in the spleen, which may be looked upon as having filtered them off from the blood which passes through it.

The subtertian parasites act deleteriously on the corpuscles, making them smaller and darker. They rarely appear in the peripheral circulation in the sporulating condition, while they abound in the spleen and internal organs. On examining the organs post mortem, it will be found that the schizont and sporulating forms are found in the capillaries, while the trophozoites are found attached to the walls of the arterioles and venules.

The sporulating parasites give rise to hæmozoin, which escapes from the corpuscle along with the merozoites, and will therefore be most commonly found in those tissues and organs in which sporulation takes place—*e.g.*, spleen, liver, and bone-marrow—and will give them a definite coloration, varying from a reddish-brown to a black, according to the quantity present.

This pigment will, of course, be also met with in the peripheral blood, both free and inside mononuclear leucocytes, for, on escaping from the parasite, the hæmozoin is seized by the mononuclear leucocytes, macrophages, and the endothelial cells of capillaries; therefore, in acute malaria, it will be distributed evenly through the organ affected. The pigment is later conveyed from the blood-vessels into the tissues by the phagocytes, and is found in the connective tissue of the organ close to the bloodvessels. Eventually it disappears, being partially digested by the phagocytes and tissue cells and partially removed by the lymph. This process, however, cannot continue without causing irritation of the connective tissue.

Not merely does pigment escape from the sporulating parasite, but also hæmolysin, which damages the red cells, and causes the appearance of another pigment, yellowish in colour, called 'hæmosiderin.' This is deposited in the parenchyma cells of the organs—*e.g.*, the liver—and may perhaps damage them. The presence of this hæmolysin has been confirmed by the researches of Simpson.

Another toxin—this time pyrogenous—also escapes from the sporulating parasite, and may be the cause of the hyperæmia found in the internal organs—*e.g.*, the spleen and the liver in acute malaria—and may also cause the destruction of the parenchyma cells of those organs. After a series of attacks the blood capillaries and lymph spaces in the liver and spleen remain permanently dilated, and separated by only a slight amount of damaged parenchyma tissue. Later, regeneration of the parenchyma takes place, but the organ will remain permanently altered, even though all pigmentation may have disappeared.

In the case of the subtertian parasite, serious local damage may be caused to the brain, the intestine, the pancreas, or other organs, by the parasites massing in the capillaries and forming, with free pigment and swollen endothelial cells laden with pigment and parasites, regular thrombi, sufficient to impede the circulation, and thus to still further damage the toxin-poisoned organ. Finally, the toxins are excreted by the skin and by the kidney, and in doing so may damage the latter organ.

There are two main conditions, the pathology of which must be explained—viz., acute and chronic malaria. In acute malaria there are the effects produced by each of the three parasites, of which the subtertian is liable to seriously damage important organs.

Chronic malaria should also be described according to the three types, but there is at present lack of material to evolve such a description. Chronic malaria may, however, pass to an advanced condition called 'malarial cachexia,' which shows itself in three ways—as (1) a rare acute cachexia; (2) a more common chronic cachexia; (3) cachexia with amyloidosis.

In addition, there are the pathological features of latent malaria and the relapses.

Before, however, proceeding to describe the actual morbid anatomy of these conditions, a few words must be said upon what we know of the chemical pathology of the disease and on the blood changes which take place.

Chemical Pathology.—The pyretogenous toxin has already been mentioned among the poisons of animal origin, and, though long suspected of being present, its actual occurrence was first proved by Rosenau and his collaborators. Probably it is the poison which acts deleteriously upon the tissues of the organs and causes metabolic changes, but this is only a matter of conjecture.

We know that the heat output in the cold stage of the attack is markedly diminished—a condition met with in many fevers—but the chemistry of the metabolic changes is but little known. During the attack the urine is at first increased in quantity, which is thought to be due to the rise of blood-pressure internally, owing to the contraction of the cutaneous vessels during the cold stage. Notwithstanding this increase in quantity, the specific gravity is raised, because of the increased metabolism caused by the toxins, as is shown by the large increase in solids. The colour is dark, and the acidity of the urine is increased, as in most fevers. Nitrogen is excreted in excess, which is largely due to the increase of urea. Chlorides, sulphates, and bases, especially potassium, are all increased in quantity. Phosphates, however, are diminished during the actual attack, but increased as it is passing off, and are considerably increased in the intermission. Phosphoric acid is therefore retained in the body during the attack.

As would be expected, iron is excreted in increased quantity, probably due to hæmozoin and hæmosiderin, but this increase does not really appear until after the actual attack is over, and then continues for some days.

As before remarked, the urine may contain a considerable quantity of urobilin, and the indigo-blue may be also increased.

Schlesinger's test for urobilin in the urine is performed by adding to the unfiltered urine an equal quantity of a solution of 10 parts of zinc acetate in absolute alcohol, shaking the mixture, and adding a few drops of a solution of lugol, stirring and filtering, when a fluorescence will appear, varying in intensity according to the quantity of urobilin present.

The diazo-reaction is said to be obtainable in about 5·5 per cent. of cases. Serum-albumen may be present after severe attacks, and protcose has been reported, as well as nucleo-proteid.

When the intermission comes, the urine diminishes in quantity, but nitrogen is still excreted at a higher rate than it should be, though less than during the attack.

Chlorides are diminished, phosphates increased; sulphates, though still higher than normal, are less than during the attack, while the excretion of the bases is diminished. The excretion of iron is marked, and the toxicity of the urine is said to be considerable.

During convalescence the most marked features are the polyuria, with low specific gravity, which in subtertian fevers may be so marked as to alarm the patient, while in quartan and tertian it may be so slight as to escape attention. There is also increase of chlorides and potassium salts excreted.

Urriola states that if the urine in malarial ca[illegible] is centrifuged, four types o pigment granules may be found: (1) very fin[illegible]ranules; (2) larger granules in groups; (3) large masses; (4) granules in [illegible]cocytes and hyaline casts It is, however, difficult to exclude extraneous matters.

As regards the fæces, the most noticeable feature is the increase in the excretion of bile and iron, both of which are related to the blood-destruction. Ross and Thomson have shown that the quantity of fæcal urobilin (stercobilin) shows a marked correlationship with the occurrence of the fever, being increased during the attack.

The sweat of a malarial patient is well known to have a peculiar odour, and contains substances very toxic to rabbits.

The above chemical features point to the fact that the toxins of malaria are excreted from the body by the sweat and the urine, and that during the fever there is very active nitrogenous, potassic, chloride, and sulphate metabolism.

That there may be other toxins as yet unknown is obvious from the fact that the *Plasmodia* cause marked shivering and a sensation of coldness, even though the actual blood temperature is rising. It would appear as though this is due to the constriction of the cutaneous vessels by some poison which acts on non-striped muscle, for the arrectores pilorum are also affected, producing goose-skin. *Laverania malariæ*, however, because it sporulates internally, and not in the peripheral blood, causes chills more rarely than the other two.

De Blasi has shown that an antihæmolysin is formed in the human body, and Casagrandi, as already mentioned, has performed experiments on *Halteridium* in birds, tending to show that this substance has a restraining power against increase of the parasites.

The only other remarks we can offer on the chemical pathology are limited to the nature of the pigments, hæmozoin and hæmosiderin.

HÆMOZOIN.—Hæmozoin is the black pigment formed from hæmoglobin by the malarial parasites while living in the erythrocytes, and is afterwards distributed over the body on the disruption of the red cells. It is taken up by phagocytes, as already described, and removed from the bloodvessels to the connective tissue, in which it can be seen in the liver and spleen. It is soluble in alkalis, but not in water, alcohol, chloroform, ether, or acids. It contains iron, but in the form of an organic compound, which will not give the Berlin-blue reaction. Eventually it disappears from the connective-tissue cells, but whether it is eliminated from the body or used in some altered form we do not know. As it is formed by malarial parasites, it is peculiar to the diseases caused by them. Brown considers that it is formed by the action of a proteolytic enzyme from the parasite acting upon the hæmoglobin of the erythrocyte, and that therefore it is formed from hæmatin, a conclusion also arrived at by Carbone and V. Ascoli.

HÆMOSIDERIN.—This is the yellow pigment found in the form of yellow granules in the parenchyma cells of the liver, spleen, kidney, bone-marrow, endothelium of capillaries, and occasionally in leucocytes, after any great destruction of blood cells. In malaria it is undoubtedly due to the action of hæmolysins destroying the red cells. It contains iron in the form of an inorganic compound, and gives the usual Berlin-blue reaction. It is insoluble in alkalis and acids, but is soluble in alcohol.

The Blood.—The parasites live in the blood, in which they produce changes by their own action and by that of their toxins.

The malarial parasites, being true blood parasites and living in the red cells, form the most important feature of the pathology of the blood, but their structure and life-history having already been described in Chapter XVII., it only remains to estimate their numbers.

Ross estimates that a medium-sized person of 68 kilogrammes (150 pounds) body weight possesses 25,000,000,000,000 erythrocytes. In a severe infection he estimated the parasites as numbering 12 per cent. of the corpuscles—*i.e.*, 3,000,000,000,000—and, further, he considers that if they fall below 1 to 100,000 corpuscles—*i.e.*, 250,000,000—they will cause but little disease. Certainly, large numbers of parasites can exist in the body and go through their life-cycle in the spleen without causing symptoms. This condition is called 'latent malaria,' and can be easily converted into active malaria by any cause which depresses the vitality of the body.

ERYTHROCYTES.—In quartan malaria the corpuscle containing the parasite is a little smaller than a normal corpuscle, and, if anything, more darkly coloured. In tertian malaria it is swollen and more lightly coloured, and on treatment with Leishman's stain exhibits fine red granules (Schüffner's dots), which are to be looked upon as a sign of degeneration of the corpuscle. In subtertian malaria the corpuscles when stained in the same way may exhibit Maurer's dots or clefts, which appear as large, irregular red formations, and also Marshall-Plehn's bluish dots, the significance of which is uncertain. The red cells may become transformed into brassy bodies, which are shrunken red corpuscles which have taken on the colour of brass. These are corpuscles which have undergone some form of necrosis, probably due to the hæmolysin, though it has been thought that they were infected corpuscles in which the parasite had died as a result of the necrosis.

FIG. 616.—BLOOD FILM SHOWING SCHIZONT OF *Plasmodium vivax*.

(From a microphotograph by J. J. Bell.)

FIG. 617.—BLOOD FILM SHOWING HEAVY INFECTION WITH *Laverania malariæ*.

(From a microphotograph by J. J. Bell.)

Partial decolorization of the erythrocytes has been recorded in subtertian infections, and is especially well marked in those containing crescent bodies. Bignami thinks that in the subtertian fever the red corpuscles, which are infected with the parasite, have a diminished elasticity, and therefore are not so capable of circulating, and cling to the walls of small capillaries.

As every sporulation causes the destruction of red cells, anæmia is one of the marked features of malaria. This destruction takes place at each paroxysm, and though in quartan and tertian fever it may be slight, in subtertian fever it is apt to be considerable.

After a certain number of attacks of fever the loss becomes much less than in the earlier seizures.

When the fever is intermittent, regeneration takes place quickly, so that before the next paroxysm the normal number of erythrocytes may be nearly reached; but even in quartan and tertian fevers, if long-continued, anæmia will result.

The histological changes in the unaffected corpuscles are pallor and poikilocytosis, with demi-lune and crescentic forms, and in severe cases megaloblasts, with polychromatophilia and basic granular degeneration, together with normoblasts, may be noted. The tonicity of the corpuscles is increased after a number of attacks, according to Viola. In the blood of malarial cachectics the brothers Sergent have described basophile formations having the shape of a figure 8, with a double contour, and Brumpt and others have described basophile rings with a single contour. Laveran considers these appearances to be due to artefacts.

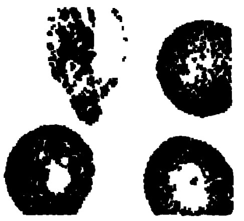

FIG. 618. — BLOOD FILM SHOWING PARTIAL DECOLORIZATION OF AN ERYTHROCYTE BY A CRESCENT BODY OF *Laverania malariæ*. (X 1,000.) (After Norman.)

LEUCOCYTES.—The leucocytes are at first increased during the paroxysm, and then markedly diminished, so that a leucopenia is the characteristic of the simple malarial fevers. The normal ratio of white to red corpuscles is 1 to 500 or 600. From observations of Stephens and Christophers this may be 1 to 90, 1 to 200, 1 to 290, or 1 to 300 during the rigor (*i.e.*, leucocytosis), becoming 1 to 764 (*i.e.*, leucopenia) when the rigor is completed, and when the temperature falls altering to 1 to 968. Billet has shown that if curves are made of the leucocytic count and the temperature in simple tertian and quartan fevers, the two curves follow one another in their rises and falls. In pernicious malaria there may be leucocytosis.

Another important matter is the relative increase of the large mononuclear leucocytes, and this is better marked during the leucopenia of apyrexia than during the leucocytosis of the attack, for Thompson finds that it is usually low during the rigor and the febrile stage, but with the decrease of the fever it may become as high as 90 per cent. of the total leucocytes. This mononucleosis is observed for a long time after an attack of fever, even when quinine therapy is persisted in continuously.

The following are some examples of the differential count according to various observers:—

Kind of Corpuscles.	*Da Costa.*	*Billings.*	*Christophers and Stephens.*	*Bastianelli.*
Polymorphonuclears	67·00	65·04	50·2	39·0
Large mononuclear and transitional	15·94	16·90	31·4	41·9
Lymphocytes	15·33	16·90	18·1	19·1
Eosinophiles	0·83	0·96	0·4	0·0

It must be remembered that this relative increase in the mononuclears has been noted in other protozoan infections.

Phagocytosis is particularly seen in the large mononuclear and transitional leucocytes, and to a less degree in the polymorphonuclear leucocytes and very rarely in the eosinophiles. In these cells clumps of pigment and the residue left after segmentation of a schizont are not uncommonly seen. If, however, something abnormal takes place in the red corpuscle, a phagocyte may engulf it and its parasite, or only the parasites if they have escaped from the red cell, or only the débris of the red cell.

Vacuolization and diminution of the staining power of leucocytes are to be seen. Myelocytes are said by Da Costa to be found in subtertian infection up to 0·51 per cent. Eosinophiles diminish during the paroxysm, and increase during the apyrexia.

HÆMOGLOBIN.—This is, of course, reduced, but the colour index may vary sometimes, being less than normal. Ross and Thomson find that it falls markedly with an attack of fever, but rises rapidly during convalescence.

THE SPECIFIC GRAVITY OF THE BLOOD.—Diminution of the density of the blood begins at the onset of the attack, and becomes more marked as it proceeds, and may amount to a diminution of 6·2 degrees. This fall is probably due to destruction of red cells and the breaking up of large parasites, which more than balances any loss of liquid by vomiting, diarrhœa, sweating, and polyuria.

The diminution is most marked in full-blooded persons, in primary affections, and first attacks, less in later attacks, and least in chronic malaria. The density recovers after treatment by quinine.

CHRONIC MALARIA.—In chronic malaria there is a leucopenia and a marked decrease in the numbers of the red cells, which is but little affected by febrile attacks.

POST-MALARIAL ANÆMIA.—Bignami points out that there are cases in which, in spite of the cessation of the malarial fever, the anæmia tends to progress, and these he calls post-malarial anæmias. They are generally induced by age, malnutrition, overwork, pregnancy, nursing, etc., and are not due merely to the malarial infection. Bignami divides these into four types, according to the characters of the blood.

First Type.—This form of anæmia comes on after attacks of ordinary acute malaria, and is characterized by well-marked diminution in the erythrocytes, the presence of normoblasts, diminution of the colour-index, and leucopenia associated with relative mononuclear increase. In this type the prognosis is good.

Second Type.—The second type is severe, and the prognosis is exceedingly bad. It is characterized by great diminution in the red cells, presence of poikilocytes, megalocytes, normoblasts, and megaloblasts, with leucopenia and relative mononuclear increase.

Third Type.—This is rapidly fatal, and has similar characters to the second type, but is without normoblasts.

Fourth Type.—This type is really grave chronic anæmia, resembling the first type, but being specially characterized by the paucity of the normoblasts and the marked leucopenia.

Wassermann reaction is in our experience generally negative.

Morbid Anatomy.—The morbid anatomy of malaria has been most carefully studied in recent years by Bignami in Italy and Ewing in America. It may be considered under the following headings:—

A. ACUTE MALARIA.

1. Lesions caused by *Plasmodium malariæ.*
2. Lesions caused by *Plasmodium vivax.*
3. Lesions caused by *Laverania malariæ.*

B. CHRONIC MALARIA.

1. Lesions caused by *Plasmodium vivax.*
2. Lesions caused by *Laverania malariæ.*
3. Malarial cachexia.
4. Latent malaria.

A. MORBID ANATOMY OF ACUTE MALARIA—1. LESIONS PRODUCED BY *Plasmodium malariæ.*—*Plasmodium malariæ* goes through the entire process of schizogony in the circulating blood, and hence is evenly distributed all over the body, and therefore does not especially accumulate in any one organ. Marchiafava and Bignami mention that they have made two autopsies, one on a case of acute quartan malaria, in which the patient died of nephritis, and the other in a case of the same fever, in which the patient died of spinal disease.

The visceral lesions are: *Spleen* enlarged, not softened nor very melanotic; *liver* and *bone-marrow* not markedly melanotic; *parasites* in the spleen and in the blood, but not in the brain.

Leishman has mentioned that he has received films from the peripheral blood and spleen of a fatal case, in both of which the parasites were very numerous, but he was not in a position to state whether the patient died of malaria or not. If *P. malariæ* is to produce severe symptoms, it would appear necessary for it to exist in very large numbers.

2. **LESIONS PRODUCED BY *Plasmodium vivax*.**—It is rare for death to ensue as the result of an infection with *P. vivax*. Still, this does occur at times when there is a heavy infection. Ewing has described a case of tertian infection causing coma, hæmoglobinuria, and either causing or associated with catarrhal colitis.

The principal features are the pigmentation of the bone-marrow, liver, and spleen, which last is also enlarged. The blood and spleen show large numbers of *P. vivax*. The kidneys and colon are inflamed, and the endothelial cells of the brain are swollen and contain pigment.

3. LESIONS PRODUCED BY *Laverania malariæ*.—We have already insisted several times upon the fact that *L. malariæ* differs from the other malarial parasites in sporulating in the organs, generally in the spleen, but at times choosing one organ and at other times another. The organ in which it sporulates in large numbers suffers most, and produces symptoms which give the characters of that particular type of malarial fever.

Thus the parasite may attack principally the brain, the intestine, the heart, or the pancreas, producing marked signs of disease therein. Therefore the conditions of the organs vary with the localization of the parasite.

Macroscopical Examination.—In general the body is pale, with a yellowish tinge, which may be noted superficially in white races, but which may only be observed in the subcutaneous tissues in native races. The heart may be small or dilated, the muscle flabby and pale or brownish, and ecchymoses may be present in both the epicardium and endocardium. The lungs may be normal, anæmic, or hyperæmic and congested. Hæmozoin is not easily detected in the lungs, because of the usual pigmentation. As first described by Laveran, a sclerosis of the lungs is not infrequently met with.

The liver is generally enlarged, and varies from a dark brown to a slate colour. It is soft and congested, and the outlines of the lobules are usually indistinct. The gall-bladder is full of dark-coloured bile.

The spleen is enlarged, with a tense capsule, but its consistency is usually much less than normal, and at times it may be almost diffluent in very acute cases. We have, however, seen it quite firm in a recent infection. Its colour varies from a deep brown to black

The stomach and intestines may show but little change, except in the choleraic forms, in which their mucosa may be intensely congested and dark red in colour, except where the Peyer's patches and the solitary glands stand out clearly. The intestine is darker red in certain places, giving it a mottled appearance, and the contents may be blood-stained fluid with flakes of mucus. In fact, the appearance post mortem and the history, if death takes place rapidly, so much resemble those of cholera that in regions where that disease is prevalent mistakes may arise, though, indeed, the dark pigmentation should enable errors to be avoided. We have not infrequently met with dark pigmentation of the small and large bowels in cases of pernicious cerebral malaria, and in general infection without cerebral symptoms. This pigmentation is due to hæmozoin, as can be easily proved by microscopical examination.

The lymphatic glands may be swollen, while the pancreas is usually normal, but it may be very rarely swollen and hæmorrhagic—*i.e.*, in a condition of hæmorrhagic pancreatitis. We have seen it quite brown, and pigmented with capillaries choked with infected corpuscle débris, pigment, etc.

The suprarenal capsules may be congested. The kidneys are more or less normal, but sometimes they are congested, with punctiform hæmorrhages in the pelvis and cloudy swelling in the parenchyma, or brownish. The serous membranes, pleura, and peritoneum, show as a rule nothing remarkable, except, perhaps, a little pigmentation. The bone-marrow is generally hyperæmic and chocolate-brown in colour. The brain may appear normal, but in the cerebral type of pernicious malarial fevers there will be marked changes. In slight cases there may be only œdema without pigmentation or petechiæ. Sometimes there is brownish pigmentation without petechiæ, and with or without œdema. Typically, however, there are:—(1) Hyperæmia of the leptomeninges, which may be œdematous and thickened; (2) brownish, or even blackish, pigmentation of the cortex; and (3) punctiform hæmorrhages in the white matter under the cortex or elsewhere. The spinal cord exhibits changes similar to those in the brain, while the retina shows numerous hæmorrhages.

Microscopical Examination.—After death, parasites may be found in the blood of the heart, spleen, bone-marrow, and at times in the capillaries of the brain, intestines, pancreas, etc.

The parasite, however, is much shrunken, and the typical forms seen during life are not distinct after death. Thus the ring form shrinks and becomes a rounded disc, with the chromatin particle situated at the periphery. The fully developed schizont is more typical, the merozoites being arranged in a ring around the central pigment block. If the post-mortem is made quickly this shrinking is not noted. The mononuclear leucocytes will be noted to have pigment granules, while the polymorphonuclears may show phagocytosis. In films from the internal organs macrophages with parasites and red cells may be seen.

In the heart there may be a few parasites, but very rarely the capillaries will be found filled with red cells containing numerous parasites, and the heart muscle laden with hæmosiderin as has been described in a pernicious cardiac form of malaria, but may also be seen in cases of general infection.

The lungs may contain parasites in all stages of their existence, as well as pigmented macrophages and leucocytes. It is, perhaps doubtful whether there is a true form of malarial pneumonia. Bignami has stated that the pneumococcus is always present, and that a pneumonia in a malarial patient is a double infection.

The capillaries of the liver are much enlarged, with swollen endothelial cells often laden with pigment. These capillaries are filled with blood cells containing parasites and leucocytes with pigment. The perivascular lymph-spaces are swollen, and Kupfer's cells contain pigment. The liver cells are compressed between the dilated capillaries, and contain hæmosiderin and bile-pigment, and, in addition, isolated cells or groups of cells may be necrosed, but this is rarely extensive. The portal canals are infiltrated with red cells containing parasites in all stages of development.

In the spleen the red cells of the pulp are seen to be filled with schizonts and crescents, while pigment is present in leucocytes and macrophages. The kidneys show pigmentation in the walls of the capillaries of the glomeruli, as well as those lying between the tubules; but parasites are rare in the former, though common in the latter situation. Phagocytes are not uncommon, containing pigment, red cells, and parasites. The cells of the glomeruli degenerate, and are thrown off into the capsule along with exudation, and the epithelial cells of the convoluted tubules degenerate, and are cast off into the lumen.

The suprarenal capsule shows irregular areas of vascular dilatation full of erythrocytes, many of which contain parasites, while macrophages may also be present.

The capillaries of the abdominal fat are often full of red cells containing parasites. The bone-marrow is chocolate-coloured in the small bones, and brownish-red in the long bones. Often it is soft and diffluent, and contains sporulating parasites and, in particular, crescents (gametocytes), which are thought to start their life here.

When the intestine shows the choleraic appearances described above, the capillaries of the mucosa and villi are filled with parasites in all stages of schizogony, and leucocytes with pigment masses. The epithelial cells are necrotic, but the submucosa and deeper layers escape injury, and their blood-vessels contain nearly normal cells.

The brain in pernicious cerebral fevers has its capillaries filled with sporulating parasites and mononuclear macrophages containing degenerated parasites, while the arterioles and venules are freer, and only contain young forms. Sometimes no parasites are to be seen, and only pigment in the endothelial cells, which may be swollen and fatty, or may be found free in the vessel, and may have parasitic inclusions. The nerve cells may be affected, showing damage to or disappearance of Nissl's bodies, and at times degeneration of their nuclei, the whole cell being sometimes filled with small granules. There may be fibrolysis—*i.e.*, degeneration of the neurofibrils—only small argentophile granules remaining. Rod-like cells attached to the processes of the ganglion cells may be seen. The punctiform hæmorrhages are due to the diapedesis of apparently normal red cells. Occasionally the cerebro-spinal fluid is increased, and there may be a slight lymphocytosis.

B. Morbid Anatomy of Chronic Malaria.—The lesions of chronic malaria fall principally upon the spleen, the liver, and the bone-marrow. There are no records of post-mortems on persons suffering from chronic malaria due to *Plasmodium malariæ*.

1. Lesions due to *Plasmodium vivax*.—The best recorded case of this infection is that given by Ewing of a man who suffered from the disease for about a year, and died from endocarditis about three months after the last attack.

The spleen was enlarged, firm, and dark, and contained parasites and pigment in endothelial cells about the Malpighian bodies. Some hæmosiderin could also be seen. The liver showed no gross signs indicating malaria, but microscopically, pigment was collected in large intracellular masses in the portal canals and slightly in a few endothelial cells throughout the lobule. Macrophages also contained pigment. The marrow was but slightly pigmented, showing a few endothelial cells with black pigment.

2. Chronic Malaria without Definition of the Parasite.—These lesions are generally due to *Laverania malariæ*, and, as stated above, affect the spleen, liver, and bone-marrow.

The spleen is always enlarged, often considerably, and is firm in consistence, but its colour varies from a slate to a dark red, which depends upon the amount of pigment deposited therein. Usually there are some adhesions, indicating old perisplenitis. On section it generally appears quite black, but this depends upon the amount of pigment; the capsule is thickened; the Malpighian follicles stand out clearly, as they are enlarged and non-pigmented. Microscopically the capillary vessels are seen dilated and separated by splenic pulp, or by connective tissue containing giant cells. The pigment may be diffused through the organ, but is generally either collected around the follicles or extracellular, and contained in the lymphatics of the arterioles or septa, both of which are thickened.

The liver is larger and harder than usual. If pigment is present, it will usually be gathered around the periphery of the lobules, which will, therefore, stand out clearly. Later the pigment becomes perivascular, and finally disappears. The capillaries or lymph-spaces may be considerably dilated, and the liver cells atrophied by pressure. On the other hand, proliferation of the hepatic cells and repair of the damage may be seen taking place. Atrophy of the liver is not usual, but may occur in old people from thrombosis of the portal vein, and is then associated with necrosis.

The bone-marrow is usually pigmented, and of a chocolate hue in the small bones, while in the long bones it may be reddish, except, perhaps, in the very centre. This colour is due to the replacement of the fat by vascular tissue.

3. Malarial Cachexia.—This may be acute when it develops after a few attacks of fever, but more commonly it comes on as a sequela to chronic malaria.

The anæmia is marked, and there is fluid about the ankles and in the abdominal cavity. The spleen is enormously enlarged, as is also the liver, while the bone-marrow is yellow, sclerotic, or gelatinous Parasites may be found or they may be absent.

A special form of cachexia is that in which amyloid changes are found in the kidney along with parenchymatous nephritis, associated more rarely with amyloid changes in the intestine, spleen, and liver, with sometimes simple ulceration of the intestine.

4. Latent Malaria.—*Plasmodium vivax* and *Laverania malariæ* can exist in the spleen of persons who show no sign of fever or malarial cachexia. These parasites can go through their life-cycle in that organ, and in the case of *L. malariæ* in the liver also, but it would appear that they are restrained from invading the circulation by the action of some antitoxin, and therefore do not increase to such numbers as to cause toxic symptoms.

It is obvious from the above that, if the restraining influences which conduce to the condition of latent malaria are removed, an attack of malaria will follow, or if there has been a previous attack, a relapse will take place.

Observers have always had a difficulty in admitting that the ordinary form of the parasite could be latent and cause a relapse, though there appears no doubt that this can take place. Schaudinn, as has already been mentioned, considers that the macrogametocyte is capable of undergoing parthenogenesis and forming merozoites, thus starting a cycle of schizogony anew and causing fever. Craig and other observers insist upon conjugation, causing a rejuvenescence of the parasite and a relapse of the fever.

Classification.—As there are three parasites—*Plasmodium malariæ*, *P. vivax*, and *Laverania malariæ*—there are therefore three clinical entities—quartan malarial fever, tertian malarial fever, and subtertian malarial fever—due to these parasites.

Quartan and tertian parasites go through their whole life-history in the circulating blood, and though the tertian sporulating forms are found in internal organs, such as the spleen, yet they do not tend to accumulate in those organs or to produce special effects. On the other hand, the subtertian parasite sporulates entirely, or almost entirely, in the internal organs; and if one particular organ is especially attacked by the parasites, there will be special clinical features to that phase of the disease. This is the cause of the ***atypical subtertian fevers***, and is also the basis of those serious symptoms which have for many years been alluded to as the perniciousness of this type of fever. The nature of these pernicious symptoms will depend upon whether the parasite is principally localized in—(1) the cerebro-spinal nervous system; (2) the gastro-intestinal mucosa; (3) the pancreas; (4) the heart; (5) the lungs; (6) the liver, etc.

We will give clinical descriptions of the different quartan, tertian, and subtertian fevers.

II. THE QUARTAN FEVERS.

Quartan malarial fever depends for its symptoms and course upon the life-history of *Plasmodium malariæ*, introduced into the blood of man by an anopheline mosquito. Its clinical course will depend entirely upon whether the parasites are of approximately the same age, or whether they have been introduced into the body on different days.

If only parasites of approximately one age exist in the blood, a typical quartan malarial fever ensues, with an interval of seventy-two hours (the length of time which a merozoite takes to become the fully developed schizont). Such a fever is called '*quartana simplex*,' or simple quartan fever.

If the parasites have been introduced on two different days, and are therefore of different ages, the patient will develop fever on two successive days, and be free from it on the third day; such a fever would be called '*quartana duplex*,' or double quartan fever.

If, however, the parasites were introduced on three successive days, the fever may be daily—that is to say, may be a quotidian fever—and this could only be recognized as belonging to the quartan fevers by its parasite being discovered microscopically; such a fever would be called a '*quartana triplex*,' or triple quartan fever.

If the parasites exist in greater numbers and groups than usual, the fever may be irregular and subcontinuous.

There are, therefore, several types of quartan fevers—viz.:—

A. *Acute quartan malaria* :—
   1. Simple quartan fever.
   2. Double quartan fever.
   3. Triple or quotidian quartan fever.
   4. Irregular subcontinuous quartan fevers.
   5. Mixed infections.

B. *Chronic quartan malaria.*

Simple Quartan Fever.

Definition.—*Simple quartan malaria* is characterized by attacks of fever recurring every seventy-two hours and separated by apyrexial intervals which occupy the time required by *Plasmodium malariæ* to pass from the merozoite to the fully developed schizont.

Incubation.—This has not been determined with any degree of certainty. It is without doubt longer than either tertian or subtertian. Celli, by experiment, came to the conclusion that it might be very long—two months or more.

By the experimental inoculation of blood, Marchiafava and Bignami calculated the maximum incubation at 18 days, the minimum at 11 days, and the mean at 14·3 days. We are not aware of any accurate experiment to determine the incubation period after the bite of infected mosquitoes. The only observation which we know is the very doubtful one recorded by Buchanan in 1901, when anopheline mosquitoes of undetermined species were allowed to bite men in India from the 9th to the 21st of January, with the result that one developed a temperature of 38·9° C. on the 5th of February, but parasites were not found, and the other cases were negative.

Remarks.—The clinical description may be divided into the febrile attack and the apyrexial interval.

THE FEBRILE ATTACK.—Generally there are prodromata before an attack of quartan fever. Some few hours previously the patient may complain of giddiness, weakness, malaise, headache, or even nausea and vomiting. If the blood is examined during the occurrence of these symptoms, the parasites will be seen to be schizonts, and the commencing formation of merozoites may also be noted.

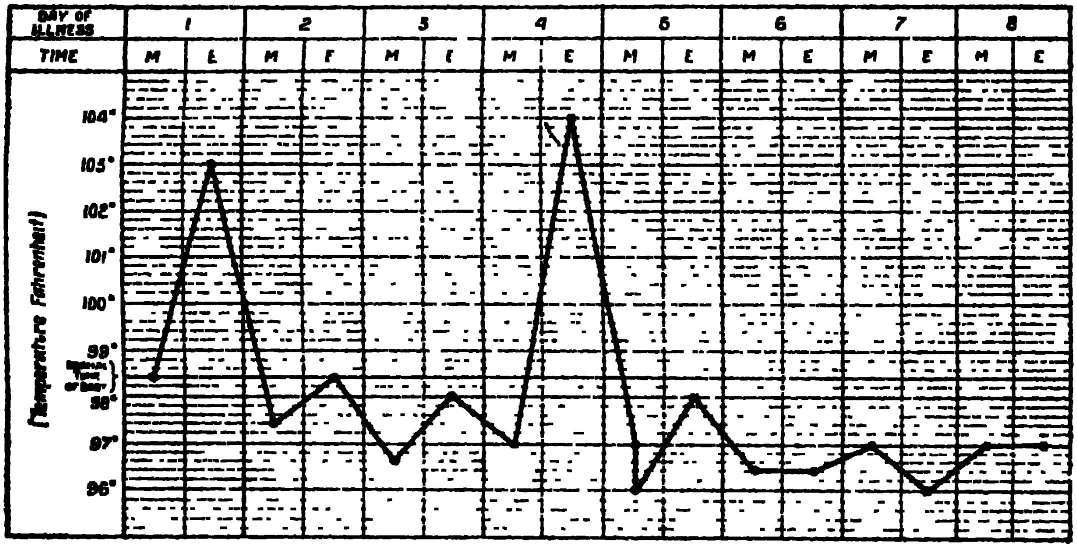

FIG. 619.—TEMPERATURE CHART OF A CASE OF SIMPLE QUARTAN MALARIAL FEVER IN THE GENERAL HOSPITAL, COLOMBO.

In a short time the definite attack begins. It may roughly be divided into three stages: (1) The cold stage; (2) the hot stage; (3) the sweating stage.

1. *The Cold Stage.*—The patient begins to feel cold, either in the legs, arms, or back. This sensation increases until actual shivering sets in. In quartan fever the rigors are well marked and characteristic, and the patient may shiver until he shakes the bed; the teeth may chatter, the lips become blue, the arms and legs cold, and goose-skin may be present. If the blood is examined in this stage, some of the parasites may be seen fully sporulated, or only young parasites may be found.

During this cold stage, which is the most uncomfortable of the three stages, the internal temperature is rising rapidly, and the internal organs must be somewhat congested during the chill; for there are symptoms of intense headache, visual disturbance, vomiting, and at times diarrhœa. The temperature, which rises before the chill begins, varies at first from 100·4° to 102·2° F., but generally rises rapidly to its maximum—about 104° or 105° F.

The cold stage does not last long, fifteen to thirty minutes being the average time, but it may be longer or shorter, and may be irregular, being preceded by a transient sensation of heat.

2. *The Hot Stage.*—Gradually the shivering ceases, and the patient begins to feel warmer and more comfortable, though sensations of cold and heat may succeed one another. By degrees the sensation of heat increases, until the patient becomes burning hot, and as in the cold stage he desired to wrap himself up with coverings, now he desires to throw these off. The skin feels hot and dry, the pulse and respirations increase, the conjunctivæ become injected. Vomiting and diarrhœa may take place, and an erythematous rash sometimes appears. The temperature reaches its maximum, and soon declines.

This stage may last about three to four or more hours.

3. *The Sweating Stage.*—Towards the end of the hot stage the forehead is noticed to be damp, and presently the sweat begins to appear profusely, and great relief is felt by the patient. As the sweating increases, the temperature falls rapidly and the pulse-rate declines. As the temperature approaches normal the patient may fall into a sleep, from which he will wake feeling much better, and with a normal or subnormal temperature. The total duration of the attack may be about eight to ten hours.

THE INTERVAL.—After awaking from his sleep the patient feels quite well, though weak, and generally goes about his ordinary work during the two days of this interval. But signs are not wanting that everything is not well; for the temperature is often subnormal and the pulse slow, while in the blood the developing parasites may be traced, and leucopenia with relative mononuclear increase noted. At the end of seventy-two hours the apyrexial interval will end in an attack of fever, as described above.

The Course of the Fever.—Quartan, rightly or wrongly, is believed to have a great tendency to relapse, to go on for months, and even, it is said, for years, if not treated. The parasites rarely appear to multiply to any great extent in the blood, and hence pernicious symptoms are usually absent. If left to itself, the fever is supposed to gradually die out, but to recur at times. Spontaneous cure is, however, rare.

Irregularities.—Prolongation of the attack has been noticed. Marchiafava and Bignami state that it may very exceptionally last for more than twenty-four hours, in which case the temperature shows two chief undulations—one near the beginning and the other near the end of the attack—separated by a marked remission.

Children.—Children may show neither cold nor sweating stages. Very often convulsions take the place of the cold stage, but these may be so slight as not to be noticed. On the other hand, they may be very severe.

Double Quartan Fever.

In this form there is an attack of fever on two successive days, and an apyrexial interval of twenty-four hours.

Typically the two attacks should be equal in severity, but often that is not so, for one attack is less severe than the other. As already stated, this may be due to two groups of parasites, inoculated on separate days. But sometimes quartana simplex may become quartana duplex, and this is explained by the fact that there may be a double infection, but that while there are many of one brood of parasites, and hence fever, the other brood may be so few at first that they require time to develop to such numbers as are necessary for the production of fever. Consequently quartana duplex may at first show itself by a very slight rise in the temperature on the second day, which increases gradually till equal to that produced by the stronger infection.

Triple Quartan Fever.

This is a quotidian or daily fever produced by three broods of quartan parasites coming to maturity on three successive days, and can only be diagnosed by an examination of the blood. The three attacks may be similar, and may begin at the same hour, or they may vary in severity and begin at different times. In quartana triplex sometimes an attack may be 'subintrant'—that is to say, the cold stage of one attack may begin before the sweating stage of the other attack is finished; but this is not common, and usually there is a distinct interval of normal or subnormal temperature.

A simple or a double quartan may become a triple quartan in the manner described above for the origin of a double from a simple fever. On the other hand, it may start as quartana triplex, and become a duplex, and finally a simplex. This may be due to the weakening of certain groups of parasites. Sometimes a triplex may directly become a simplex from the linking together of two other groups of parasites at the same time.

Irregular Subcontinuous Quartan Fevers.

Quartan parasites are believed not to cause continuous fever, but very rarely they may cause subcontinuous or remittent fever. Such a condition is due to the presence in the blood of parasites of all ages, which, therefore, are continually sporulating and disturbing the metabolism, thereby producing the remittent type of fever.

Mixed Infections.

Mixed infections may occur with either of the other two parasites —viz., *P. vivax* or *L. malariæ*—and an intermittent irregular fever be produced, only to be diagnosed by the microscope.

Chronic Quartan Malaria.

See Chronic Malaria, p. 1182.

III. THE TERTIAN FEVERS.

Tertian malarial fever depends for its symptoms and course upon the life-history of *Plasmodium vivax*, introduced into the blood of man by an anopheline mosquito. Its clinical course will depend entirely upon whether the parasites are of approximately the same age or whether they have been introduced into the body on different days.

If only parasites of approximately one age exist in the blood, a typical simple tertian malarial fever ensues, with an interval of forty-eight hours (the length of time which a merozoite takes to become a fully developed schizont). Such a fever is called 'tertiana simplex,' or simple tertian fever.

If the parasites belong to two distinct broods, or have been introduced on two different days, and are therefore of different ages, the patient will develop fever every day. Such a fever would be quotidian in type, and would be called 'tertiana duplex,' or double tertian fever.

If many broods of parasites are present, the fever becomes subcontinuous and irregular.

There are, therefore, several types of tertian fevers—viz.:—

A. *Acute tertian malaria :—*
   1. Simple tertian fever.
   2. Double or quotidian tertian fever.
   3. Irregular subcontinuous tertian fevers.
   4. Mixed infections.

B. *Chronic tertian malaria.*

Simple Tertian Fever.

Definition.—*Simple tertian malaria* is characterized by attacks of fever recurring every forty-eight hours, and separated by apyrexial intervals which occupy the time required by *Plasmodium vivax* to pass from the merozoite to the fully developed schizont.

Incubation.—The natural incubation period is believed to be from eight days upwards. The period of incubation in experimental cases in which quantities of infected blood were inoculated varied from four to twenty-two days. The period of incubation after the experimental bites of infected anophelines varies from seven to twenty-five days.

Remarks.—The clinical description may be divided into—(1) the attack of fever; (2) the apyrexial interval.

The Attack of Fever.—There may be no prodromata, or, on the other hand, these may be most characteristic. When present, they take the form of pain in the head and the back, and especially in the bones of the limbs—more particularly the joints—which lead to their being considered to be rheumatic, together with a feeling of lassitude and illness. On the day succeeding these sensations the patient may feel quite well, but on the next day they may recur.

If treated in this stage, the fever may never develop, but if neglected, it will appear in the course of a few days.

After a feeling of illness, giddiness, nausea, or vomiting, with perhaps a slight rise of temperature, the patient suddenly becomes very cold and shivers, and his symptoms resemble in detail those already described for quartan malarial fever, except that they may not be so severe. In about ten to thirty minutes the warm stage begins.

As the chills diminish, sensations of warmth appear; at first pleasurable, they soon become intense, and the patient feels burning hot. The skin is hot, flushed, and dry: the conjunctivæ injected; the pulse full, quick, and often dicrotic, and the pains in the head, back, and limbs increase. A slight cough may be noted; vomiting is common, and sometimes diarrhœa occurs. Very often the white skin shows a sallow or slightly yellowish tinge, which is also present in native races, but can only be seen in the conjunctivæ. The heart-sounds are usually normal, but sometimes a soft systolic murmur can be heard. In the lungs, at times, sonorous and sibilant râles occur. The spleen is enlarged and tender, which is characteristic, and a soft murmur over the splenic area, like a uterine souffle, is said to be sometimes heard. Skin eruptions have been described; the commonest in our experience is erythematous or urticarial. Herpes may occur on the lips.

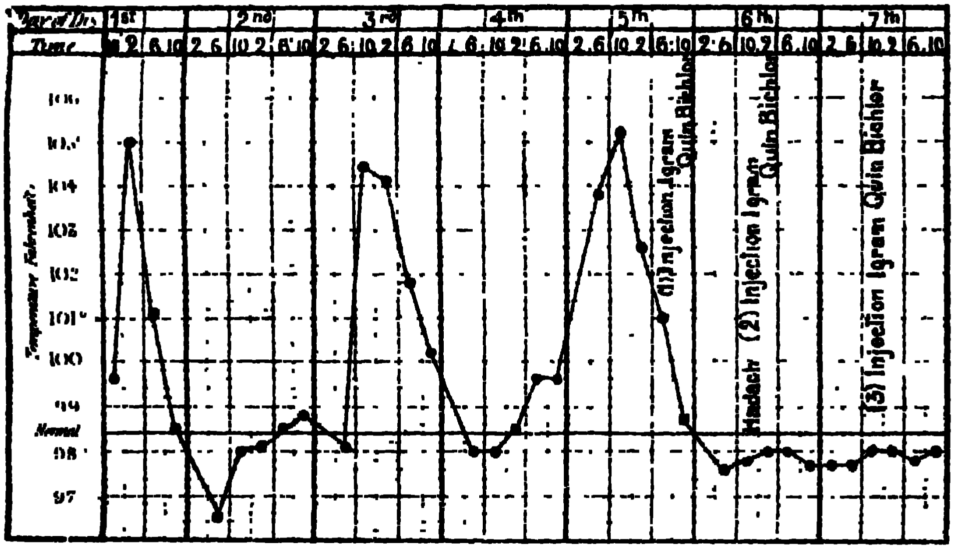

FIG. 620.—TEMPERATURE CHART OF A CASE OF SIMPLE TERTIAN MALARIAL FEVER, SHOWING THE EFFECT OF INTRAMUSCULAR INJECTIONS OF 1 GRAMME OF QUININE BIHYDROCHLORIDE.

The temperature begins to rise before the chill, and continues to ascend during the cold stage, reaching a maximum in the hot stage, which may be anything from 102° to 108° F., but is generally about 104° or 105° F. The warm stage may last four or five hours, when it passes into the sweating stage.

The mouth becomes moist, and sweat gradually comes out all over the body, and soon a most profuse perspiration may take place, and the pulse, respirations, and temperature may fall to normal in about four hours, when the patient, as in quartan fever, goes off into a sleep. The attack lasts about ten to twelve hours, and generally begins in the morning, but may take place at any time of the day.

Apyrexial Interval.—This lasts about thirty-six hours, during which the temperature is often subnormal. In the interval the patient may feel well, but his blood will show developing parasites, reduced erythrocytes, and a leucopenia with a mononuclear increase.

Peculiarities.—As in quartan, so in tertian fever, children may have neither chill nor sweating stage, but may, on the other hand, show convulsions.

Double Tertian Fever.

When parasites mature on two separate days, fever is produced every day, which is therefore quotidian in type, and is called a double tertian (tertiana duplex). The attacks are similar to those described above, but usually are shorter, and, of course, the apyrexial interval is shorter. As a rule, the attacks begin at the same hour each day, but sometimes one attack is later than the other. Very often one attack is not so severe as the other, but if left to itself without treatment, it may become similar to the more severe attack.

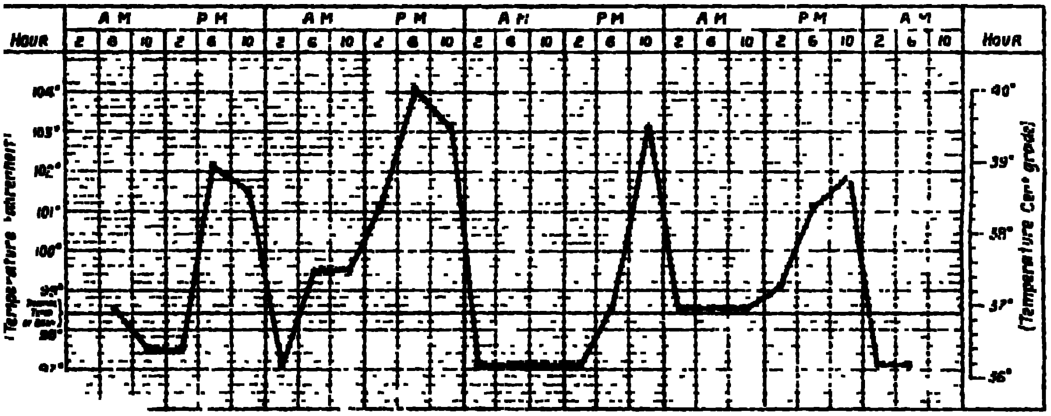

FIG. 621.—CHART OF A CASE OF DOUBLE TERTIAN MALARIAL FEVER IN THE GENERAL HOSPITAL, COLOMBO.

(Note postponement of attack in third and fourth days.)

Double tertians may arise by a simple tertian anticipating. If this is continued after the double tertian is developed, or if one of the attacks of a double tertian anticipates, in course of time it will join in with the originally previous attack, so that a person who is in the sweating stage of one attack may suddenly start the cold stage of the other.

Clinical Course.—Left to itself, tertian malaria tends to a spontaneous cure after a series of attacks, but relapses may occur. Groups of more severe attacks alternate irregularly with groups of milder attacks. Usually, recurring attacks take place about the same time on the succeeding days.

The anæmia of tertian fevers is more easily overcome than that of quartan, and great exhaustion is only seen in old debilitated subjects.

Two interesting points may be noticed—(1) anticipation of the attacks; (2) retardation of the attacks. Anticipation of the attacks means shortening of the apyrexial interval, so that they begin at short intervals. Retardation means prolongation of the apyrexial interval, and is generally due to the action of quinine, but may be due to spontaneous weakening of the parasite.

Irregular Subcontinuous Tertian Fevers.

Irregularity may be brought about by parasites maturing at different times on the same day, and thus producing an almost continuous fever with exacerbations and remissions; but tertian fever is rarely duplicated—that is to say, it rarely shows two distinct attacks in one day. Prolongation of the attack produces a fever resembling the subtertian, while in very chronic tertians just the reverse may take place—viz., prolongation of the apyretic intervals—so that fever appears at the end of seven, eight, fourteen, or sixteen days.

Mixed Infections.

Irregularity may also be produced by mixed infections of *Plasmodium vivax* with *Plasmodium malariæ*, or with *Laverania malariæ*. These mixed infections can only be recognized by the microscopical examination of the blood.

Chronic Tertian Malaria.

See Chronic Malaria, p. 1182.

IV. THE SUBTERTIAN FEVERS.

Synonyms. –*Tropical malaria, Summer-autumnal fever, Malignant tertian.*

Definition.– *Subtertian malarial fevers* depend for their symptoms and course upon the life-history of *Laverania malariæ*, introduced into the blood of man by an anopheline mosquito.

Remarks.–Their clinical symptoms may approximate to the type described for the other two malarial fevers when *Laverania malariæ* lives mainly in the spleen and in the peripheral blood, but more generally the symptoms of these fevers are very different from those produced by the tertian parasites. The essential difference is that *Laverania malariæ* can, and does, live largely in the internal organs, and may even concentrate its forces upon one organ. As clinical symptoms are produced by the derangement of the functions of the organs and systems of the body, so the symptoms of these types of subtertian fever may point to a given organ or to a given system of the body. It is in this way that the subtertian fevers can produce signs and symptoms which medical practitioners are more accustomed to associate with some other disease, and this explains the curious phenomenon of *malarial mimicry*. As the parasite *Laverania malariæ* can live in any organ, it can therefore produce the signs and symptoms of any disease, and we know practically of *no clinical picture* which it is *impossible* for this parasite *to reproduce*, be it an acute illness or a chronic ailment, be it associated with febrile symptoms or free from fever. Hence the great necessity for the practitioner to be careful as to the diagnosis of malaria, and to remember that in atypical cases which are of frequent occurrence it is most difficult, and that the microscope is not infallible in its aid, as *negative microscopical findings do not exclude a diagnosis of malaria*, as will be emphasized in the section on diagnosis.

The subtertian fevers are therefore capable of division from a practical point of view into two great groups:—

A. Typical Subtertian Fevers.
B. Atypical Subtertian Fevers.

In the first group comes *simple subtertian fever*, which shows an intermittency of the symptoms, which is due to the fact that the time required by a merozoite of *Laverania malariæ* to attain to the stage of a schizont is thirty-six to forty-eight hours, while a *double infection* produces a quotidian fever, and *more severe* infections, irregular, remittent, and bilious types of fever. Mixed and chronic infections may also ensue as in the other types.

The fevers of the second group may be subdivided according to the syndrome which is produced, and which depends upon the organ or system of the body which is attacked.

We will now consider these various clinical conditions.

A. TYPICAL SUBTERTIAN FEVERS.

The typical subtertian fevers may be divided into:—

1. Simple subtertian fever.
2. Double subtertian fever.
3. Irregular subtertian fever.
4. Remittent subtertian fever.
5. Bilious subtertian fever.
6. Mixed infections.

1. Simple Subtertian Fever.

Definition.—This form of subtertian fever usually shows intermissions based upon a tertian type.

Incubation.—The incubation period has been studied by Marchiafava and Bignami, who considered it to be of nine to ten days' duration when acquired by natural mosquito infection, and to vary from nine to nineteen days when acquired by experimental mosquito infection. Prodromal symptoms resembling those of tertian fevers may exist before an attack.

Febrile Attack.—The cold stage may be entirely absent, but it often occurs, and is sometimes severe. Sometimes the attack begins with the warm stage, in which the symptoms are very severe pains in the limbs, back, and head, with gastro-intestinal disturbance in the form of vomiting, diarrhœa, and coated tongue. The skin is often flushed and dry and sometimes icteric, while the eyes are injected. The sweating stage is never absent, and may be marked. The spleen is usually tender, as well as the liver. The four-hourly temperature chart is most characteristic, for the invasion takes place with a rapid rise to 104° F. to 105° F., after which the temperature remains high, oscillating about 1° F. The oscillation which immediately precedes the crisis is larger than the others, and is called the pseudo-crisis. After this the temperature rises to its highest point (precritical elevation), and then suddenly falls (crisis) below normal, where it remains, as a rule, until the next attack. It may, however, rise from subnormal to normal, and just prior to the next attack show a distinct depression. This typical temperature may, however, be greatly masked by an absence of the sudden rise at the invasion, or of the precritical elevation, or by an exaggeration of the pseudo-crisis, making the single attack appear double.

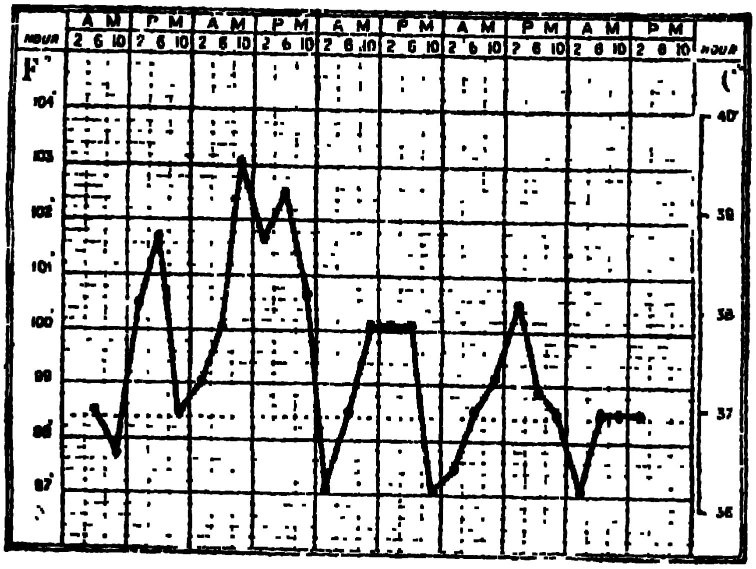

FIG. 622.—CHART OF A CASE OF SUBTERTIAN MALARIAL FEVER.
The curve is most typical on the second day, before quinine was administered.

Lastly, the whole attack may be shorter than usual, and resemble, as regards the temperature, a simple tertian fever.

The duration of the attack in subtertian fever is about twenty-four hours or more.

The Interval.—The interval will be twenty-four, ten, or even eight hours in duration, varying, of course, with the length of the attack.

2. **Double Subtertian Fever.**

This is a quotidian fever, caused by two broods of *Laverania malariæ*. The cold stage is less marked than in a quotidian fever, due to quartan or tertian parasites. The temperature rises rapidly, the fastigium is very short, and the fall is to below normal. There is nothing particular to remark about the warm or sweating stages, which resemble those of the simple subtertian fever. The whole attack only lasts six, eight, or twelve hours.

3. **Irregular Subtertian Fevers.**

When several broods of *Laverania malariæ* exist together in the blood, it is obvious that, instead of sporulation taking place regularly every day or every other day, it will be irregular, and hence the attacks will run into one another and produce an irregular type of fever, which is commonly met with on the West Coast of Africa.

4. **Remittent Subtertian Fevers.**

Remittent fevers arise by prolongation of ordinary attacks, or by anticipation or subintrance, so that two attacks become continuous, the onset of the second attack beginning before the first one is concluded. Duplication may also lead to a remittent fever.

Febrile Attack.—These fevers may be mild or grave, and may become pernicious. The symptomatology is briefly as follows: After one or two days of prodromal lassitude, pains, and sensations of chilliness, etc., fever comes on without any cold stage. The skin becomes hot and dry, and often turns yellowish, and headache, with pains in the different parts of the body, is a source of trouble to the patient.

The tongue is coated; thirst is sometimes intense, and may be associated with vomiting and purging, together with pains in the region of the liver, spleen, and stomach. The toxins affect the brain, causing sleeplessness, restlessness, and delirium. The liver and spleen are both enlarged and tender, and at times there is slight cardiac dilatation on the right side. The temperature is characterized by high fever with remissions.

Interval.—The time of the remission is by no means certain. It may take place in the morning and the rise in the evening. Under treatment the parasites rapidly disappear from the peripheral circulation, but last longer in the viscera, so keeping up the fever.

Course.—Mild attacks get well under the week, but without treatment they would soon become the more serious or grave type of fever, which is part of the atypical group of subtertian fevers which are dealt with in the next section. Three variations may be mentioned here. The first resembles typhoid in its clinical features; the second is distinguished by the bilious vomiting and diarrhœa, with marked enlargement of the liver and jaundice, which is often called bilious remittent fever; and the third shows a tendency to hæmorrhages, local gangrene, hæmoglobinuria, and great weakness, sometimes called 'adynamic remittent fever.'

Remarks.—Only the bilious remittent will be considered here, as *malarial hæmoglobinuria* will be treated in the next chapter on Tropical Hæmoglobinurias, and the atypical subtertian fevers will be described directly after bilious remittent fever.

5. Bilious Remittent Fever.

This is a type of subtertian remittent fever in which there is great blood-destruction, and consequently much bile-production. We have seen it repeatedly in Africa, and more recently in the Balcanic Zone, and it is said to occur in all highly malarious districts.

The attack begins as an ordinary remittent fever, but is associated with jaundice, bilious vomiting, and usually bilious diarrhœa, though in its place there may be constipation. The patient also complains of pain and tenderness in the stomach and liver. After a few days' illness the symptoms may gradually subside, or, with or without hiccough, epistaxis, or hæmatemesis, the temperature may rise considerably, and the patient, becoming comatose, dies.

We have noted at times a curious intermission in the symptoms, of short duration, after which high fever ensues, quickly followed by coma and death (*vide* Yellow Fever-like Type, p. 1172).

6. Mixed Infections.

Mixed infections of *L. malariæ* with the other malarial parasites are not uncommon, and lead to a type of quotidian fever which can only be diagnosed accurately by an examination of the blood and a differentiation of the parasites concerned.

The blood may show only forms belonging to *P. vivax* at times, and only forms belonging to *L. malariæ* at other times.

B. ATYPICAL SUBTERTIAN FEVERS.

The causation of this group of subtertian infections is due to the fact that *Laverania malariæ* undergoes schizogony in the internal organs, and is apt, at times, to specialize upon one particular organ, which becomes seriously affected, not merely because it has to bear the full brunt of the liberated toxins, but also because it suffers from malnutrition, because its capillaries become blocked by swollen endothelial cells belonging to their walls and by red blood-corpuscles filled with malarial parasites, as well as by leucocytes laden with pigment, and by the pigment and merozoites set free during schizogony.

This explains not merely the special character of the symptoms exhibited in any case, but also the multiplicity of clinical types caused by this parasite, and the peculiar conditions called *masked malaria* or *malarial mimicry*.

These various syndromes may for purposes of description be arranged as follows:—

I. Subtertian syndromes without localization.
II. Subtertian syndromes with localization.

I. SUBTERTIAN SYNDROMES WITHOUT LOCALIZATION.

Though it is true that one and the same case may show fever on one day and not on another, still, for practical purposes, it is convenient to subdivide these subtertian syndromes into two groups, according as to whether fever at the time of first examination is or is not a marked feature.

A. NON-LOCALIZED SUBTERTIAN SYNDROMES WITHOUT MARKED FEVER ON FIRST EXAMINATION.

1. Hæmorrhagic non-febrile type.
2. Anæmic type.
3. Mental types.
4. Algide type.
5. Pseudo-alcoholic type.

Hæmorrhagic Non-Febrile Type.—The patients are pale, very weak, and languid, and complain of pains in the loins and limbs. In most cases the whole body is covered with petechiæ, and tense indurated swellings, due to large extravasations of blood, may be present. The gums are often swollen, spongy, and hæmorrhagic. Epistaxis, hæmatemesis, and passage of blood *per rectum* may take place, as well as hæmoptysis and hæmaturia from kidney or bladder. Some patients have large indurated spleens, but febrile symptoms are almost constantly absent. Malarial parasites can be found in the peripheral blood in some cases. Quinine is the infallible remedy.

Anæmic Type.—The patient shows no sign of typical malaria; on the contrary, he is pallid, and possesses the lemon-yellow tinge of *pernicious anæmia.* The liver, and more rarely the spleen, is enlarged. Usually there is no fever, but in some cases the temperature may rise to 99° or 100° F., which is common in *pernicious anæmia.* Malarial parasites may not be found in the blood, even after repeated examinations, while the usual signs of *pernicious anæmia—e.g.*, poikilocytosis, nucleated red blood-corpuscles, high colour index, relative *increase of small mononucleurs* in place of the increase of the large mononuclears which one expects to see in malaria, may be present.

This type of anæmia may lead the physician to suspect *malignant growth* in elderly patients, especially if there is vomiting and pain after taking food.

Quinine acts as the diagnostic and therapeutic agent.

Leukæmia.—Certain authors believe that malaria can cause leukæmia, but this appears to us to be more of the nature of a complication.

Mental Types.—The patient is melancholic or apparently demented, or more rarely acutely maniacal and violent, with usually a normal, subnormal, or but slightly raised temperature. The spleen may or may not be enlarged, but a careful examination of the blood generally reveals a mononucleosis or at times a very few malarial parasites, while quinine therapy effects a disappearance of the symptoms.

The violent cases may be of interest from a medico-legal point of view, because the patient never has the slightest recollection of his acts, and cannot be held responsible for them.

Algide Type.—The patient is, as a rule, first seen in a condition of such extreme collapse as to make the practitioner suspicious of cholera. The nose is sharp, the cheeks sunken, the lips and extremities cyanotic, the nails livid, the pulse small, soft, and frequent, becoming thready and imperceptible, the skin cold and clammy, and the respiration laboured. The patient may, however, be conscious, and be able to answer questions and to complain in a weak voice of severe thirst. This is a very serious and fatal form of pernicious malaria, and generally kills the victim in a few hours.

Pseudo-Alcoholic Type.—The patient may not have been very well for a few days, being capable of doing his work, but irritable and complaining of not feeling fit. In order to carry on his duties he may or may not take a certain amount of alcohol. Suddenly, during or after a dinner or at a public performance, he tumbles off his chair, and the impression at first is that he has taken too much alcohol, and this may be considered to be confirmed by the odour of his breath. It will, however, soon be evident that the patient is seriously ill, and the diagnosis will be revised and apoplexy probably instituted. Finally a blood examination will generally reveal a number, and sometimes a large number, of malarial parasites of the subtertian type. At a post-mortem these parasites will be seen to be blocking the capillaries of the cerebral cortex.

The poorer type of native patient will be taken as a 'drunk' to the local lock-up, and in the morning the so-called drunken man will be found to be seriously ill and may even be dying. Blood examination generally, but not always, reveals malarial parasites. Generally these are serious infections, and the prognosis is grave.

B. Non-Localized Subtertian Syndromes with Marked Fever on First Examination.

The non-localized subtertian syndromes with marked fever on first examination may be divided into—

✓ 1. Subtertian hyperpyrexial fever.
2. Subtertian syndromes resembling a specific fever.
3. Subtertian syndromes not resembling a specific fever.

Subtertian Hyperpyrexial Fever.

This type of fever is characterized by very high temperatures, often commencing at the onset of the illness. It may be continuous or intermittent, and often attains temperatures exceeding 105° F. Sometimes the temperature may reach heights which can hardly be believed—*e.g.*, in two of our cases the temperature exceeded 108° F. These cases have a very serious prognosis, but recoveries are not unknown.

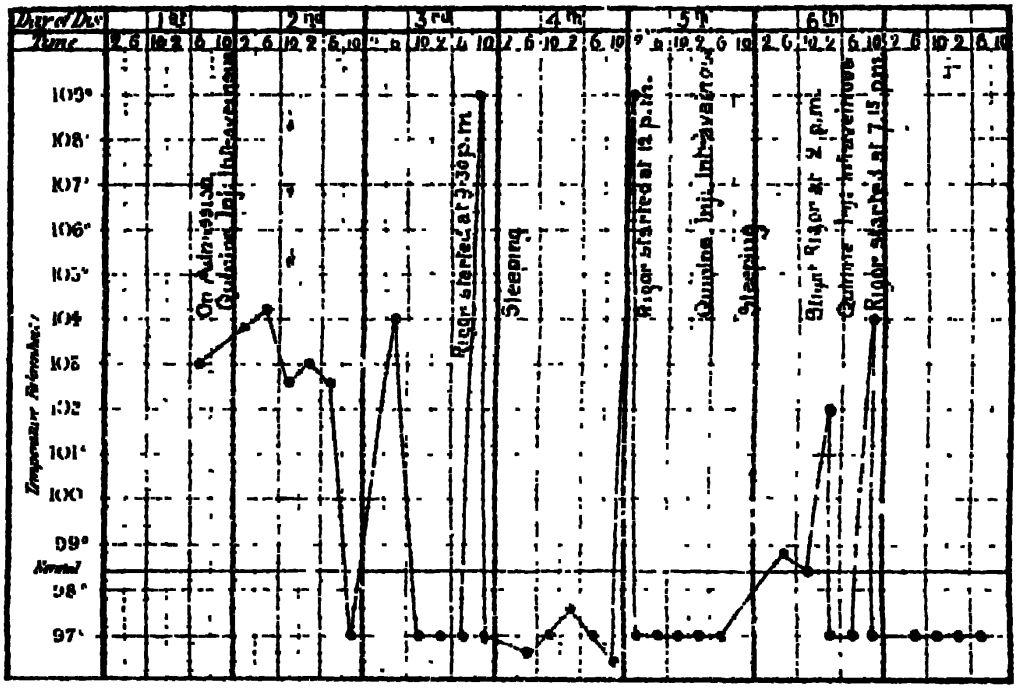

FIG. 62:—TEMPERATURE CHART OF A CASE OF HYPERPYREXIAL SUBTERTIAN MALARIA.

Syndromes resembling a Specific Fever.

The syndromes resembling a specific fever may be divided into types as follows:-

1. Typhoid-like type.
2. Malta-fever-like type.
3. Typhus-like type.
4. Cerebro spinal like type.
5. Yellow-fever-like type.
6. Weil's-disease-like type.
7. Scarlet-fever-like type.

Typhoid-like Type.—This fever resembles enteric fever, as may be judged by the temperature chart (Fig. 624). The onset is slow, the patient apathetic, the tongue coated, and headache present, while the temperature is continuous or subcontinuous. The abdomen is slightly tumid, the spleen usually palpable, but not large or hard. The blood usually shows subtertian parasites, and the bacteriological examination for 'enterica' is negative, but quinine here has but slight action on the course of the fever for some time. The complication of typhoid infections in the course of malaria is mentioned on p. 1184.

Malta-Fever-like Type.—This is very rare, and resembles Malta fever, but malarial parasites can be easily found in the blood; while bacteriological tests for *Micrococcus melitensis* and its allies are absent. Finally quinine effects a cure.

Typhus-like Type.—The cases exactly resemble typhus fever, but malarial parasites are often present in the blood, and the disease yields to quinine therapy.

Cerebro-Spinal-like Type.—The symptoms are those of epidemic cerebro-spinal meningitis, but the cerebro-spinal fluid is clear, though its pressure may be increased; its cellular contents are normal in number and character, while meningococci are absent and the blood shows malarial parasites. The spleen may or may not be enlarged.

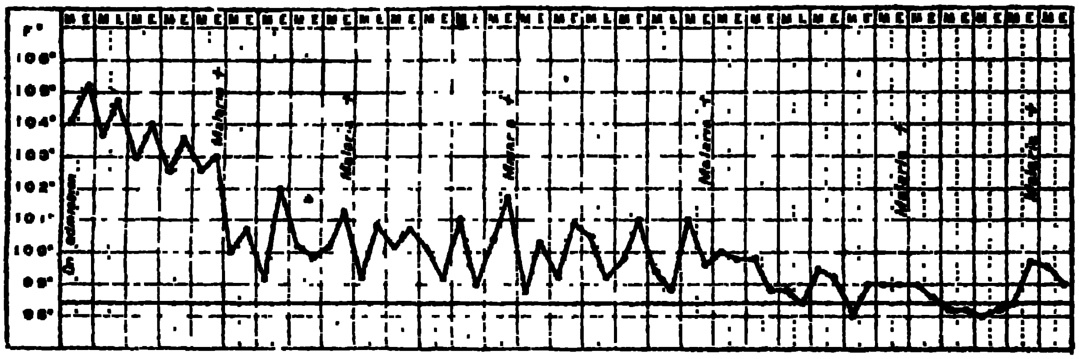

FIG. 624.—ATYPICAL SUBTERTIAN MALARIA SIMULATING TYPHOID FEVER. Hæmocultures and serological reactions for germs of the Enteroidea group of fevers were negative.

Sleeping-Sickness-like Type.—This, which is rare, is characterized by low fever, slight trembling of the hands and tongue, and progressive general weakness, drowsiness, and occasional convulsions. The lymph glands in the neck are not enlarged, and the cases may occur in regions where sleeping sickness is unknown. Malarial parasites may be hard to find, but quinine in large doses cures the affection.

Yellow-Fever-like Type.—This is characterized by fever, without rigors, severe headache, flushed face, pains in the body, pulse quick, full, and bounding at first, severe vomiting, tenderness in the epigastric region, and slight albuminuria. On the third day the temperature falls from 103° to 100° F., and the symptoms abate, while the patient feels better; but the temperature rises again, jaundice appears, the pulse slows to about 60-70 per minute, dark brown vomit appears containing red blood-corpuscles. The symptoms may get worse, the jaundice may deepen, and death ensue. Subtertian parasites may be present in abundance in the blood, and quinine may be ineffective unless given in massive doses.

Weil's-Disease-like Type.—Cases like Weil's disease, with cutaneous hæmorrhages, are occasionally malarial, and may end fatally. The mild type of camp jaundice may also be simulated by malaria, but this is rare.

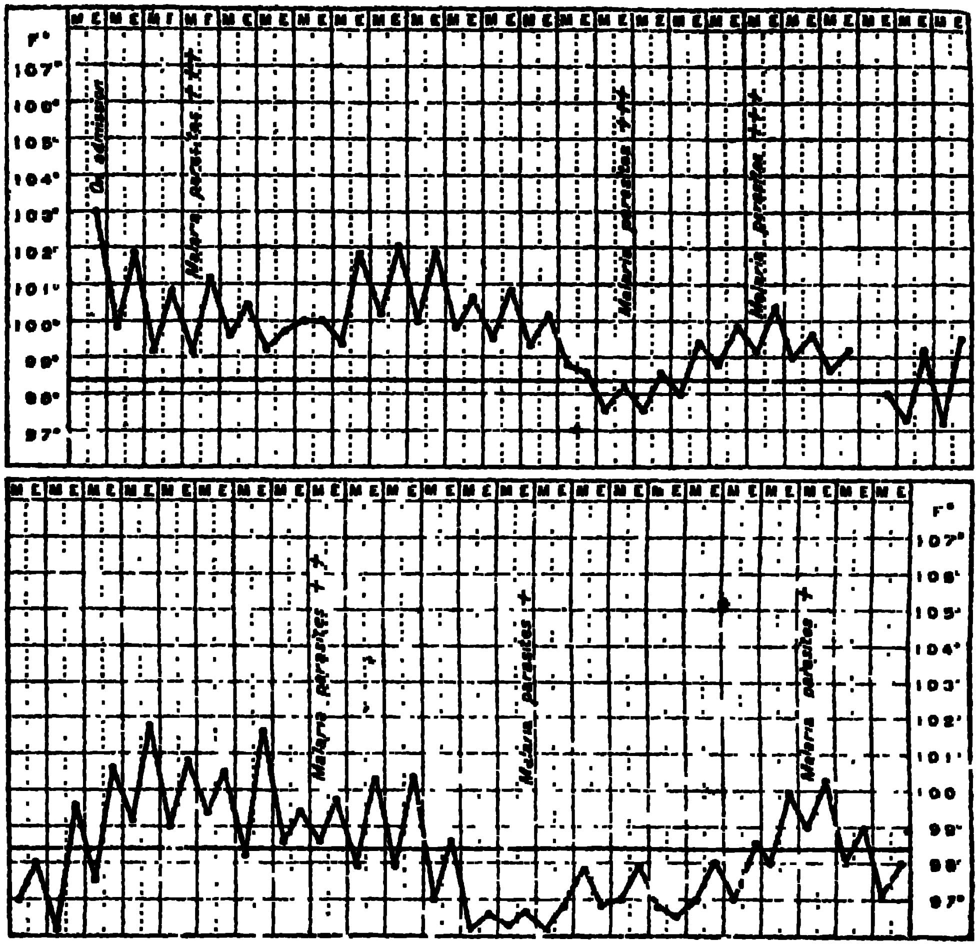

FIG. 625.—ATYPICAL MALARIA SIMULATING MALTA FEVER.
Hæmocultures and serological reactions for *Micrococcus melitensis* and *M. paramelitensis* were negative.

Scarlet-Fever-like Type.—Scarlatiniform pernicious fever is characterized by a diffuse scarlatiniform rash all over the body, with desquamation of the horny layer and erythema of the fauces, and may lead to a typhoidal state in which the patient dies.

Syndromes not resembling Specific Fevers.

The subtertian syndromes not resembling specific fevers are:—

1. Hæmorrhagic febrile type. √
2. Hydrophobia-like type.
3. Kussmaul coma-like type.
4. Diaphoretic-like type.
5. Comatose type.
6. Delirious type.
7. Tetanus-like type.
8. Convulsive type.

Hæmorrhagic Febrile Type.—This form of pernicious fever is apparently rare. It is characterized by hæmorrhages from the skin and mucosæ of the nose, bronchi, intestines, stomach, and generative organs, during the attack, but not during the intermission.

This condition rapidly produces acute grave anæmia, with thready pulse, coma, delirium, convulsions, and death, or may become the milder type, in which fever is not a marked symptom (*vide* p. 1169).

Hydrophobia-like Type.—Signs of hydrophobia associated with fever, a large spleen, and malarial parasites in the blood, call for energetic quinine treatment, when the symptoms disappear, unless it is true hydrophobia in a malarial patient.

Kussmaul Coma-like Type.—Signs of Kussmaul's coma coming and going every alternate day and associated with fever in a diabetic patient call for quinine therapy, even if the spleen is not enlarged, the blood free from malarial parasites and mononucleosis. Occasionally after the exhibition of a small dose of quinine, parasites may be found in the blood.

Diaphoretic Type.—In this type the sweating of the third stage of an attack is so exceedingly copious that not merely is the bed saturated, but a pool may even form on the floor. Such excessive excretion of sweat is dangerous, as the patient becomes more and more exhausted as it goes on, and a most dangerous collapse may ensue.

Comatose Type.—This may begin suddenly or slowly. If the latter, there may be weakness, sleepiness, headache, disturbance of vision, stupor, or delirium, which ends in coma. But more often the patient is brought to the hospital quite comatose. He lies flat upon his back, with usually no paralysis and no alteration in the reflexes. The pupils may be contracted and give the idea of opium-poisoning, while the patient cannot be roused to answer questions, but will only frown or groan.

Hæmorrhages may be found on the skin and in the retina. The urine, which may have casts and a little albumen, is usually passed involuntarily, as are the motions. The heart is dilated, and the pulse, at first slow, soon becomes quick, and towards the fatal termination very quick and thready. Respiration may be quiet or noisy. If death is to take place, the patient becomes colder and colder, the tongue dry and thick, and respiration ceases.

If he is about to recover, the coma will gradually pass away; he will be able to answer questions when roused, and after a time gradually recovers consciousness. The speech is at times most peculiar, being scanning in character.

The coma may be present one day, but the next day the patient may be slightly better, with a subnormal temperature and a slower, fuller pulse; towards evening, however, the temperature rises, and the coma returns. This second attack is, as a rule, fatal. The fever may be remittent or intermittent. In the latter case it returns before death. Quinine treatment by injection and otherwise appears to be of no avail at times, and after two or three days of coma, even when the parasites have disappeared from the peripheral blood, the person may die.

Delirious Type.—In this form delirium is the most marked feature, and in a short time is followed by exhaustion, coma, and death. Such cases are apt to come on suddenly, and to be mistaken for drunkenness, sunstroke, or mania. The fever is usually very high. Recovery is supposed to occur, but we have never seen these cases end otherwise than fatally.

Tetanic Type.—Patients delirious from malaria may show trismus, contraction of the limbs, opisthotonos, retraction of the abdomen, and conjugate deviation of the eyes. The contractions of the muscles may relax and increase as in tetanus, and there may be priapism. The attack may resolve, or end in death with high temperature.

Convulsive Type.—Children during an attack of fever may develop convulsions, followed by stupor, or even coma and death.

II. SUBTERTIAN SYNDROMES WITH LOCALIZATION

The subtertian syndromes with localization may be classified into:—

I. Syndromes with 'nervous system' localization.
II. Syndromes with 'digestive system' localization.
III. Syndromes with 'respiratory system' localization.
IV. Syndromes with 'circulatory system' localization.
V. Syndromes with 'ductless glands' localization.
VI. Syndromes with 'urogenital' localization.
VII. Syndromes with 'cutaneous' localization.
VIII. Syndromes with 'special sense' localization.

1. With 'Nervous System' Localization.

The atypical subtertian malarias with nervous system symptoms may be classified as follows:—

1. Meningitic type.
2. Hemiplegic type.
3. Monoplegic type.
4. Myelitic type.
5. Ataxic type.
6. Disseminated sclerotic type.
7. Bulbar type.
8. Cerebellar type.
9. Cerebral type.
10. Polyneuritic type.
11. Korsakoff type.
12. Aphasic type.

Meningitic Type.—Fever with signs of meningitis may be found in young persons and children. The symptoms are vomiting, headache, retraction of the head, and rigidity of the neck, convulsions, hyperæsthesia, going on to coma and death. There may be hypertension and slight lymphocytosis of the cerebro-spinal fluid.

Hemiplegic Type.—The patient may be suddenly taken ill with fever, and develop a typical hemiplegic attack.

Monoplegic Type.—This simulates a cerebral hæmorrhage, but is associated with high fever, and in both it and the two preceding subtertian parasites can be found in the blood.

Myelitic Type.—This simulates a transverse myelitis.

Ataxic Type.—The symptoms are slow and scanning speech, great muscular weakness, exaggeration of tendon reflexes, ataxia, together with vomiting. Subtertian parasites are found in the blood. At first there is no fever, but this may develop later. Such patients generally recover on quinine treatment, or, indeed, they do so spontaneously.

Disseminated Sclerotic Type.—There is scanning speech, intentional tremor, nystagmus, spastic gait, and increased reflexes, all of which yield to quinine therapy.

Bulbar Type.—A fever with bulbar symptoms—that is to say, difficulty of speech and deglutition, with facial paralysis, or with a weakening of the muscles of the face and also frequently of the legs. This appears to be by no means rare, and yields to quinine therapy if taken in time. Malarial parasites are often absent from the blood, and the spleen need not be enlarged.

Cerebellar Type.—The symptoms of this type are ataxia, the patient walking like a drunken man and complaining of severe headache and almost complete loss of vision. Vomiting is frequent: often there is no fever, and the spleen and liver are not enlarged. The blood may show parasites, and quinine therapy cures the condition, which may be suspected to be cerebellar tumour or abscess, according to the absence or presence of fever.

Cerebral Type.—This type resembles a cerebral abscess to such a marked degree that an operation may be considered to be necessary, when a blood examination reveals the subtertian parasites and quinine cures the condition.

If there is no fever cerebral tumour may be suspected, but the blood examination reveals the true condition.

Polyneuritic Type.—This type closely simulates 'wet beri-beri,' because the patient is œdematous, with the characteristic gait and loss of knee-jerks. There is neither fever nor enlargement of the liver or spleen, but the blood contains subtertian parasites, and the condition is cured by quinine therapy.

Polyneuritis without œdema is also known.

Korsakoff-like Type.—This resembles the preceding in that the patient shows polyneuritis, but in addition he suffers from mental symptoms, among which the most important is the loss of memory for recent events, all of which disappear under the influence of treatment by quinine. Subtertian parasites may or may not be present in the blood, and the liver and spleen may not be enlarged.

Aphasic Type.—In this type motor aphasia develops with or without other paralyses.

II. WITH 'DIGESTIVE SYSTEM' LOCALIZATION.

The subtertian malarias with digestive system symptoms may be classified as follows:—

1. Pseudo-cholera type.
2. Pseudo-dysentery type.
3. Pseudo-appendicitis type.
4. Pseudo-peritonitic type.
5. Pseudo-liver abscess type.
6. Pseudo-cholecystitis type.
7. Pseudo-cirrhosis type.
8. Hæmorrhagic pancreatitis type.
9. Gastritis type.

Pseudo-Cholera Type.—This is merely a great exacerbation of the ordinary gastro-intestinal symptoms often met with in malarial fever. There is vomiting, abdominal pain, and severe diarrhœa, with motions typical of cholera—*i.e.*, rice-water motions. A microscopical examination of the dejecta may show a few leucocytes in stages of degeneration. The spleen may be palpable, and an examination of the blood will show subtertian parasites, while a bacteriological examination shows absence of cholera and of paracholera vibros.

During the attack the patient is pale or cyanotic, the eyes sunken, the skin cold and clammy, but the temperature may be raised, and hiccough, severe thirst, and painful cramps in the lower limbs, may also be present. The urine is scanty or suppressed. Collapse, delirium, or coma, may precede death, or the patient may be sensible to the end. If the patient is to recover, the algidity diminishes, the diarrhœa ceases, and after a long sleep he awakens refreshed and convalescence sets in.

Pseudo-Dysentery Type.—In this type there are two forms—viz., those with typical dysenteric motions containing blood and mucopus, and the other with hæmorrhagic motions without pus and with little or no mucus. Fever may be high, with great distress and prostration and a small rapid pulse, but at times the temperature may be nearly normal. The spleen may be slightly enlarged, there may be history of previous malaria, and there may or may not be malarial parasites in the blood.

Pseudo-Appendicitis Type.—The attack is sudden, with marked pain in the appendicular region, sometimes vomiting, and usually fever, but no rigors. The spleen and liver may not be enlarged, and there may be tenderness and rigidity in the appendicular region. There may or may not be subtertian parasites in the blood, but the condition is cured by large doses of quinine.

Pseudo-Liver Abscess Type.—This type is associated with fever, often of an intermittent character, profuse sweating, loss of flesh, spleen often not palpable, liver enlarged, with pain on pressure all over the hepatic area. Malarial parasites are usually present in the blood, and the condition yields to quinine therapy by proper means. The condition is rare, and must not be mistaken for true liver abscess, which is not uncommon, and the error of making the diagnosis of malaria in abscess of the liver is more common than *vice versa.*

Pseudo-Cholecystitis Type.—There is severe pain, shooting up to the right shoulder, tenderness in the region of the gall-bladder, severe vomiting, and occasionally slight jaundice. The spleen may or may not be enlarged, and the same is true for the liver. The blood usually shows subtertian parasites, and the condition, which resembles an attack of cholecystitis due to gall-stones, is cured by quinine.

Pseudo-Cirrhosis Type.—This is rare, and is characterized by the hepatic facies and ascites. After tapping, the liver and spleen may be felt to be enlarged and hard. On repeated examination subtertian parasites may be found in the blood. Quinine very slowly cures the condition.

Hæmorrhagic Pancreatitis Type.—The attack is sudden, with violent pain in the epigastrium, followed by vomiting and collapse. Tenderness and tympanites may be present in the epigastrium. Blood examination reveals subtertian parasites, and quinine effects a cure.

Pseudo-Peritonitic Type.—This is characterized by fever, pinched face, vomiting, pain and tenderness all over the abdomen. Malarial parasites are found in the blood, and quinine cures the condition.

Gastritis Type.—This is characterized by acute or by chronic indigestion, yielding to quinine treatment. In old people, especially when anæmia is present, cancer may be suspected.

III. With ‘Respiratory System’ Localization.

It will be remembered that during the ordinary attack of any malarial fever there are a few dry, rather coarse, râles to be heard when the temperature begins to fall, and earlier, at the beginning of the attack, there are often—as first noted by Castellani—very minute crepitations at the base, probably of pleural origin, which generally disappear when the temperature has reached its highest point. They both speedily disappear, but every now and then, even in ordinary attacks, they are more pronounced, and the patient suffers from cough or pain on taking a deep breath.

Slight as these usually are, they nevertheless are the basis of the respiratory system types of pernicious malaria, which may be classified as follows:—

1. Pseudo-bronchitic type.
2. Pseudo-pneumonic type.
3. Pseudo-pleuritic type.

Pseudo-Bronchitic Type.—This subacute or chronic dry bronchitis, with little or no fever, is cured by a few doses of quinine.

Pseudo-Pneumonic Type.—This is often of the nature of a broncho-pneumonia, and is accompanied with blood expectoration, in the red corpuscles of which parasites may be seen, dyspnœa, and cough. The symptoms are better in the remission of the fever, and worse during the attack. The blood is full of parasites. In many cases broncho-pneumonia in malarial patients is not due directly to the malarial parasites, but is a complication due to the pneumococcus.

Pseudo-Pleuritic Type.—Intermittent pleuritic pernicious fever has been described, with sharp pricking pain, dry cough, and friction sounds, which improve in the remission, and become worse again in the attack.

Pleurisy of malarial origin is without effusion.

IV. WITH 'CIRCULATORY SYSTEM' LOCALIZATION.

Atypical subtertian malaria with circulatory system symptoms may be classified into:—

1. Pseudo-anginal type.
2. Endarteritis type.
3. Intermittent claudication type.
4. Erythromelalgia type.

Pseudo-Anginal Type.—The right heart has been noticed to be enlarged in attacks of malarial fever, and sometimes these symptoms become marked, with severe pain in the cardiac region of an *anginal nature*, sometimes accompanied by vomiting of blood, a development of the algide condition mentioned above, and death.

Sometimes the anginal syndrome is very marked, but the condition is amenable to treatment by quinine.

Pseudo-Endarteritis Type.—A superficial artery may swell, become hard and knotty to the touch, and extremely painful. There is no fever, and the blood examination may be negative, but the condition yields to quinine.

At other times dry gangrene may be the only sign of an endarteritis of a deeper and more important vessel. Search should be made for malarial parasites, and if there is any reason to suspect malaria as a possibility, quinine should be administered.

Intermittent Claudication Type.—From time to time the patient is unable to put his foot to the ground, because he feels pain in the calf of the leg and there may be an absence of pulse in the dorsalis pedis artery or in the posterior tibial. Quinine cures the condition.

Erythromelalgia Type.—The hands, and at times the feet as well, become flushed, and the patient complains of pain and tingling in the fingers and at times the toes also. Quinine is the correct treatment.

Heart Block.—This may be due to malarial parasites.

***Rarer Forms.*—Certain authors admit endocarditis as being of malarial origin.**

V. WITH 'DUCTLESS GLANDS' LOCALIZATION.

The types with which we are acquainted are those concerning the *suprarenal capsules*—viz., suprarenal hæmorrhage and the pseudo-Addison type, and those affecting the *thyroid gland*.

Suprarenal Hæmorrhage Type.—The sign and symptoms are those of acute peritonitis, but though the blood shows no malaria parasites, it equally shows no signs of polymorphonuclear leucocytosis. There is no enlargement of the spleen. Quinine should be administered, and the blood again and again examined for parasites. So far the cases have ended fatally as far as we know.

Pseudo-Addison Type.—There is a pigmentation of the skin associated with great loss of flesh and severe asthenia, with or without splenic enlargement, with or without fever, with or without parasites in the blood, but benefited by quinine.

Thyroid Type.—Intermittent and slight swelling of the thyroid gland has been observed in cases of malaria.

VI. WITH 'UROGENITAL' LOCALIZATION.

Subtertian malaria with genito-urinary symptoms may classified into:-

1. Orchitic type.
2. Ovaritis type.
3. Priapism type.
4. Functional generative changes.
5. Nephritic type.
6. Polyuric type.
7. Malarial hæmoglobinuria.

Orchitic Type.- Sudden severe pain in the testicles in a person who may never previously have suffered from typical malarial fever. The testicles become slightly swollen and very tender. There is no effusion. The temperature rises and the patient feels very ill, but the symptoms may be intermittent. A blood examination reveals malarial parasites, and quinine cures the condition.

Ovaritis Type.—Neuralgia of the ovaries is met with at times as a malarial symptom.

Priapism Type.—This is rare and is not influenced by the ordinary drugs, but is cured by large doses of quinine.

Functional Generative Changes.—Impotence, amenorrhœa, and metrorrhagia have been assigned to malaria.

Nephritic Type.—A type of malarial nephritis has been described.

Polyuric Type.--After one or two days of malarial fever, due to the subtertian parasites, a patient may begin and continue to pass enormous quantities of urine, which may cause considerable alarm. Energetic quinine therapy will stop this excessive flow.

Malarial Hæmoglobinuria.—This will be considered in Chapter XLI., p. 1213.

Malarial mastitis has been recorded. Quarelli has described a case of malarial chyluria.

VII. WITH 'CUTANEOUS' LOCALIZATION.

Pseudo-Smallpox Type.—This is characterized by high fever, severe pains in the back, associated with the papular eruption which appears on the second or third day, and consists of small shotty papules which never become vesicles or pustules, which are especially abundant on the face. It may require repeated blood examinations to find the parasites, and the spleen may not be enlarged, but quinine quickly cures the condition.

Herpes.—Herpes is not rare in attacks of malarial fever. It recurs with each attack, and usually at exactly the same spot on which it was situate during a previous attack—*e.g.*, on the lips, the tongue, the face, and the genital organs, etc.

It may occur without febrile symptoms, at a time when an attack of fever is due. Herpes zoster is very rarely seen.

Rarer Eruptions.—Malarial erythemata, malarial urticaria, malarial purpura, and malarial patchy œdema, resembling Malabar swellings or Quincke's œdema, may be mentioned. Ulcerative and gangrenous conditions have been recorded.

Pigmentation.—The black hyperpigmentation of malaria is quite common, and may be present in patches, *chloasma malaricum*, or it may be diffused, and in the latter case may be associated with the syndrome of Addison's disease (see p. 1180). In chronic cases the skin takes on a peculiar pale yellow or ashy grey tinge.

VIII. WITH 'SPECIAL SENSE' LOCALIZATION.

Subtertian malaria may concentrate its attacks upon the eye or the ear (see also p. 2004).

Amaurotic Type.—During an attack of pernicious fever a patient may complain that he is unable to see. When treated with quinine, as a rule sight soon returns, but more rarely blindness may result, due to thrombosis of the retinal vessels, and consequently retinal hæmorrhages and optic neuritis. One eye only may be attacked. This condition must be differentiated from quinine amaurosis. In malarial amaurosis the pupils react to light, and vision is, as a rule, not completely lost. In quinine amaurosis the pupils are widely dilated, do not react to light and other symptoms of cinchonism, such as deafness, severe tinnitus aurium, etc., will be present.

Aural Type.—In this there is a deafness which is not due to quinine, but to the lack thereof permitting the subtertian parasites to damage the organ of hearing. It is rare and chronic. Richardson records cases simulating mastoid disease.

Menière's Type.—Buzzing of the ears with giddiness, and at times the patient falls down. These attacks, which are very severe, are of malarial origin, but rare. The practitioner must differentiate this disease from aural symptoms due to quinine, which may induce buzzing, but seldom severe giddiness. Moreover, symptoms due to quinine improve or disappear on the drug being discontinued.

Loss of taste and anosmia may be noted. Symptoms simulating a frontal sinus affection may occur.

PERNICIOUS MALARIA.

When any of the above-mentioned syndromes caused by the *subtertian parasite* become serious, and threaten to endanger the life of the patient, they are called 'pernicious malaria,' which is therefore commonly caused by *Laverania malariæ*.

More rarely pernicious malaria may be due to the quartan or tertian parasites being present in enormous numbers in the blood, when the syndrome usually produced is *without localization* and most frequently of the *comatose type*.

CHRONIC MALARIA.

Chronic malaria may result from infection by any of the three malarial parasites, but is usually caused by *Laverania malariæ*, the subtertian parasite.

The symptoms of chronic malaria are repeated attacks of slight fever, which may pass unnoticed; enlargement of spleen and liver; and pigmentation of the skin and mucosæ. This pigmentation is particularly to be noted in the tongue in dark races, while in white races Gerhardt's urobilin icterus may be seen in the skin. Other symptoms are œdema about the feet, associated with anæmia, which may be marked; the presence of malarial parasites in the peripheral blood during an attack of fever; and often palpitation and dizziness, bronchitis and digestive troubles, and a general disinclination for exertion and work. The urine shows an increase of urea and urobilin. If this state of affairs is allowed to continue, it may pass into malarial cachexia with enormous enlargement of the spleen, which is firm to the touch and not tender or painful, associated with a profound secondary anæmia, and great reduction of red cells and hæmoglobin, with increase of mononuclear leucocytes. In boys and girls the onset of puberty may be arrested (malarial infantilism).

In malarial cachexia the apyrexial intervals are long, during which search may in vain be made for the parasite in the peripheral blood, but it is usually found during the febrile attacks, which may be quite mild. This is a condition, however, in which blood examination does not help the diagnosis as it does in other forms of malaria, and the clinical symptoms require to be studied, for the disease resembles kala-azar, while it may also be mistaken for ankylostomiasis.

Chronic malaria, of course, is due to insufficient treatment of the acute disease by quinine.

MALARIAL RELAPSES.

The cure of an attack of malaria, unfortunately, does not end the disease, for relapses are the rule and not the exception; in fact, using an expression of Mannaberg's, 'Malaria is one of those infectious diseases in which a relapse may be considered as an essential feature.' The reason is that the parasites are not all killed off by the quinine. There are two different types of relapses: the first, after a short interval, may be called the true relapse; the second, after a longer interval, may be called the recurrence. Relapses and recurrences are probably caused by parasites belonging to the cycle of schizogony, and by the parthenogenesis of the macrogametocyte, which belongs to the cycle of sporogony.

Relapses of quartan fevers take place at irregular intervals, and the suggestion that they are most usual at about the twentieth day is not correct. Tertian fevers relapse most commonly from the fifth to the eighteenth day, and subtertian about the end of a week after the original attack, but these times are extremely variable. These relapses are historically interesting, as they probably represent the quintans, sextans, septans, octans, nonans, etc., of ancient authors.

Recurrences take place after long intervals without fever and without reinfection. Exactly how long the parasites can lie dormant in the human body and then wake to activity and cause fever is not known. Intervals of two and three years are readily credited nowadays, but it is in our experience certain that the length of time may be much longer.

Parasites can certainly be found in the blood of persons long after they have left the tropics: thus, Ross mentions that they were found in a case in Liverpool four years after absence from any malarious locality, and also states that his own father suffered from attacks once or twice a year, even after nine years' residence in England.

It is probable, then, that the old idea that the malarial parasite can exist or lie dormant for years in the system, and awake to renewed activity when given a suitable opportunity, is true. During the apyrexial intervals it must, of course, be going through a cycle of schizogony, but not in sufficient numbers to cause disease. These parasites will increase rapidly, and cause fever when the general vitality of the body is lowered by any of the predisposing causes already mentioned, but especially by a chill, coming into action.

MALARIAL REINFECTIONS.

In tropical countries where there are plenty of anophelines and many inhabitants, European and native, adults and children, with numerous gametocytes in their blood, reinfections are found to be common. Many cases of apparent recurrence in these countries must be reinfections, which, of course, may be with the same or a different species of parasite from that causing the first fever. Repeated infections are the great cause of the quotidian and irregular fevers of the tropics.

COMPLICATIONS.

Many other diseases may occur in the human body at the same time as an attack of malaria; but of all, the most important are typhoid, dysentery, pneumonia, and nephritis.

Typhoid as a complication is, of course, due to the *Bacillus typhosus* occurring in a person who is also infected by malarial parasites, and in that sense, therefore, the old term ' typho-malaria ' is correct.

Dysentery may be a complication due to the *Loeschia histolytica* or to the dysenteric bacilli, but it may also be directly caused by the malarial parasite alone (p. 1177).

As to whether there is or is not a malarial pneumonia is a vexed question; personally, we are of the opinion that a severe subtertian fever may produce symptoms resembling a pneumonia, but that true lobar pneumonia, when present in a malarial subject, is due to the pneumococcus, and is therefore a complication.

Nephritis may be found in tertian and subtertian fevers, being directly due to the irritation of the kidney by the malarial toxins.

SEQUELÆ.

Many so-called sequelæ have already been described under Atypical Subtertian Fevers (see p. 1168). The possible sequelæ of malaria are very numerous, and may be classified into those belonging to the nervous system and sense organs, the blood, the liver, and the spleen.

The subtertian parasite may leave severe traces of its action upon the brain after pernicious attacks, and, indeed, the mind may never regain its old condition. Apart from the milder alterations of disposition and character, actual *insanity* in the form of mania or melancholia may result.

Neuritis in some form is sometimes of malarial origin, but it is quite possible that alcoholic and arsenical poisoning, and, indeed, beri-beri, may have been confused with it. We have seen cases of polyneuritis of malarial origin, but the condition is rare. *Neuralgias* have already been mentioned, and are probably in some cases due to the direct influence of the malarial toxins. *Tinnitus aurium, vertigo, deafness, anosmia,* and *loss of taste,* are said in some cases to be malarial in origin.

Severe and long-continued *anæmia* may result as a consequence of malaria caused by the subtertian, and much more rarely by the other parasites. The classification and characters of these anæmias have already been given in the section on Pathology, to which reference should be made (pp. 1144 and 1151).

Cirrhosis of the liver of malarial origin is, in our experience, much less frequent than admitted by many writers. Cirrhosis of the liver is common in the tropics, and in certain cases is due to alcohol; but one of the writers has pointed out that, at all events in Ceylon, a polyfibrosis of liver, pancreas, and kidney can be met with which has no malarial origin.

The *enlargement of the spleen* has already been described, and rupture as the result of blows or injuries is by no means unknown, though not common, and requires prompt surgical attention. We have only come across one case in our experience.

Tremors are not infrequently seen in chronic malaria, though more rare in acute malaria. *Fine tremors*, consisting of bilateral fine oscillations of small amplitude, caused by the alternate action of antagonistic muscles, may occur in the limbs and more rarely in the head. They are most common in the upper limbs, and especially in the hands. In the head there may be nystagmus or the tongue may be implicated. These tremors are increased by effort, fatigue, or emotion. *Coarse tremors* are usually exaggerations of fine tremors, and are often due to emotion, such as examination by the physician. *Intentional tremors* are produced in the hands, and sometimes in the head and neck, and are due to voluntary movement. They are not very uncommon in malarial infections.

The fine tremors must be distinguished from the fine tremors due to quinine, which are not very rare when the drug has been given for long periods. These tremors disappear in days, weeks, or months after the drug has been discontinued.

In malarial patients coming from war zones tremors and ataxic movements are not rarely seen, but these tremors are neither due to malaria nor to quinine, being of hysterical origin (*sensu lato*), and disappear often after treatment by suggestion.

DIAGNOSIS.

The diagnosis of malaria may be simplicity itself, or, on the other hand, it may be most difficult, as there is practically *no sign or symptom of disease of the human body which it cannot mimic.* We venture to impress upon the reader the vital necessity of making a thorough and *careful clinical examination*, as in many cases this alone may be the key to a correct diagnosis.

The positive signs of malarial infections are:—

1. *Tertian or quartan periodicity*, no matter what the symptoms may be.
2. *Tertian, quartan, or subtertian parasites* present in the peripheral blood.
3. *Pigment in the leucocytes.*
4. *Quinine*, properly administered, producing beneficial effect upon the symptoms.

The complementary signs suggesting malarial infections are:—

1. *Spleen enlarged and hard*, no matter what the symptoms may be.
2. *Slightly enlarged and tender spleen* in cases exhibiting syndromes usually significant of another disease, if the usual tests for the causal agent of the other disease are negative.

3. *Presence of mononucleosis* in association with other features of malaria.

4. *Pigmentation of the skin.*

5. *History of old malarial infections.*

Malaria should not be excluded by:-

1. *Absence of malarial parasites from the blood*, even after repeated examinations, especially in people who have taken quinine, and unless the examinations have been repeated many times and at varying intervals.

2. *Absence of mononucleosis.*

3. *Absence of enlargement of the spleen.*

4. *Absence of 'prompt reaction' to quinine.*

The question of driving the malarial parasite from a hiding-place in some organ into the peripheral blood by giving a small 'provocative dose' of quinine, injections of vaccines, of sterile milk, of strychnin, of adrenalin, by spleen douches, violent exercise, by ultraviolet light, etc., has been attempted, but reliance cannot be placed upon these methods as a practical aid to diagnosis.

Splenic puncture, and the subsequent examination of the blood obtained in this way, would help diagnosis considerably, but is not devoid of risk.

It is generally stated that a fever which within four days is not influenced by quinine in full doses is not malaria. This is correct as regards malarial fevers due to tertian and quartan parasites, but not always as regards those caused by the subtertian parasite. We have met with cases in which the fever has remained unaffected, while the parasite can be found in the peripheral blood, notwithstanding several weeks' quinine therapy by various methods.

In malarial cachexia James has pointed out that the microscopical is inferior to the clinical examination, drawing attention to the fact that a four-hourly temperature chart carefully kept during one of the febrile attacks will often show the typical curve of subtertian fever. In such difficult cases the clinical signs, together with the reaction of the disease to quinine, must be utilized.

In latent malaria the frequent increase of the urobilin in the urine may be of some slight help in the diagnosis, as pointed out by Plehn, together with indefinite periodical rheumatoid pains. Thomson has devised a diagnostic method based on complement deviation, using as antigen a culture of malaria parasites from a heavily infected case. The reaction, however, seems to be positive also in cases of syphilis. Details may be found in Thomson's paper, *British Medical Journal*, December 7, 1918.

The *differential diagnosis* of the various forms of malarial fever should be confirmed, no matter how evident the clinical symptoms may be, by microscopical examination.

The most important diseases to differentiate from malaria are typhoid, insolation, liver abscess, kala-azar, Malta fever, influenza, yellow fever, dengue, and seven-days' fever. For the differential diagnosis see Chapter LX. (p. 1511), which deals with the diagnosis of a tropical fever.

The pernicious forms of malaria, in whatever way they attack the patient, will in most cases be readily diagnosed by blood examination, as will also the masked form of the disease.

Fevers due to septicæmia caused by a streptococcus, the pneumococcus, and the gonococcus, may resemble malaria, but can be excluded by bacteriological examination, as can influenza when it gives rise to an intermittent type of fever.

PROGNOSIS.

Quoad vitam the prognosis is usually good if an appropriate quinine therapy is carried out, but it must be remembered that pernicious cases tend to a high mortality, notwithstanding all treatment, and even in the usual benign cases the cure is very often merely clinical and not complete, as is also seen in other protozoal diseases such as syphilis, yaws, and amœbiasis.

There are two further points to be considered under this heading, and they are:—

1. The probability of recovery.
2. The probability of a cure.

1. **Probability of Recovery.**—This depends upon:—

(*a*) The type of fever.

(*b*) The condition of the patient with regard to race, age, sex, physical fitness, the presence or absence of other diseases, idiosyncrasy to quinine, and the duration of the symptoms.

(*c*) The nature of the country in which the patient is living.

THE TYPE OF FEVER.—Quartan and tertian infections, especially in the simple type, give the best prognosis, but quotidian infections and fevers due to the subtertian parasite should be viewed as more dangerous, while pernicious malaria must be regarded as extremely dangerous.

RACE.—The mortality among natives of bad malarial regions is usually low, while that among Europeans is high. The death-rate in a native race which has comparatively recently been subjected to increased danger of malarial infections is sometimes truly appalling.

SEX.—There is a better prognosis for males than for females, and there is a distinctly worse prognosis for an attack taking place during pregnancy.

AGE.—Children often have more severe attacks than adults, but can usually stand quinine well, which rather balances this disadvantage.

PHYSICAL FITNESS.—Persons debilitated by long residence in tropical countries or from existence upon poor food are not in a condition to resist severe malarial infections, and therefore the prognosis is rendered more serious.

COMPLICATIONS.—The presence of complications in any form—*e.g.*, typhoid fever, etc.—naturally makes the outlook more serious.

QUININE.—Idiosyncrasy to quinine of an anaphylactic nature is most serious, but can be combated by commencing with very small doses, and slowly and steadily working upwards.

DURATION OF THE SYMPTOMS.—If the symptoms persist in the face of quinine therapy the prognosis is serious.

2. **Probability of a Cure.**—The probability of a cure—that is to say, of a so-called bacteriological sterilization of a patient with regard to the malarial parasites—is a very doubtful matter, as the

affection is able to lie dormant for months and years, even after the tropics and any source of infection have been parted with entirely. At times one may be lucky enough to catch all the parasites sporulating, and to kill them with one large and properly applied dose of quinine. This has certainly happened to us with regard to the subtertian parasite in certain cases, but it may have been accidental. The infection may remain dormant for years, and be reawakened by any cause lowering the resisting powers of the individual, such as a chill, a traumatism, or an operation. In temperate climates there is often a seasonal dormancy in winter.

TREATMENT.

Essential Treatment.—There is one specific remedy for malaria, and this is *Quinine*, which should be given *immediately* upon the diagnosis of malaria being made, and may be administered as follows:—

A. WHEN THE PATIENT IS FIRST SEEN IN AN ACUTE ATTACK.

I. *In Benign Intermittent Fevers* (Quartan and Simple Tertian) give *quinine in solution* by the mouth, if the patient is not sick, in 10 grain doses three times a day, or in doses of 15 grains in the morning and 15 grains in the evening.

In a certain number of cases it is advisable to give with each dose of quinine 5 grains of *sodium bromide* in solution, in order to combat any nerve effects of the drug. The bowels should be freely opened with calomel, followed by salines.

If the heart is not working properly, *caffeine citrate* in 1 to 3 grain doses may also be administered, either by the mouth or hypodermically.

If this dosage of quinine is found to be insufficient, as judged by the persistence of the symptoms, *increase* it to 10 grains every four hours instead of three times a day.

II. *In Severe Intermittent, Remittent, and All Subtertian Fevers* give *quinine* by intramuscular injection in a dose of 15 grains *as soon as the diagnosis is made*. Repeat the injection daily, and in addition administer the drug by the mouth in 10 grain doses three times a day.

In these fevers as much as 45-60 grains of quinine may be required in twenty-four hours to combat the symptoms, and should be given by a combination of intramuscular injections with oral administration.

Sodium bromide, the purgative and cardiac drugs mentioned in the preceding section, may also be given.

The injection is to be made in a thoroughly antiseptic manner. Use a vial, containing 15 grains of quinine bihydrochloride in 1 cubic centimetre of fluid, manufactured by some reputable firm. The injection may be made *deep* into the muscles of the gluteal region, care being taken to avoid the line of the sciatic nerve, or *deep* into the loose tissue, extending from the lower angle of the scapula to the crest of the ilium. The vials made by different firms vary

very much in the degree of pain or discomfort which they produce, but some (in pre-war preparations) caused very little pain if given, as should always be done, with the strictest antiseptic precautions. For fuller instructions see Method of Administration, p. 1193.

Do not hesitate to give *intramuscular injections of quinine.* They *have saved many lives*, but the strictest antiseptic methods must be used.

III. *In Pernicious Malaria.*—In pernicious fevers give *quinine at once by intravenous injection.*

The quinine injection should be made into the median basilic or median cephalic veins, and not less than 1 gramme (15 grains), dissolved in sterile 5 c.c. of physiological salt solution, should be injected at a time. The skin over the selected vein should be rendered thoroughly aseptic by soap and water and carbolic lotion, or by painting with tincture of iodine, and then a bandage tied round the arm, so as to retard the flow of venous blood and make the selected vein stand out. Then the needle should be inserted into the vein (care being taken that there is no air in needle or syringe) in a sloping direction, with the point towards the heart, so that the injection can flow with the circulation. The point of the needle should be felt to be loose (*i.e.*, in the vein). The bandage must now be loosened and the injection made *slowly*, the effect on the pulse being noted. The needle is now withdrawn, and an aseptic pad fixed in position by a bandage.

The effect of quinine on the circulation must be remembered, and if the pulse is bad, it is advisable to give an injection of ether as a preliminary.

If the serious symptoms persist the intravenous injection may be repeated in four hours, and further medication may then be carried on by intramuscular injections. Not more than two intravenous and two intramuscular should be given, under any circumstances, in twenty-four hours.

When the serious symptoms abate the intramuscular injections alone should be used, and should be given once or twice a day, and supplemented by oral administration, as indicated above.

B. DURING THE COURSE OF THE FEVER.

I. *If the symptoms are abating* the dosage of quinine may be reduced slowly to about 30 grains per diem, but this must not be done too quickly, and care must be taken to increase this dosage at once if there are any signs of a return of the symptoms.

During the course of the fever the bowels must be kept regularly open, the urine must be carefully watched as to quantity and colour, and tested chemically from time to time, while blood examinations should also be made at times and the pulse carefully noted.

II. *If the symptoms are not abating* the probability is that insufficient quinine is being administered, and in such cases the drug should be carefully increased.

If only oral administration has been used it should be at once supplemented by intramuscular injections.

Care should also be taken that the bowels are kept well opened, that a sufficiency of fluid is drunk to provide a good flow of urine, and that the heart's action is well supported by stimulants and by drugs if necessary.

In order to combat severe symptoms, it may be necessary to give 45-60 grains of quinine, or even more, per diem, but this must be done carefully, and the dosage must at once be reduced when improvement appears. As a rule, not less than 30 grains in the twenty-four hours should be given.

Quinine often takes effect before the expiration of four days of thorough treatment, but it may be necessary to continue the administration of large daily doses longer than this period. If quinine appears to be ineffectual in checking the symptoms, care must be taken to exclude any other possible cause for the symptoms.

C. When the Acute Attack has Subsided.

Continue to administer quinine orally for at least *three months*.

During the first month give it in 10 grain doses twice or thrice daily. During the second month 5 grain doses thrice daily. During the third month 5 grain doses twice daily.

The quinine may be administered, as the *bihydrochloride*, in crushed tabloids, but if it is desired to use the more insoluble salts (see the paragraphs on the theoretical considerations lower down in this chapter) a mixture such as the following may be given:--

Quinine sulphate	10 grains.
Dilute sulphuric acid	10 minims.
Syrup of orange	1 drachm.
Distilled water	1 ounce.

Euquinine may be substituted for quinine for the purposes described in this paragraph, but must be given in slightly larger doses.

With the commencement of convalescence it is useful to give some tonic mixture such as:

Iron and quinine citrate	10 grains.
Liquor strychninæ hydrochloratis	3-5 minims.
Syrup of orange	1 drachm.
Distilled water	1 ounce.

This should be taken three times a day half an hour after meals.

See that the patient's bowels are kept regularly open every day.

Notwithstanding all care and energetic quinine treatment, relapses are prone to occur some variable time after medication has ceased.

D. Relapses.

When relapses occur after thorough quinine treatment it is advisable to combine with this drug arsenic and at times tartar emetic and phosphorus.

The following mixture introduced by Castellani indicates the line of medication suggested:—Quinine sulphate, 10 grains; dilute sulphuric acid, 10 minims; tartar emetic, ⅛-¼ grain; codein, ⅛-¼ grain; syrup, 1 drachm; chloroform water, to 1 ounce.

Another formula used by Castellani is: Quin. hydr., gr. x.; tartar emetic, gr. ⅛; liq. Fowleri, ♏i.; syr., ʒii.; aq. chlorof. ad ℥i.

Two tablespoonfuls of this mixture may be taken, well diluted with water, every four hours.

In addition it may be necessary to resort to intramuscular injections of 15 grains of quinine daily, and it is sometimes advisable to alternate this, every other day, by a subcutaneous injection of the *phosphorated oil* of the British Pharmacopœia in doses of from 1 to 4 minims.

The above forms the quinine-phosphorus-tartar-emetic treatment for malarial relapses devised by Castellani, and found useful by Quarelli and others.

Baccelli's mixture, slightly modified, has the following formula: Quin. bisulph., gr. 8; ferri perchlor. (Ital. Pharm.), gr. 3; liq. Fowleri, ♏.½; aq. to ℥i. It is very bitter.

E. CHRONIC MALARIA.

Chronic malaria should be treated by the methods given just above for relapses. Intramuscular injections of quinine are specially useful in this condition, and should be given in courses of fifteen daily injections. The courses should be repeated two or three times after varying intervals.

F. MALARIA IN PREGNANCY.

Give the usual twenty-four hourly dosage of quinine, but divide it up into small individual doses of 2 to 5 grains.

G. MALARIA IN CHILDREN.

The dosage of quinine for children is as follows:—

Age of Child.	*Dose of Quinine.*	*Number of Doses in Twenty-four Hours.*
Under twelve months ..	½ to 1½ grains.	Six.
1 to 3 years	1 to 2 grains.	Six.
3 to 10 years	2 to 3 grains.	Six.
10 to 16 years	3 to 5 grains.	Six.

H. REMARKS.

It may be thought that in the above we have been too dogmatic, but our excuse is that we desire to lay before the practitioner our experience of many years of tropical practice.

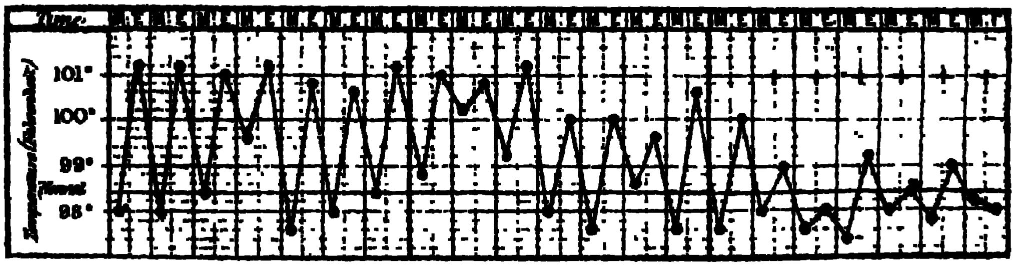

FIG. 626.—TEMPERATURE CHART TO ILLUSTRATE THE BENEFIT OF INTRAMUSCULAR INJECTIONS GIVEN AT + + + + + +, AS COMPARED WITH THE PROLONGED ORAL THERAPY OF DAYS PREVIOUSLY.

The dosage of quinine in use in England and non-malarial countries is perfectly useless in highly malarial tropical districts.

An attempt is made in the above system of treatment to prevent relapses and recurrences as far as is possible.

DETAILS OF TREATMENT.—The various other points connected with treatment may be considered as follows:—

A. Quinine therapy.
B. Symptomatic treatment.

Quinine Therapy.—There are a number of details which require elaboration with regard to quinine therapy, and these are:- (1) The dose; (2) the time of administration; (3) the method of administration; (4) the duration of treatment.

THE DOSE.—To adults we generally give three times a day by the mouth 5 to 10 grains of the ordinary preparations (sulphate, hydrochloride, etc.). The routine mixture is composed of quinine sulphate, 5 to 10 grains; dilute sulphuric acid, 5 to 10 minims; syrup of orange, 1 drachm; distilled water, 1 ounce. We give euquinine in slightly larger doses.

By intramuscular or intravenous injections we give 15 grains, by the rectum 30 grains; but when given by the last method, some tincture of opium should be added, to prevent irritation, which otherwise is liable to occur. Five or ten grains of potassium bromide added to each dose of quinine will, to a certain extent, prevent tinnitus aurium. In cases in which the heart is weak a few minims of tincture of digitalis should be prescribed.

Children suffering from malaria stand quinine well, and the minute doses advised in so many treatises on the diseases of children are, in our experience, utterly inadequate in the tropics. Infants under one year of age may receive from ½ grain to 1½ grains six times a day; children between one and three years of age from 1 grain to 2 grains six times a day, and those between three and ten years 2 to 3 grains six times a day.

Nocht has advised the administration in adults of quinine in small repeated doses of 2½ grains five times a day. This method is useful when there is a tendency to hæmoglobinuria and in pregnant women in whom the administration of full doses may induce abortion; but this action has been greatly exaggerated, many cases ascribed to quinine being due to some other cause. We have often given 15 grains of quinine daily to pregnant women, but divided into small doses of 2 to 3 grains, and in severe cases have pushed the drug without bad effects. The addition of a little opium may prevent bad effects.

In patients showing anaphylactic symptoms such as dyspnœa dysphagia urticaria, etc., Héran and Saint-Girons give quinine as follows: the first day a 'defensive dose' of gr. ½ quinine sulphate mixed with gr. 8 sodium bicarbonate is given, and two hours later, gr. 1½. The second day, two hours after the 'defensive dose,' gr. 3 is administered. The third day, two hours after the defensive dose, gr 6 is given, and so on, gradually increasing the amount of quinine.

TIME OF ADMINISTRATION.—The best time to give quinine to a *healthy person* for purposes of prophylaxis, or to a convalescent for purposes of effecting a cure, will be at meal-times, and preferably directly at the end of the meal, so that it can enter the blood with the products of digestion, and so obtain its fullest action. It has been our rule in most cases to advise that it should be taken directly after the early morning meal.

The hæmolytic action of quinine must be remembered, and the fact that it may by this action give the liver more work by extra bile production. Consequently, it is most necessary to remind the above class of patients to take care that the bowels are open regularly, and to correct by suitable aperients any irregularity that may exist.

With regard to *mild quartan and tertian fevers*, there is not the slightest doubt that excellent effects are obtained by giving the drug four hours before the attack—*i.e.*, before the sporulation of the parasite is due. In this way the merozoites are most likely to be killed. This may be modified by giving the drug twice daily, one dose of 10 grains by the mouth in the morning, and the other dose of 10 grains at the above-stated time. This method we have found most useful, as it allows for irregularity in sporulation.

In many cases, however, we give the drug three times a day, without regard to the conditions of parasitic life, and this method is apparently not less successful.

In more *severe forms of quartan and tertian*, and in cases of *subtertian fever* in which the patient is seen for the first time during the attack, the drug should be given intramuscularly or by the mouth, when it may be administered on the fall of the temperature, when the gastric irritation is lessening, and then continued by one of the above methods.

In cases of *serious and of pernicious attacks*, time must not be wasted in waiting for temperatures to fall or for symptoms to improve, otherwise the patient will die, and there must be no hesitation in giving either an intramuscular or an intravenous injection, according to the severity of the symptoms.

Method of Administration.—For practical purposes there are only four methods of administration:—

1. By the mouth.
2. By the rectum.
3. By intramuscular injections.
4. By intravenous injections.

By the Mouth.—If expense is no object, take the most soluble drug that can be got, and use either the bihydrochloride or the bisulphate; otherwise the sulphate must be used. In cases of women and children, euquinine may be used with advantage, but it should be remembered that it is very insoluble and expensive.

The forms in which the chosen drug may be administered are:—

1. Powder.
2. Solution.
3. Tabloid, tablet, or pill.
4. Cachet or capsule.

It is presumed that no doctor would allow his patient to take quinine in a cigarette-paper, though non-medical people are found who have got into the habit of using this method.

As regards the powder, it is an efficient method of administering the drug to the healthy, if given directly after a meal, but the taste is most unpleasant. It is certainly the cheapest method.

The acid preparations—for example, the bihydrochloride and bisulphate—may be dissolved in water, but should have some flavouring added to disguise the taste, while the sulphate requires an acid, which may be provided by suspending some of the powder in natural limejuice; but in order to dissolve the sulphate properly a mineral acid should be used, in the strength of 1 minim to each grain, but more than this will be required if the unpleasant after-taste is to be avoided.

In hospitals the sulphate must be used, as it is cheap and effective, but it is as well to have it periodically reported upon by an analyst, in order to see what is really being given to the patients. For hospital use it may be dissolved in dilute sulphuric acid, and have some cheap form of flavouring added.

We have used Warburg's tincture on the West Coast of Africa with apparent success in cases of chronic subtertian infection, which resist the ordinary methods of administering quinine, but care is required, as it may have a depressing effect upon the heart.

Tabloids, tablets, and pills are pleasant methods of taking quinine for prophylaxis, convalescence, and mild attacks. Moreover, they are extremely useful for journeys, being readily carried, but in order to be successful they must not be old and hard. The hydrochloride or bisulphate should be used and the solubility tested from time to time in water, otherwise the tabloid must be reduced to powder and taken as indicated above.

Pills and capsules are quite good when fresh, but they are apt to get hard when old, and are then useless, and must be opened and the powder used, if they form the only supply available.

The quinine tannate chocolates are, of course, only used for prophylaxis in children.

By the Rectum.—This method may be useful in gastric disturbance, but is not to be compared with the intramuscular. Twenty grains of the bihydrochloride are made into a solution in water, and then mixed with an ounce of mucilage of starch solution, and used as an injection. It is advisable to add a few drops of tincture of opium.

Quinoform suppositories (gr. iii.) have been used in children by Pedro and others.

Intramuscular Injections.—We are not in favour of hypodermic injections of quinine—*i.e.*, of injections simply under the skin—but strongly recommend intramuscular injections in all cases of malarial fever in which there is gastric disturbance, where, for any reason, the quinine is apparently failing to act, when the disease is becoming chronic, or in serious subtertian infections. For this purpose the bihydrochloride should be dissolved in normal (0·75 per cent.) saline solution, and carefully sterilized. Baccelli's formula is 10 grammes of quinine and 0·075 gramme ($1\frac{1}{6}$ grain) of salt dissolved in 10 grammes ($2\frac{1}{2}$ drachms) of water, one-tenth of which is used for an injection; but the greatest care must be taken that this solution is properly sterile. A good formula for a solution which does not cause pain is Gaglio's or Giemsa's: Quinine hydrochloride, 10 grammes; aquæ destillatæ, 18 grammes; ethylurethane, 5 grammes, of which one-twenty-fifth portion is used for an injection (1·5 c.c. of the solution contains 0·5 gramme of quinine).

If, however, the solution is to be prepared and sterilized while the patient is waiting for treatment, much time is lost. We therefore recommend the tropical practitioner to purchase and keep by him the sterilettes, which are little hermetically sealed vials containing a gramme (15 grains) of quinine in solution. These sterilettes may be purchased from Squire and Sons, or Martindale, of London; Burroughs Wellcome and Co.; or Molteni, of Florence. Giemsa's solution may be obtained in similar sterile vials.

The technique is simple: First cleanse the skin of the patient carefully with 1 in 40 carbolic lotion; then break off the glass seal of the vial at the nick in the neck, and pass the open mouth of the vial through a flame; then draw up the contained fluid into a sterilized all-glass syringe provided with a platinum iridium needle. Plunge the hypodermic needle deeply into the deltoid or gluteus maximus, and make the injection. Withdraw the needle, and place a little pad of wool, wrung out in 1 in 40 carbolic lotion, on the site of the injection. Performed carefully in the above manner, there need be no fear of tetanus or abscess formation, and the injection can be repeated at will. If necessary, a stimulant or an injection of ether may be given in the old and feeble before this intramuscular injection. After repeated injections of quinine, even if administered antiseptically, hard swellings may appear at the seat of the injections. In such cases the hypodermics should be stopped for a few days, and an ice-bag may be applied to the painful part.

Notwithstanding the objections to this method brought forward by some authorities, we still strongly recommend it, as we have found it to be most successful in intractable cases, and have never so far seen any untoward symptoms. We advise that the hypodermic syringe and needle should be sterilized by rinsing with 1 in 20 carbolic acid after boiling, as the carbolic acid does not interfere with the action of the quinine, and has an unfavourable influence upon any tetanus spores which may by any chance be present. Care should be taken that not too much carbolic lotion is left in the syringe and needle; otherwise a precipitate will form

Intravenous Injection.—In cases of pernicious infection with subtertian parasites, no delay should be made in giving the patient an intravenous injection, but the effect of quinine on the circulation must be remembered, and if the pulse is bad, it is advisable to give an intramuscular injection of ether as a preliminary. The same vials and apparatus should be used in the intravenous as in the intramuscular injection.

The injection should be made using a 5 c.c. or 10 c.c. syringe, into the median basilic or median cephalic veins, and not less than 1 gramme (15 grains) of the bihydrochloride dissolved in five or ten cubic centimetres of sterile physiological salt solution should be injected at a time. The skin over the selected vein should be rendered thoroughly aseptic by soap and water and carbolic lotion, or by tr. iodi. and then a bandage tied round the arm, so as to retard the flow of venous blood and make the selected vein stand out. Then the needle should be inserted into the vein (care being taken that there is no air in needle or syringe) in a sloping direction, with the point towards the heart, so that the injection can flow with the circulation. The point of the needle should be felt to be loose (*i.e.*, in the vein). The bandage must now be loosened and the injection made *slowly*, the effect on the pulse being noted. The needle is now withdrawn, and an aseptic pad fixed in position by a bandage.

DURATION OF TREATMENT.--When the fever has subsided and the patient is feeling better, the administration of quinine must not be discontinued, because there is the fear of a relapse, caused by parasites which have not yet been destroyed, and which may be living in the spleen; or, again, there is the fear of the parthenogenesis of the macrogametocyte. In order that the treatment may be successful, the quinine must be continued for a long time. Our routine practice has been to continue with 10 grains three times a day for a month after the cessation of the fever, 5 grains three times a day during the second month, then 5 grains twice a day during the third month. In some cases when the fever has ceased it is advisable to associate some iron and arsenic with the quinine, but these drugs should not be administered during the febrile attack.

Symptomatic Treatment.--The symptomatic treatment may be considered under the following headings:--

1. Symptomatic treatment of acute malaria.
Diet in acute malaria.
Treatment of symptoms and special condit
Treatment of convalescence.
Treatment of chronic malaria.
Treatment of malarial cachexia.

SYMPTOMATIC TREATMENT OF ACUTE MALARIA.--The practitioner who works in the tropics must often be prepared to do the nursing as well as the medical treatment. When the attack begins, the patient must go to bed, and in the cold stage wrap up well with blankets. At the same time arrangements must be made in case of sickness or diarrhœa. The treatment of this and the warm stage must be to encourage perspiration, by warm lime-drinks, hot tea, etc., in order that the toxins may be passed out as quickly as possible. Ziemann recommends hot-air baths to bring on the perspiration. We have tried this method a few times, but have not been greatly impressed with the advantages.

The headache may be relieved by cold applications, and where there is no ice, dissolve some salt and juice of fresh limes or lemons, together with some vinegar or weak acetic acid and Florida water or eau-de-Cologne, in a small basin of water, and, after soaking handkerchiefs in this mixture, apply them one after the other, changing as they get warmed, to the patient's forehead.

A little stimulation of the auricular branch of the pneumogastric by applying some of this cool lotion to the lobule and behind the ear is most refreshing to the patient.

Another method of relieving the headache and pains about the body is to give phenacetin and caffein. Phenacetin or antipyrin should only be given in small doses (gr. ii.-iii.), and not to debilitated patients.

When the sweating begins, the patient usually feels much better, but care must be taken to change the damp clothing, and when this stage is drawing to a close a sponge over with tepid water is most refreshing, after which he will probably go to sleep and wake feeling much better.

DIET IN ACUTE MALARIA.—During the attack the strength must be maintained by light food, such as Brand's essence or chicken-broth, and stimulants, in the form of brandy or champagne, may be required. Milk or whey may also be given, and in cases of stomach irritation albumen water.

During remissions broths and clear soups and milk-puddings should be allowed. In the intermission of a quartan or tertian, and during convalescence, regular meals of good plain food may be given.

TREATMENT OF SYMPTOMS AND SPECIAL CONDITIONS.—*Vomiting* is often distressing, and can be relieved by sips of iced soda-water or champagne. When there is no ice, cover the bottle with a thin layer of flannel soaked in water, and hang in the breeze. If these simple remedies fail, and the symptom is really urgent, apply a mustard-leaf to the pit of the stomach, or give a mixture containing chloroform or a hypodermic of morphine. If, despite all this treatment, the vomiting still continues, the stomach may be washed out with slightly alkaline water.

Hiccough is not often present, and would be a most unpleasant sign. It can be checked by the mustard-leaf, by codein, or by a hypodermic of morphia (gr. ¼).

Cough not infrequently worries the patient. It may be sharp and dry, and is best treated by codein or morphia in some form, *e.g.*:—

Codeinæ	gr. ¼.
Syrupi tolutanæ	ʒi.
Aquæ chloroformi	ad ℥i.

administered every four hours.

Constipation must not be allowed, and should be promptly relieved by a dose of calomel (1 to 3 grains), if necessary, followed by a saline. Ziemann strongly recommends washing out the rectum with warm normal saline solution as a routine practice, but though we have used this in bad cases, we have no experience of it as a routine practice.

Diarrhœa is at first useful in ridding the body of excess of bile and other waste products. Prolonged diarrhœa must be treated with astringents (bismuthi subnitratis or salol gr. x. every four hours). Meanwhile it should be borne in mind that though quinine is absorbed by the stomach, still, with much diarrhœa there is often gastric disturbance, and therefore, if the drug is given by the mouth in these conditions, its utility may be small.

Splenic pain and liver pain are not, as a rule, severe enough to make special treatment needful, but occasionally the splenic pain may be severe (due to perisplenitis), when hot fomentations will relieve it, if it is thought necessary to use them.

Hyperpyrexia must be treated by cold sponging—if possible, with ice; if not, with the mixture mentioned above, or by cold packs, cold baths, and cold enemata.

Cerebral Malaria.—Give large hypodermic saline infusions to wash out the toxins (*vide* Algidity).

Algidity requires special treatment with hypodermic saline injections and warm applications to the body, and especially to the region of the heart. The saline injections consist of sterile normal saline solution, and are injected by gravity from the ordinary glass reservoir via a long piece of indiarubber tubing and a stout hollow needle, such as those in the Potain's aspirator-case. The usual sites for the injection are the sides of the chest, just below the armpit, and the outer aspect of the thighs. At least a pint should be injected in one place. Oxygen inhalations, if available, may also be used.

Diaphoretic pernicious fever requires stimulants, hypodermics of atropine, and ether or strychnine, and treatment as for algidity.

Hæmorrhagic perniciosa may be treated with calcium chloride, and with local applications or injections of adrenalin.

Scarlatiniform perniciosa obviously calls for dilution of the toxins by saline injections.

In *pernicious cases*, when the patient becomes *delirious* or comatose, the practitioner must be careful that the attendants in whose charge he is left are really trustworthy, as unfortunate accidents have been known to happen. Particularly we warn the practitioner to make sure that the bladder has been emptied, especially in delirious patients, not by mere causal inquiry, but by percussion of the abdomen.

In choleraic perniciosa the treatment for cholera should be adopted in addition to quinine. In *dysenteric perniciosa* the treatment must be that suggested for mild dysentery, and, in addition, quinine, while the *pseudo-Addison's* disease is best treated in our experience by 10 minims of adrenalin, given twice daily in addition to quinine.

Treatment of Convalescence.—The important point to be remembered in convalescence is to continue the quinine in smaller doses for at least three months after the attack. The patient should be placed on a tonic with iron and arsenic in some form, and if he has been seriously ill he must have a change to a colder climate. The patient must be impressed with the fact that he must not discontinue the quinine on arriving in a cooler climate, as an attack of fever will surely take place if he does so.

TREATMENT OF CHRONIC MALARIA.—If a person is constantly suffering from attacks of malarial fever, he should be sent, whenever possible, for a change to a cooler climate in the hills or to the temperate zone, but should, of course, continue the quinine treatment. If he cannot afford a change of climate, he must be placed in bed and given rest from work, and a course of quinine therapy by intramuscular injections carried through. Arsenic is useful.

TREATMENT OF MALARIAL CACHEXIA.—The most important feature, in addition to quinine treatment, is to send the malarial cachectic for a change of climate, as mentioned above, and treat the anæmia with iron and arsenic. A course of injections of cacodylate of quinine is often useful.

Theoretical Considerations.—There are a number of theoretical considerations with regard to the treatment which may perhaps interest the reader, and these may be divided into:—

1. Quinine.
2. Effects on man.
3. Effects upon malarial parasites.
4. Immunity of parasite.
5. Prophylactic use.
6. Other drugs.

QUININE.—The aim of the treatment of malaria is to kill the parasites and to aid the excretion of the toxins and relieve the symptoms of the patient.

Fortunately, since the days of the Countess del Chinchon, the world has known the value of cinchona bark in malaria, and later it learnt that this important action was due to an alkaloid, quinine, which exists in the bark in the form of a hydrate. In 1807 Binz showed that quinine killed infusoria, and he believed that this action was due to its checking oxidation.

Quinine is usually sold in the form of the sulphate, $[(C_{20}H_{24}N_2O_2)_2.H_2SO_4]_2.15H_2O$, which is only soluble 1 in 800 of cold water, but is readily soluble in water acidulated with a mineral acid. The solution gives a bluish fluorescence.

It must be remembered, however, that it may not be pure, and may contain lime, chalk, magnesia, starch, etc. It is also important to remember that it is incompatible with alkali, alkaline carbonates, and astringent infusions.

Quinine sulphate is by no means the best preparation, for the hydrochloride, $(C_{20}H_{24}N_2O_2).HCl.2H_2O$, is soluble 1 in 40 of water; but better than this are the acid salts of the sulphate, called the 'bisulphate,' $(C_{20}H_{24}N_2O_2)H_2SO_4.7H_2O$, which is soluble 1 in 11 parts of water, and of the hydrochloride, called the 'bihydrochloride,' $(C_{20}H_{24}N_2O_2)2HCl$, which is soluble 1 in 1 of water. Numerous other preparations are on the market, of which quinine bihydrobromide is recommended in persons who suffer from deafness, and quinine valerianate in those who are very nervous; while quinine tannate, which is not nearly so bitter as the other compounds, especially when made up with chocolate, has been used by Celli in quinine prophylaxis for children and in cases of hæmoglobinuria.

Euquinine, which is quinine ethylcarbonate, $C_2H_5O\text{--}CO\text{--}OC_{20}H_{23}N_2O$, is also not so bitter as the ordinary preparations, and is therefore suitable for administration to women and children, but it has the disadvantage of being expensive and very insoluble in water, and must be given in cachets or dissolved in acidulated water. It has not such deleterious effects on the stomach and nervous system.

Another remedy which contains quinine sulphate, and which was much vaunted in days gone by, is Warburg's tincture, which is said to be prepared by macerating for seven days the following ingredients—

	Grains.
Aloes socotrinæ	240
Rhei	80
Fructi archangelicæ officinalis	80
Radicis inulæ helenii	40
Croci	40
Fructi fœniculi	10
Cretæ preparatæ	40
Radicis gentianæ	20
Radicis curcumæ zedoariæ	20
Cubebæ	20
Myrrhæ	20
Polypori officinalis	20
Opii	2½
Piperis nigræ	4
Cinnamonis	3
Zingiberis	8

in a pint of 60 per cent. alcohol for a week; then pressing, filtering, and dissolving in the filtrate: –

	Grains.
Quininæ sulphatis	175
Camphoris	20

and after three days' filtering, making up to the pint with alcohol. The dose of this mixture is 1 to 4 drachms.

Other preparations can hardly be said to have any particular interest.

In order, however, to bring these various preparations into line with one another, it is necessary to have some arbitrary standard, and this is generally taken as quinine sulphate, which is reckoned as equal to 1. The hydrochloride will then be 0·9, the bisulphate 1·24, the bihydrochloride 1·02, the bihydrobromide 1·23, the valerianate 1·01, the tannate 3·67, euquinine 1·0, and Warburg's tincture 1·09

New Salts of Quinine.—Dihydroquinine hydrochloride (0·6 gramme = 1·0 gramme quinine hydrochloride) is said to be have a specific antimalarial action, but aurochin, chitenin, and tetrahydro-quinine are not satisfactory.

Cinchonin Salts.—Various cinchonin salts have been used in the treatment of malaria, and Sir Leonard Rogers has recently recommended intramuscular injections of cinchonin bihydrochloride.

Effects on Man.—When taken by the mouth, quinine should be dissolved in the acid gastric juice, converted into the bihydrochloride, and absorbed completely into the blood from the stomach, especially if food is taken at the same time. If this does not happen, then such a salt as the sulphate may not be absorbed at all, as it will be precipitated in the alkaline intestinal contents. When given in large or frequent doses, it is apt to irritate the stomach. As to what happens to it in the blood, there are two distinct views—one pointing to rapid elimination, and the other to the fact that it undergoes changes in the tissues. It would appear to be retained longer in the body if absorbed together with food.

It can also be administered by intramuscular injections, when it is said to be largely precipitated at the site of the injection. We have no knowledge personally of this precipitation, and our experience is that intramuscular injections have been most satisfactory, though it must be admitted that there are observers who think that administration *per os* is more valuable than that by intramuscular injections. It may also be given intravenously, as will be explained later.

Quinine in small doses is a vascular tonic, but in large doses it is a cardiac depressant, producing a fall in the arterial pressure, with decrease in the pulse-rate and strength. This is an important matter, to be remembered in administering the drug to the old and the feeble, especially by intravenous or intramuscular injections. On the nervous system it acts as a stimulant, and also increases the flow of blood to the brain. In the tissues it is partly destroyed by oxidation, and therefore the whole quantity administered is hardly likely to be obtained in the urine. Excretion takes place by the kidney almost entirely in the form of quinine dihydroxyl. It can be recovered from urine by acidulating with sulphuric acid, treating with solid picric acid, filtering until clear, digesting with 3 per cent. caustic soda solution, and extracting with chloroform, from which the quinine can be obtained by evaporation. Ramsden and Lipkin have described a new process for isolating quinine from urine (*Annals of Tropical Medicine and Parasitology*, May, 1918).

When given in large doses, the cerebral congestion which it produces causes buzzing in the ears, deafness, due to congestion of the middle ear, and headache, both of which can be treated by bromides, with or without a little ergot. It may also cause erythematous, erythemato-papular, vesicular, and urticarial eruptions.

Quinine Hæmoglobinuria. In persons who have suffered from malaria there is no doubt that quinine can cause hæmoglobinuria, but the way in which it acts is doubtful. Stephens believes that the hæmoglobinuria stands in no relationship to the dose of quinine, and, further, that a second dose may not produce the result, and that it is the blood condition of the malarial patient which is the determining factor. Our experience has tended to show that there is a direct relationship between the quinine and the hæmoglobinuria. Quinine acts in this way by causing hæmolysis of the red corpuscles. Stephens and Christophers found that 0·001 to 0·00082 gramme of quinine hæmolyzed 1 c.c. of a suspension of normal human red cells at 37° C. The hæmolytic action naturally increases the quantity of bile produced. For further remarks on this subject, see the next chapter, on Tropical Hæmoglobinurias (p. 1211).

Quinine Amblyopia.—Amblyopia may result as the effect of large doses of quinine, and appears to be due to constriction of the retinal arteries in temporary cases, and to degeneration of the retinal ganglion cells and their processes in permanent cases (see also p. 2007).

Quinine Fever.—In latent malaria a small dose of quinine may occasionally provoke a febrile paroxysm. This has been compared to the action of a small dose of salvarsan in provoking an exacerbation of symptoms in latent syphilis (Herxheimer's reaction).

Action on the Uterus.—Quinine appears to act upon the uterus, and may therefore produce an unpleasant effect in pregnancy, though whether this is really due to the quinine or to the malaria, or to the two combined, is doubtful.

EFFECT UPON MALARIAL PARASITES.—Quinine appears to particularly affect the merozoites, trophozoites and schizonts, and to act much less vigorously, if at all, upon the gametocytes.

It appears to act most vigorously upon the merozoites, perhaps because they are free in the plasma; next upon the young trophozoites, whose cytoplasm is broken up, and finally it and the nucleus destroyed, but it has much less effect upon the fully grown schizont, not preventing sporulation.

With regard to the gametocytes, it probably has a deleterious action upon the young forms, but certainly not upon the fully grown micro- and macrogametocytes. It is thought probable that it may act upon the very old form of microgametocyte, but this cannot take place, as a rule, with regard to the ordinary fully grown microgametocyte, for anophelines can be infected by the blood of persons containing the two kinds of gametocytes even when treated vigorously with quinine. On the macrogametocyte, particularly that of ***Laverania malariæ***, it appears to have no action. Hence, to get the full effect of quinine on the parasites it must be present in the blood at the time of sporulation, in order that it may kill the merozoites, young sporonts, and schizonts. In order to produce this effect, it is judged that the quinine must be present in the blood in a strength of at least *1* in 20,000. According to Thomson, though quinine has no direct destructive action upon the crescents, it reduces their numbers to less than one per cubic millimetre of blood if given daily in doses of 20 to 30 grains for three weeks; this action is believed to be due to cutting off the source of supply by killing the asexual forms. Methylene blue in doses of 12 grains daily is said by Thomson to reduce the number of crescents, probably by some direct destructive action. Quinine-resisting forms of the parasite have often been reported from South America, and have also been studied by Ross and Thomson, who have found a true parasitic relapse during thorough quinine treatment. In these cases the quinine dosage must be increased. We have administered 2 grammes by intramuscular injection and 1 gramme by the mouth after a few hours as a single dose in such a case with very beneficial results.

Immunity of the Parasite.—The immunity of the malarial parasite against quinine has as yet been but little studied, but this is a subject of the greatest importance at the present time, when quinine prophylaxis is being extensively employed. It has, however, been commonly noticed that the doses of quinine have often to be increased in order to cure an attack of fever in the individuals who have taken quinine more or less irregularly, and that persons who have taken quinine regularly when in an endemic area may have an attack of malarial fever after leaving this area and ceasing the drug.

Prophylactic Use.—This will be discussed in the section on Prophylaxis.

Other Drugs.—It is almost a work of supererogation to mention other drugs in the treatment of malaria, such as cuprein, mercury, atoxyl, and treatment by the serum of immune animals, and by violet light or in the dark. Methylene blue, however, has been used by several authors in the dose of 2 grains every four hours. In our experience its efficacy cannot be compared to that of quinine.

Surveyor has recommended the administration of 2 grains of picric acid twice or three times a day by the mouth as a method of destruction for the crescents of *L. malariæ*. The drug can also be administered by injections of sodium picrate. Nicolle and Conseil and more recently Falconer, Anderson, Micheli, Quarelli and others have tried salvarsan in malaria, with only moderate results. If used, it must be combined with quinine. Neosalvarsan has been found to be useless in subtertian fevers, but it and salvarsan may act upon *Plasmodium vivax* intravenously or intramuscularly. For dosage see p. 1313.

Tartar emetic has been used by Rogers, but the researches by Low and others have shown that when administered alone it has no effect upon the malaria parasites. Röntgen therapy is useless, though the spleen may get smaller.

PROPHYLAXIS.

The very great success which has followed every serious attempt at prophylaxis undertaken during the last few years has made it the urgent duty of each community to scientifically apply a well thought out scheme of a not too expensive nature to its district with the view of reducing the malaria endemic therein.

In order that a disease may be scientifically prevented, a thorough knowledge of its ætiology must be acquired and disseminated not merely among medical men, but also among the public. We know that malaria depends upon—

1. The presence of numerous human beings infected with male and female gametocytes.
2. The presence of numerous anophelines in which the gametocytes are capable of developing into sporozoites.
3. Free access of these anophelines to the infected human beings.

4. Air-temperatures suitable for the development of the malarial parasite in man and anophelines.
5. Free access of infected anophelines to non-immune human beings.

To summarize, there are three factors: (1) Man; (2) the anopheline; (3) the air-temperature.

In the tropics this third factor is in favour of malaria, and it cannot be altered; therefore methods of prophylaxis must be devoted to the human being and the anopheline.

Man.—The preliminary step with regard to man is to ask his intelligent assistance, and for this purpose education with regard to disease in general and malaria in particular is required. First of all it was necessary to bring the medical profession into touch with the discoveries made by Laveran, Manson, Ross, and Grassi, and this has been done. Secondly, it was and is necessary, by lantern lectures, illustrated pamphlets, etc., to convince the educated public of the tropics of the monetary loss caused to the Government, the planter, the merchant—*i.e.*, to the employer of labour—by malaria. Unless this can be done, the money necessary for the effective prophylaxis will not be forthcoming. No one will deny that malaria is the greatest cause of sickness in the tropics, though there may be places where its mortality is low and places where it is high, but that which people fail to recognize is the financial loss caused by this sickness.

Therefore we quote the well-known example of the Adriatic Railway Company, which, according to Ricchi, used to spend on account of malaria among 6,416 workmen living in malarious areas no less than 1,050,000 francs per annum.

But a serious attempt should be made to impress the uneducated masses of the tropics with some sort of knowledge about the disease. This can best be done by simple kindergarten-like instruction, with demonstration of actual living specimens of *anopheles* and their eggs, larvæ, and pupæ, together with the presence of a young child with a huge spleen and of a person suffering from malarial cachexia, and then, at the close of the lecture, to distribute illustrative pamphlets in the vernacular, written in simple language, reviewing the subject of the lecture, together with, if possible, the demonstration of the larvæ in a neighbouring stream or pool.

This attempt to instruct the poorer classes of the tropics may not be productive of much immediate good, but it may bring home to them that malaria is a potent factor in causing illness and death among their infants and young children, and that it is caused by the bite of a particular kind of insect, and can be to a great extent prevented by proper treatment with quinine.

Another method employed is to give the teachers of the elementary vernacular schools a course of instruction in elementary hygiene, including, of course, malaria, so that they may be able to give their pupils elementary instruction in these matters.

In such instruction no pamphlet or book should be used, otherwise there is a danger of the knowledge being acquired by rote. The only way, however, to bring about any result by this method is to award a special grant to the school, based upon the knowledge of the scholars.

All these methods have actually been and are being carried out, but in any case they are only preliminaries, and any good which may result therefrom will not be immediate.

Another preliminary matter is to use the knowledge acquired concerning the life-history of the anophelines, and not to build houses, coolie-lines, etc., in ravines and valleys, or on the margin of water likely to be a breeding-ground for these insects. Place the buildings on high ground, and, bearing in mind the fact that native children harbour gametocytes, build the houses for Europeans away from the native town or village.

Quinine. Leaving now these preliminaries, we come to the actual question of prophylaxis by reducing the malaria in man by quinine administration, as recommended by Koch, Celli, Plehn, Lustig, Negri, and others.

Koch's method consists in taking a large dose (15 grains) of quinine on two consecutive days every eight or ten days for three months, while Celli's method consists in taking about 6 grains (0·40 gramme) of quinine daily; Plehn's, in taking 8 grains of quinine every fourth day. Our own method is to give 5 grains daily, and, in addition, a double dose (10 grains) once a week; and in order to enable the patient to remember the routine, we advise him to take the double dose on a Sunday. For children 1 grain of quinine may be given for every three years of age, or euquinine may be used with advantage in doses of 2 to 5 grains daily. It is not very bitter, and may be given with a little sweetened condensed milk, as advised by Watson, or chocolates of tannate of quinine (2 to 5 grains), as advised by Celli, may be administered.

In very malarious zones such as certain tropical countries and the Balkans, the doses mentioned are not sufficient and should be increased.

All these methods, if properly carried out, give fairly good results, but it must be remembered that unpleasant symptoms may arise after a long use of quinine, of which the most frequent in our experience is a tremor of the hands; but various other nervous symptoms may appear—*e.g.*, irritability.

The advantages of quinine prophylaxis are, however, in excess of its disadvantages, and we strongly recommend its use. In Italy special laws have been passed, due to the efforts of Celli, which render quinine prophylaxis practicable among the poorer classes. The quinine is manufactured by the State and distributed gratis to the poor, while employers of labour are compelled to supply it to their work-people. Governments, municipalities, etc., can also help in this way by giving free quinine to the populace.

The systematic free distribution of quinine powders, tinted if necessary, and enclosed in papers, with a vernacular label informing the recipient that there is no charge, is also useful among the native population, as is the distribution of quinine to children in the schools by the teachers. The distribution must be carried out by itinerary dispensers, for the native will not travel far to obtain quinine. It is, however, necessary to see that the quinine is actually taken, and the use of Tanret's reagent will be found useful in detecting individuals who do not take quinine. Tanret's reagent is prepared by dissolving 1·35 grammes of mercuric perchloride in 75 c.c. of water, and 5 grammes of potassium iodide in 20 c.c. of water in a 100 c.c. measuring flask. The mercuric solution is poured into the iodide solution under agitation and water added to the mark. A few drops of this reagent are added to about 5 c.c. of urine. If no distinct turbidity appears, it means, as a rule, that quinine has not been taken. Turbidity indicates presence of quinine in the urine, but may indicate also presence of various other substances.

By this method Koch freed Stephansort, in New Guinea, from malaria, but there is a doubt as to whether the disease will not recur if this method alone is used. It must be remembered that free quinine distribution on a large scale is very costly.

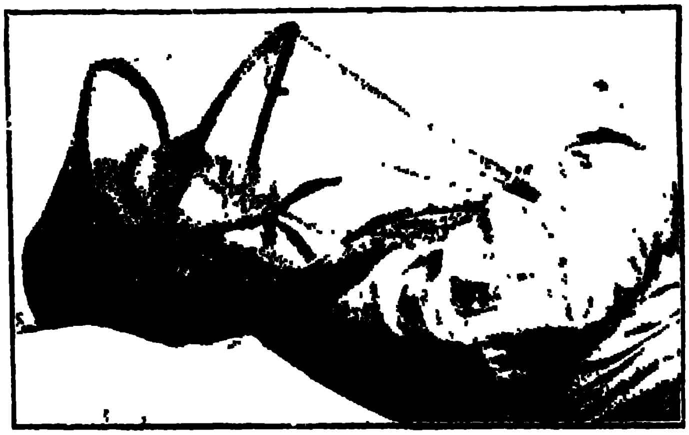

FIG. 627.—THE SIMPSONETTE DESIGNED TO PROTECT THE WEARER FROM MOSQUITO BITES. (From a photograph given us by Mrs. Mary Simpson.)

Bite Prevention. — The next method is to prevent man from being bitten by anophelines. This may be effected by the constant and intelligent use of the mosquito-curtain; by rendering the dwelling, or certain portions of it, gnat-proof; or by the application of chemicals which will keep the mosquitoes away. It is also advised not to go out after sunset, and to protect the whole body against bites.

Firstly, with regard to the mosquito-curtain, the mesh must be suitable—*i.e.*, twenty to twenty-four meshes to the square inch. The lower part of the net should be tightly tucked in under the mattress: on no consideration whatever must it be allowed to hang loosely or to fall on to the ground. It should be in position in the early afternoon, and must be in good repair, for if it is torn it is worse than useless, becoming a mosquito-trap. It must be kept clean, especially at the top, which is apt to accumulate all sorts of queer things from the roof. Never travel into a malarious region without your own net, as the condition of those in rest-houses may be far from good. The *Simpsonette* anti-mosquito and fly protective, non-inflammable headgear, designed by Mrs. Mary Simpson is most useful, as it can be worn under or over the helmet or hat as well as when lying down or sleeping.

Secondly, with regard to gnat-proof rooms or houses, these can be easily constructed at but slight cost by using wire-netting of twenty to twenty-four meshes to the inch, preferably the latter. Rooms and verandas enclosed in this way are a great convenience, preventing molestation from mosquitoes and other insects.

The Irrigation Department of Ceylon possesses movable mosquito-proof rooms, which its engineers can take with them as their work requires. These are constructed of a wooden framework, supporting the gauze, and have a double door. They are only 12 feet by 12 feet by 8 feet, and can therefore be erected inside the room of a native house if desired, or on a veranda. The cost is small.

Hospital wards ought certainly to be rendered gnat-proof in malarious districts, as persons are often found in the wards with their blood teeming with gametocytes. Hence, if there are any suitable anophelines in the hospital, the chance of future patients suffering from other diseases becoming infected is considerable.

With regard to coolies, the third method has been tried to a certain extent with success—viz., that of rubbing all over the body an oil composed of 1½ parts of citronella oil, 1 part of kerosene, and 2 parts of cocoanut oil, to which 1 per cent. of carbolic acid is added. Coolies seem to like this mixture, which is called the 'bamber-green oil.' Menthol, cinnamon oil, eucalyptol, camphor ointments or powders, may be used.

Electric fans and punkahs are secondary methods of preventing anophelines from biting human beings.

Sulphur.—According to some authorities, mosquitoes and flies will not bite persons who take small doses of sulphur regularly, but this is not so in our experience.

The healthy may also be segregated as far from sources of infection as possible. This may be temporary or permanent, according to local conditions.

The Anophelines.—It has already been indicated that it is not necessary to exterminate the anophelines in order to prevent malaria, but that all that is needful is to reduce their numbers. The objection has been raised to anopheline destruction that as fast as they are destroyed in a given area others will immigrate into that place from surrounding areas.

Ross has rather aptly answered that objection by pointing out that if the human birth-rate in a place was suppressed without attracting special immigration, the population would soon decrease, and Professor Pearson, on conjectural bases, has shown that if mosquito propagation is suppressed within the circular area of a mile, the mosquito density at the centre will be 3 per cent., a quarter of a mile from the centre 18 per cent., and at the periphery 75 per cent.

of the density surrounding that area. A square one mile wide will have a central density of 2 per cent., at a quarter of a mile from the boundary 11 per cent., and at the boundary 50 per cent. of the surrounding density. No experiments have, however, been carried out to determine whether these assumptions are correct.

There is, however, no doubt that anopheline reduction leads to the reduction of malaria. The work done under Ross's direction at Ismailia proves this, for the cases of malaria were reduced from 1,551 in 1902 to 37 in 1905, and these latter were all relapses.. The cost of this is given as 50,000 francs for drainage and filling up of pools, with a yearly expenditure of 18,300 francs, which worked out at 2·3 francs per head of population.

Travers and Watson at Klang and Port Swettenham, in the Malay States, by similar methods reduced the cases of malaria admitted into the hospitals from 610 in 1901 to 23 in 1905, while the cases from the surrounding district in which no antimalarial methods were employed were 197 in 1901 and 353 in 1905. The children found infected in the two towns in 1905 amounted to 0·5 per cent. of those examined, while in the surrounding district they were more than 23 per cent. The financial saving is also shown by the fact that Government employés in 1901 obtained 236 sick certificates, amounting to 1,026 days' leave, and in 1905 only 4, amounting to 30 days' leave. The cost to the end of 1905 was £10,100, with a yearly expenditure of £410. The cost up to the end of 1905 worked out at £1 4s. per head of the population.

Similar work has been done in Hong Kong by Dr. Thompson.

In Panama, under American rule, the measures taken are very elaborate and systematic, because the sanitarian is given a free hand, and economy is not considered where health is in question, with the result that malaria and yellow fever have disappeared. There can therefore be no doubt that the destruction of anophelines will lead to the diminution of malaria.

The Insect.—The measures which are used may be classified into those directed against the insect and those against the larvæ. With regard to the insects, fumigation with some substance such as sulphur (2 pounds to be burnt for every 1,000 cubic feet of space) or pyrethrum will stupefy them and cause them to fall to the ground, when they can be swept up and burnt. This is useful in dealing with individual houses prior to residing therein. The insects may also be destroyed in houses by the use of the hand-net as advocated by Ross and Gorgas, while the use of a hand-fan is also recommended. Mosquito traps have also been used and Giemsa's pyrethrum sprays.

Spraying is specially useful for outhouses, stables, etc., and in addition to the pyrethrum spray weak formalin may be used.

The Larva.—It is, however, against the larvæ that measures are most easily taken, and these include:—

A. *Engineering works intended to eliminate breeding places:*—

1. Draining swamps.
2. Draining roads.
3. Filling in hollows.
4. Training streams.
5. Making continuous drains along ravines, etc.
6. Planting trees at intervals, not close together (this is both ornamental and useful), or the thinning down of dense plantations until the trees are at intervals, and the removal of trees with rot-holes, which, however, may be filled.
7. Segregation either of the whole community, by altering the residences from some very infected area or partial segregation of a chosen portion of the community from the worse infected portion. Simpson recommends that at least a zone of 300 yards in width, preferably 400 yards, should separate the residential European quarters from the Native town. Since segregation has been introduced in West Africa, a considerable improvement in the health of the European community has taken place.
8. Efficient drainage to keep down subsoil water-level.

B. *Sanitary works:*

1. *Removal* of small collections of water. Regular inspection of compounds and careful collection and disposal of household utensils likely to harbour mosquito larvæ. Repair of house gutters.
2. *Oiling* collections of water with kerosene (crude petroleum) by means of sprays every ten days, 1 gallon being allowed for 1,000 square yards.
3. *Larvicides.*—Measure the length and breadth of the area of water and add 1 in 20,000 to 1 in 50,000 sanitas okol or 1 in 40,000 izo-izal, or the Panama disinfectant.

Wise and Minnett have recommended that 1 ounce of crude carbolic acid be added to every 16 cubic feet of water, thus giving a dilution of 1 in 16,000, which they maintain will kill the larvæ without injuring any animal which might happen to drink the water.

4. *Screening* wells, cisterns, cesspits, etc., with wire gauze.
5. *Removal* of plants likely to contain water and act as breeding-places (the following may be specially noted bamboos, pineapple plants, travellers' palms, fibre plants). Water-weeds in streams should also be removed, as the larvæ are often found to be protected by these against their natural enemies. Water-weeds should be removed before oiling. Brush and grass should be cut.
6. *Introduction of fish*, especially 'millions,' into collections of water.

It is always easy to find some local fish which will eat larvæ readily. Thus, in Bengal the larvæ-eating fish are: *Haplochilus panchax, H. melastigma, Ambassis nama, A. ranga, Anabas scandens, Barbus ticto,* and several species of *Trichogaster.* Tadpoles and water-boatmen also eat mosquito larvæ.

7. *Growth of weed* in water, especially *Lemna,* the duckweed.
8. *Attention* to the non-stagnation of water in gutters.

Summary.—Every district must be considered separately, and a systematic malarial survey having been made, those methods should be applied which seem most adapted for success. A combination of methods must be better than any one individual method. In any case, a definite scheme should be devised, and thoroughly and continuously carried out. But a word of caution is necessary. Having made the survey and estimated the cost, firstly, leave a good margin for contingencies, and, secondly, insist upon an adequate supply of money being provided: but it is not necessary to embark upon an expensive scheme, as a great improvement can be effected with but little expenditure. It is, however, important to make a beginning, and to attempt to gain the confidence of the public, as to-day there is no difficulty with the authorities, who are usually very willing to help.

The methods mentioned above may be summarized as follows:—

Reduction of Bites.—Mosquito-net, screening the house, use of fans, use of hand-net, use of protective oils.

Mosquito Reduction.—Insects may be killed by hand-net, by culicides, by natural enemies, or inconvenienced by diminution of dense vegetation.

Larvæ may be attacked by removing, oiling, or screening collections of water, natural or in plants, by introducing fish or beetles into water, or by the engineering works mentioned above.

The smaller methods are usually carried out by gangs of workmen—mosquito brigades—under trained supervisors.

Case Reduction.—By quinine prophylaxis and by segregation.

Relative Values.—The relative merits of protection against mosquitoes and quinine prophylaxis have been investigated by Celli, whose results are embodied in the following table:—

Relative Values of Quinine Prophylaxis and Antimosquito Protection.

Method of Prophylaxis.	*None.*	*Quinine Prophylaxis alone.*	*Anti-mosquito Protection alone.*	*Quinine Prophylaxis plus Antimosquito Protection.*
Percentage of infections ..	33%	20%	2·5%	1·75%

Results.—In British Guiana the cases treated in hospitals have been reduced from 33,748 in 1906-07 to 7,384 in 1912-13. In the

Panama Canal Zone the death-rate from malaria in 1881 was 20·5 per 1,000; in 1911 0·96 per 1,000. The malaria cases in 1906 were 821 per 1,000, and in 1911 184 per 1,000. In Ismailia in 1900 there were 2,284 cases; in 1906-08 not a case. In Kuala Lumpur the death-rate was 9·7 per 1,000 in 1907, and 3·9 per 1,000 in 1914. These figures speak for themselves.

CHAPTER XLI

THE TROPICAL HÆMOGLOBINURIAS

General remarks—Malarial hæmoglobinuria—Quinine hæmoglobinuria—Blackwater fever—References.

GENERAL REMARKS.

HÆMOGLOBINURIA or the presence of more or less altered hæmoglobin in the urine, is found in a number of conditions which may be approximately classified into:

1. **The Symptomatic Hæmoglobinurias,** which occasionally occur in the course of such diseases as malaria, Raynaud's disease, the acute specific fevers, and after severe burns.

2. **The Toxic Hæmoglobinurias,** which are brought about by the action of a number of drugs, as, for example, quinine and its salts, chlorate of potash, antipyrin, carbolic acid, and naphthol, and by certain vegetables used as food, as, for example, certain beans (Favism, *vide* p. 201).

3. **The Specific Hæmoglobinurias,** which are specific diseases, such as blackwater fever and paroxysmal hæmoglobinuria.

In the tropics we are concerned with one entity in each of these groups—viz.:—

1. Malarial hæmoglobinuria.
2. Quinine hæmoglobinuria.
3. Specific blackwater fever.

1. MALARIAL HÆMOGLOBINURIA.

Definition.—Malarial hæmoglobinuria is simply a hæmoglobinuria caused by *Laverania malariæ* Grassi and Feletti, 1890.

History.—This form of hæmoglobinuria has been much confused with quinine hæmoglobinuria and with blackwater fever. It is simply a hæmoglobinuria occurring in the course of atypical subtertian malaria, and caused by the malarial parasites. Stephens has seen it associated with quartan parasites.

Ætiology.—The ætiological factor is *L. malariæ* Grassi and Feletti 1890, together with some other factor, which inhibits the production of antihæmolysins.

Climatology.—The distribution is coextensive with the distribution of the more severe forms of malaria, and is therefore most evident in the tropics and subtropics.

Pathology.—As has been shown by de Blasi, Brem, and Zeiler, the malarial parasites give rise to a hæmolysin which probably varies in quantity and quality with different strains of parasites, but is kept in check by the action of antihæmolysin, which is formed in the body, but which under certain circumstances—*e.g.*, exposure to the weather, etc.—may fail to be produced in sufficient quantities, and hæmoglobinæmia with hæmoglobinuria may occur. Brem found that three parts of a hæmolysin extract from a case of pernicious malaria completely destroyed (hæmolyzed) one part of a 5 per cent. suspension of erythrocytes in twenty minutes. This hæmolysin is thermolabile. Zeiler and Brem have also demonstrated the presence of antihæmolysin in the serum of normal individuals as well as in that of persons suffering from pernicious malaria. It would therefore appear as though the presence or absence of hæmoglobin in an attack of pernicious malaria depends upon the relationship between the quantity of hæmolysin produced, and the amount of antihæmolysin also produced.

Bijon considers that the resistance of the red corpuscles to lysin is diminished, and Gasbarrini believes that the lysin lies inside the red cells.

Symptomatology.—The symptoms are those of an attack of pernicious malaria, in which the main feature is the presence of hæmoglobinuria, the other symptoms being high fever, shivering, vomiting, great prostration, and rapid anæmia.

Diagnosis.—The diagnosis is to be made by first demonstrating the presence of *L. malariæ* in the blood, and then by the rarity of severe jaundice.

Treatment.—This is the same as for other forms of atypical subtertian malaria (p. 1188)—viz., quinine in large doses, before which calcium lactate in 5 to 10 grain doses may be given with advantage.

Prophylaxis.—The prophylaxis is the same as for malaria. This has been exemplified in Robertville, an Algerian village which was highly malarious and where the malarial fevers were associated with pyrexial hæmoglobinuria. After 1910, when preventive measures were instituted, according to Ciavaldini, the malaria decreased and the hæmoglobinuria disappeared.

2. QUININE HÆMOGLOBINURIA.

Definition.—An acute non-contagious fever caused by the administration of any of the ordinary salts of quinine in certain cases of malarial cachexia and chronic malaria, and characterized by hæmoglobinæmia and hæmoglobinuria.

Remarks.—Sir Patrick Manson has pointed out that an attack of hæmoglobinuria can be produced in certain cases by the ingestion of a single small dose of quinine. Ross and Low have reported such a case, under the care of Sir Patrick Manson, where the administration of a 9-grain dose of quinine was followed by hæmoglobinuria in a few hours. Ketchen has recorded a case of seven consecutive hæmoglobinurias in the same individual in whom each attack was the sequel to a dose of quinine. We have met with similar cases, but our maximum is six attacks in one year.

History.—Veratas in Greece, in 1858, was the first to draw attention to this form of fever, and to definitely ascribe the hæmoglobinuria to quinine, and he was followed and supported by Tomaselli, Grocco, and many other Italian and Grecian observers. Later Plehn, Koch, and others, have strongly advocated this theory, but these last observers have applied this one hypothesis for the explanation of all the conditions included under the term 'blackwater fever.'

Climatology.—The attack can take place anywhere for the first time, provided that the individual is suffering from chronic malaria, etc., and the unknown factor or factors to be mentioned below, and has taken the requisite dose of quinine.

Ætiology.—The causation of this condition is the administration of quinine in cases of malarial cachexia and chronic malaria, but this is not the entire ætiology, otherwise the condition would be more commonly met with than at present, and also it is quite safe to administer quinine to the majority of cases of chronic malaria and malarial cachexia without causing hæmoglobinuria. Moreover, the administration of a dose of a salt of calcium prior to the quinine will prevent the hæmoglobinuria, which in the same individual has occurred after such administration.

From one observation which we have made we would throw out the suggestion that one of the other factors in quinine hæmoglobinuria may be the condition of the kidney, and that the site of the hæmolysis may be in that organ.

Pathology.—The pathology of quinine hæmoglobinuria is but little understood, but it has been very ably studied by Barratt and Yorke, who demonstrated the action of quinine in alkaloidal form, and as the bihydrochloride as well as hydrochloric acid and sodium hydrate upon healthy red blood cells, and found that:—

1. All the above-mentioned agents produced hæmolysis.
2. In equimolecular concentration the hæmolytic power is nearly the same.
3. The hæmolysis produced by quinine (alkaloid) resembled a catalytic action, and took place at a monomolecular rate.
4. During life it is not possible to reach a percentage of quinine in the blood sufficient to cause hæmolysis, owing to the toxicity of the drug.

With regard to the action of the quinine, some observers believe that it produces the hæmolysis by lowering the osmotic pressure of the blood plasma.

Morbid Anatomy.—We are not acquainted with any direct observations on this subject, but the appearance of the kidney in people who have died from pernicious malarial fever in which large doses of quinine have been administered without success resembles both macroscopically and to some extent microscopically the kidney seen in blackwater fever.

Symptomatology.—The general symptoms resemble those of an attack of blackwater fever, but are not so severe, and the jaundice is slight or absent.

Diagnosis.—The history of the attack following the administration of quinine in persons suffering from malaria cachexia or chronic malaria may give a clue.

It is suggested that the rate of hæmolysis of the erythrocytes, when treated with quinine, may be compared with that for normal erythrocytes similarly treated. The method adopted to test hæmolysis is to allow 1 c.c. of blood from the pricked finger to fall drop by drop into a 1 per cent. solution of potassium oxalate, which also contains 0·5 per cent. of sodium chloride, until a proportion of four parts of blood to one part of the oxalate is reached. Then the mixture is added to 10 c.c. of a 0·9 per cent. solution of sodium chloride, and centrifugalized until the red cells are completely precipitated, when the supernatant fluid is pipetted off, and then sufficient 0·9 per cent. solution of sodium chloride is added to make a 2·5 per cent. emulsion of red cells. This emulsion is then placed in a series of test-tubes containing various strengths of an isotonic solution of quinine made up with 0·9 per cent. sodium chloride when necessary. The tubes are incubated for three hours at 37° C., and stirred with a glass rod every fifteen minutes, and the result noted at the end of the time.

Prognosis.—This is usually good.

Treatment.—Quinine administration should be stopped, and calcium lactate administered, and the ordinary treatment for blackwater fever as indicated below should be carried out.

Prophylaxis.—Europeans about to visit or reside in the tropics should be given a test dose of 10 or 15 grains of quinine by the mouth, in order to exclude idiosyncrasy. In cases of chronic malaria or malarial cachexia, in which this condition may appear, calcium lactate in 10 grain doses should be given before each dose of quinine.

3. SPECIFIC BLACKWATER FEVER.

Synonyms.—Malarial Hæmoglobinuric fever, Bilious Hæmoglobinuric fever, Bilious Remittent fever, Malignant Bilious fever, Hæmorrhagic Malarial fever, Melanuric fever. *French*: Fièvre Bilieuse Hématurique, Fièvre Bilieuse Hémoglobinurique, Fièvre Bilieuse Grave, Fièvre Bilieuse Mélanurique, Fièvre Jaune des Créoles ou des Acclimatés. *Italian:* Febbre emoglobinurica. *German* : Gallenfieber, Schwarzwasserfieber.

Definition.—Blackwater fever *sensu stricto* is an acute specific fever of unknown causation, characterized by the severity of the symptoms, great blood destruction, jaundice, and hæmoglobinuria.

History.—The knowledge of this fever is recent, for it does not appear to have been noted by Torti, the celebrated writer on pernicious fevers, nor by his predecessors, and the first information of its existence appears to have been given by the French naval surgeons Lebeau, Daullé, and Le Roy de Méricourt in 1850-53, who drew attention to the disease in Madagascar and Nossi-Bé, after which it is mentioned as occurring in Senegal, Cayenne, and the Antilles. In 1858 Veratas described its occurrence in Greece, and in 1859 Cummings met with it in America.

The clinical signs were carefully described by Dutroulau in 1858; by Corre in 1861, who showed that the colour of the urine was due to hæmoglobin, and not to bile or blood, as had been thought; by Barthélemy and Benoît in 1865; Bérenger-Féraud in 1874 (in which year Tomaselli first described it in Italy); Pellarin in 1876; and O'Neill in 1882. Kelsch and Kiener in 1889 gave an excellent description, together with a history of the disease up to that date. In 1890 Schilling met with it in Kaiser Wilhelm's Land, and Grocco and Cardarelli in Italy, after which a series of papers by Mahly, Easmon, Eyles, and Papafio appeared on the disease as seen on the Gold Coast, where it is called 'attridi assara,' which means 'bilious fever.' The name 'blackwater fever,' now universally adopted, was, as far as we know, first used by Easmon.

Researches have been made as to its nature and treatment by Koch, Plehn, Crosse, Prout, Stephens, Christophers, Bentley, Barratt, Yorke, Cardamatis, Leishman, Low and Wenyon, Balfour, and others.

With regard to the parasitic *ætiology* Mache notes that in these cases the cytoplasm of the malarial parasites is apt to stain badly, and therefore, as they are difficult to see, they may often be missed.

Laloir thinks that the peculiar organism which he has described as a malarial parasite in the red corpuscles and nuclei of the mononuclears and in the salivary glands of *Anopheles listoni* var. *albo-apicalis* may be a causal agent.

With regard to *chemical ætiology*, Lahille has shown that there is no deficiency of salts in the blood, and Burkitt has drawn attention to the high acidity of the urine and the diminished alkalinity of the blood

As regards *records* Stephens has drawn up a valuable routine form, which, modified in some particulars, has been utilized in the Sudan for some time.

In regard to *clinical features*, under the term *Icteroidela paludica* Salvin has described a sort of bilious remittent fever as a prehæmoglobinuric fever in Venezuela, and Plehn has classified blackwater into: -

1. *Simple Attack.*- Temperature falls to normal on the second to third day, and even albumen has disappeared from the urine by the third, fourth or fifth day. The only danger is anuria on the third day.
2. *Intermittent Attacks.*—The hæmoglobinuria is intermittent, with very slight icterus, progressive anæmia, and death on fourth to fifth day. Anuria is rare.
3. *Fulminating Type.*—Very slight icterus, anuria, coma; death in twenty-four hours.
4. *Hæmorrhagic Type.*—This appears to us to be the hæmorrhagic type of atypical subtertian fever.
5. *Abortive Ambulant Type.*— This appears to us to be our quinine hæmoglobinuria, as it commences after a small prophylactic dose of quinine.

It seems to us that until tropical practitioners accustom themselves to differentiate from specific blackwater fever the hæmoglobinurias due to quinine and to malaria no real progress will be made with the knowledge of this serious illness.

Climatology.—The disease occurs most commonly in tropical Africa and in certain localities in India, but it has also been reported from many parts of the tropics.

In Europe it is found in South Italy, Sicily, Sardinia, Macedonia, Greece, and Southern Russia. In Africa it occurs in Algeria, and through the whole of the tropical area of West, Central, and East Africa. In Asia it is well known in India, especially in the Duars, the Terai, Assam, the Jeypore district of Madras, and the Canara district of Bombay. It is also found in China, Cochin China, and Farther India. In America cases have been recorded in the southern regions of the United States, in Central and South America—especially Brazil—and the West Indies. It occurs in the Anglo-Egyptian Sudan, but there are many other parts of the tropics from which it has not been reported. Too much trust must not be placed upon this distribution, as confusion exists between the mild attacks of quinine hæmoglobinuria, as well as the atypical subtertian malarial form. True blackwater fever can exist in epidemic form, and is a very fatal infection.

Ætiology.—The causation of blackwater fever has been much complicated by the confusion arising from the non-recognition of quinine and malarial hæmoglobinurias, but when these conditions are admitted there is still the serious disease, 'blackwater fever,' to be explained, and its causation appears to us to be some protozoal parasite as yet unknown.

The various theories which have been advanced to explain the ætiology of blackwater fever are:—

1. The malarial fever.
2. The theory of malaria, together with some other factor.
3. Malarial anaphylaxis theory.
4. An unknown agent theory.
5. Bite of an unknown arthropod.

1. *The Malarial Theory.*—All the old writers on the ætiology of blackwater fever attributed its cause to malaria, in much the same way as they classed most tropical fevers under the same term.

When these fevers came to be differentiated, blackwater fever was assigned to the action of *Laverania malariæ*; but of late years cases have occurred in which this parasite has not been found, but only *Plasmodium malariæ* or *P. vivax*, because these parasites are very commonly met with in the tropics.

The older writers maintained that blackwater fever existed wherever there was severe malaria, and that it was not found where this was absent, and they instanced Southern Italy, where malaria causes a mortality of 7 to 10 per 1,000, as a region where blackwater fever is common, and compared it with North Italy, where the malarial mortality is only 1 per 1,000, and where blackwater fever is rare. Further, it was pointed out that the people attacked with blackwater fever had always previously suffered from malarial fever, and had generally had several attacks. This view may be said to have been supported by Stephens, who states that the blood of persons examined during the day preceding the hæmoglobinuria contained parasites in 95·6 per cent. of cases, while during the day of the attack these parasites were found in only 61·9 per cent., and during the day after the attack in only 17·1 per cent. Stephens and Christophers point out that, though they only found malarial parasites in 12·5 per cent. of all their cases, still they found evidence of malarial infection, as exemplified by the presence of pigment in the leucocytes or by an increase in the percentage of the large mononuclear cells, in no less than

93·8 per cent. Further, the presence of a hæmolysin in malaria has been demonstrated by de Blasi and others.

The reply to these points is that the geographical distribution of blackwater fever is only known in a very general way, and even this superficial knowledge is against the theory that it is due to malaria. Incidentally, we may mention that no one has attempted, as far as we know, to make a spot-map of a district where there is much blackwater fever, showing as far as possible where the disease was really contracted, and to compare this with a similar map made for the cases of malaria in that district. Nor, as far as we know, has anyone attempted to show whether the epidemiological phenomena of blackwater fever coincide with those of malaria. The West Coast of Africa would appear to be a suitable place for these inquiries.

The malarial theory is disposed of, in our opinion, in that it has many times been recorded as occurring in persons who have never suffered from malaria; indeed, according to Craig, it has occurred in people who have not only never been known to suffer from malaria, but in whom neither before, during, nor after an attack have the parasites been found, and, finally, in whom a post-mortem examination failed to reveal any evidence of malaria. Our opinion is more or less confirmed by the fact that an attack of blackwater fever is uninfluenced by quinine. However, at the present time, there are few advocates of the theory that it is simply a malarial infection. Here, perhaps, may be mentioned the fact that Donovan considers that it is malaria, but due to a species of *Laverania* as yet unrecognized. Lalor's parasite requires confirmation, and is in our opinion of doubtful value.

2. *Malaria, together with Some Other Factor.*—As malaria by itself has proved rather weak ætiologically, some other factor has been brought in to support it. Thus Corre suggested chills, Bérenger-Féraud mercury, and others acute and chronic alcoholism, syphilis, severe muscular exertion, mental excitement, and change of climate; but of all theories, that connecting malaria with quinine has been the most popular.

Malaria and Quinine.—Stephens has supported the theory that the disease is partly of malarial origin, aided by a second factor—viz., quinine. In his article in Osler's 'System of Medicine,' Stephens sums up his view: 'Blackwater is not a disease *per se*, but rather a condition of blood in which quinine, other drugs, cold, or even exertion, may produce a sudden destruction of red cells. The condition is produced only by malaria, and generally by repeated slight attacks, insufficiently combated by quinine. In such cases of chronic malaria—*i.e.*, in those suffering from anæmia, with repeated attacks of fever and repeated doses of quinine blackwater fever sooner or later almost certainly supervenes—at least, in tropical climates.'

These statements are too sweeping if genuine blackwater fever is meant, otherwise the home of the disease would be Ceylon, whereas it is so rare that we have never heard of a genuine non-imported case; for in this island there are Europeans and natives with just the conditions required by Stephens, and yet they do not develop blackwater fever, because the only two cases which we have met with or heard of in Ceylon in twelve years were most probably cases of quinine hæmoglobinuria. On the other hand, Stephens's remarks are correct if applied to quinine hæmoglobinuria.

Stephens accounts for the difference between India and Africa as regards the prevalence of blackwater fever by the common malarial parasite being the tertian in India and the subtertian in Africa. Certainly the tertian is very common in Ceylon, though the subtertian is also frequently found. Another point which is difficult to explain is the frequency of the disease in Assam, and the less frequent occurrence in other parts of India where malaria is common.

According to McCay, who has carefully investigated the action of quinine in causing hæmoglobinuria, sulphuric acid and the sulphates cause a decrease in the total inorganic salts of the plasma, which he thinks implies a decrease in its osmotic tension. Water, therefore, passes into the red cells, causing them to swell up, and, if the decrease in osmotic tension of the plasma is sufficient, to burst.

He considers that the causation of blackwater fever is threefold:—

(1) Injury to the stroma of the red cell by the malarial parasite. (2) The action of the malarial hæmolysin. (3) The administration of sulphates.

He thinks that, though the first and second causes may bring about the disease, still quinine sulphate or any other sulphate, by its action on the plasma, is the exciting cause if the former are ineffectual. On the other hand, he finds that chlorides cause an increase of the resisting power of the erythrocytes to hæmolysis. Quinine hydrochloride, especially when combined with sodium chloride and dilute hydrochloric acid, causes usually a marked rise in the resistance. Therefore, according to him, it is not the quinine, but the sulphuric acid in the form of quinine sulphate, which produces the hæmolytic action. In addition to sulphates, McCay found that alkaline carbonates, compounds of alkalis with vegetal acids and potassium salts, diminished the inorganic molecules of the plasma, thus tending to help hæmolysis. We have, however, seen hæmoglobinuria following the administration of euquinine, the hydrochloride, and even the tannate of quinine. We have already referred to Barratt and Yorke's experiments on this subject (see p. 1215).

Malaria, Quinine, or Depressing Influence.—Deeks and James maintain, from the study of 230 cases of blackwater fever in Panama, that it is a manifestation of malarial toxicity usually induced by repeated attacks, but also appearing coincidentally with an acute attack, and may be determined by any depressing influence or quinine.

This is really a malarial toxicity and other factor theory. In order to produce the requisite conditions, they maintain that there must be a population non-immune to malaria, of which infection there must be a large portion due to *L. malariæ*, and malaria must be in such quantity as to produce an almost continuous infection, and this must be associated with a neglect of a thorough administration of quinine, especially in primary attacks.

Against the view that it is caused by malaria treated with insufficient dosage of quinine, followed by a large dose of quinine, we may quote the fact that we are personally acquainted with a case of malaria associated with depressing influences in which the infection was *L. malariæ*, which had remained latent for a considerable period, and which for some weeks was treated by quite inadequate doses taken by the mouth, and after severe fever varying from 104° to 105·8° F., and lasting for two days, 1 gramme of the bihydrochloride of quinine was administered by the mouth, and 2 grammes given at the same time by intramuscular injection, with the result of a quick and lasting cure of the malaria without any signs of blackwater fever. This case appears to us to answer every point required by the supporters of the malaria quinine theory of blackwater fever, and it may further be stated that the original infection with *L. malariæ* was in West Africa in one of the endemic regions of blackwater fever.

Matko gives great importance to a disturbance in the phosphate metabolism as an ætiological factor According to his researches the secondary and tertiary phosphates, whether of sodium or potassium, protect against quinine hæmolysis, while the primary salts do not.

3. ***Anaphylaxis.***—In 1909 Cleland advanced the theory that the disease might be an expression of anaphylaxis to the malarial parasite brought about by the presence in the serum of a foreign protein in the shape of disintegrated merozoites. But this is open to serious objections, though recently supported by Cardamatis, who considers that quinine might be able, when converted into the albuminate, in certain unknown conditions to act as an antigen, which, when combined with the malarial toxin, might produce antibodies, which might provoke a sensitiveness to quinine in the person suffering from malaria, when a further dose of the drug would produce anaphylaxis, perhaps because it combines with the antibodies, or perhaps by its transformation into a hypertoxic substance.

4. *Unknown Agent.*—Sir Patrick Manson, in 1893, first promulgated the theory that blackwater fever was a disease distinct from malaria, and supported this by the peculiar distribution of the disease, which is widespread in tropical Africa, and very local in India.

Sambon, in 1898, having in mind the hæmoglobinuric fevers of animals, brought forward the theory that human blackwater fever would probably be found to be a piroplasmosis, and has informed us that on one occasion Sir Patrick Manson and he saw one body in a red blood-corpuscle of a case of blackwater fever which very closely resembled the bacillary form of Theileria, but it is possible that this was merely a peculiar form of *Laverania malariæ*.

The parasites which have been described are becoming numerous. There is a bacillus by Yersin in the renal epithelium, which has since been shown to be a strain of *Bacillus coli communis;* while the other parasites suggested as possible ætiological factors are a blood parasite by F. Plehn, which he now identifies with the subtertian malarial parasite; and a double-contoured parasite in the red corpuscles by Fisch, which has not been confirmed. A body resembling a *Piroplasma* has been described by Forau, but has been criticized by Stephens, as resembling the fragmentation and flagellation of erythrocytes commonly seen in malarial anæmia in the tropics. Leishman has described cell inclusions varying from 1 to 5 μ in diameter, and usually found in large mononuclear cells of endothelial origin. These inclusions are either structureless, homogeneous, circular forms, or ring forms. They are embedded in the cytoplasm of the cell, and usually assume a chromatin colour with Romanowsky's stain. As a rule, several inclusions are found together in the same cell; more rarely they are solitary. Leishman considers that possibly they are Chlamydozoa. These bodies have been adversely criticized by several observers, especially by von Schilling-Torgau, who considers them to be plasmosomata, and Low has found similar bodies in other diseases. Balfour has seen these inclusions in a case of blackwater fever and in a case of malaria. Schüfner has tentatively suggested that a form of the disease may be of spirochætic origin.

5. *Bite of an unknown Arthropod.*—Balfour suggests that the disease is not of parasitic origin, but due to the injection of some powerful hæmolysin introduced by the bite of some unknown insect or arachnid.

In our opinion blackwater fever is a disease of its own, though we freely admit the existence of hæmoglobinuria from quinine as well as from other drugs, such as chlorate of potash, of which we know of a case at first diagnosed as blackwater fever.

Predisposing Causes.—The predisposing causes of blackwater fever appear to be first racial, second bodily. With regard to the first, the immigrant European suffers more than the native, though the disease also attacks natives and half-castes. This racial distinction is, therefore, probably due to some acquired or inherited immunity. It is said that a person is usually not attacked until after residence for at least a year in the endemic area.

The second series of predisposing causes appears to be anything which lowers the vitality of the body—cold, change of climate, another disease—*e.g.*, malaria, syphilis—or certain drugs.

Pathology.—As the ætiology of the disease is uncertain, the pathogenesis is also little understood.

Christophers and Bentley have brought forward an explanation of the pathology. Their views may be summarized as follows:—*Laverania malariæ*, the subtertian parasite, acts upon the endothelial cells of the blood capillaries of various organs, but especially upon those of the spleen and liver, stimulating them to excessive destruction (erythrokatalysis) of red blood cells by phagocytosis. This phagocytosis results in the production of an auto-hæmolysin of the nature of a hæmolytic amboceptor, which is retained in the endothelial cells until set free by some exciting cause, which may be a chill, overexertion, etc. The result of this excitation is to suddenly set free in quantity this hæmolysin, which destroys the red cells by solution in the plasma (lysæmia), principally in the blood of the liver and kidney, and to a less extent in that of the spleen. The lysæmia produces hæmoglobinæmia, which is best demonstrated by receiving the blood into hypertonic citrate solution and then centrifugalizing, when the serum is observed to be of an orange, rarely of a reddish, colour The amount of hæmoglobin present in this condition was estimated by Christophers and Bentley to be from 1 to 3·75 per cent. of that present in normal blood. This hæmoglobin quickly appears in the urine as oxyhæmoglobin, which may become methæmoglobin on standing. All the hæmoglobin probably does not escape by the kidney, for there is evidence of increased production of bile, and it is possible that only such quantity as the liver is incapable of converting into bile appears in the urine. It is, however, by no means certain whether the pigment escapes only by the glomeruli or through the tubules, or by both, and it is also uncertain whether the hæmoglobin can pass through the cells of a normal kidney.

Barratt and Yorke, on the other hand, find that the hæmoglobinuria is not dependent upon hæmolysinæmia, but that it is due to a hæmoglobinæmia the origin of which they were unable to determine.

They, supported by de Haan, consider that the suppression of urine is due to a mechanical blocking of the renal tubes by the formation of large, firm, coarsely granular casts in the ducts of Bertini. Plehn, however, ascribes this suppression to a nervous inhibition of the glomerular secretion. Many authors ascribe the suppression to nephritis caused by the disease. Recently the subject has been reinvestigated by Yorke and Nauss, who support the mechanical theory, and find that it is considerably facilitated by any factor which tends to lower the blood-pressure, and by that means the secretion of water by the glomeruli, but that if the blood-pressure is kept up by the injection of saline solutions, the tendency to suppression is decreased. This is of importance in guiding the treatment of the condition.

Morbid Anatomy.—There are three cardinal features in the morbid anatomy of a case which has died during blackwater fever, and these are: (1) *Jaundice of the tissues*. (2) *Non-coagulated blood*; (3) *Swollen congested kidneys*. In addition, there may be the signs of acute or chronic malaria in the liver, spleen, and bone-marrow.

On making the post-mortem, the yellow staining of the skin and organs is most marked. The kidneys are enlarged, dark red to black in colour, while microscopically they show degeneration of the epithelium of the convoluted and other tubules, the lumen of which is filled with granular material, while the glomeruli may contain granular material, and show desquamated capsular cells.

The liver is enlarged, and the gall-bladder full of inspissated bile. Microscopically, areas of necrosis, with thrombi in the sublobular veins and quantities of hæmosiderin in the cells, many of which may be in a state of fatty degeneration, are to be seen.

The stomach and small intestine are often hyperæmic, and the bone-marrow is yellowish, and either fluid or gelatinous.

The Blood.—The blood is thin and watery, and there may be hæmoglobinæmia and cholæmia, with lessened tonicity. The red cells and hæmoglobin are greatly reduced, and the former may include shadow cells and small fragments of cells, and deep staining round cells (spherocytes) in the early stages, and later may show degenerative changes such as polychromatophilia and basophilia, while megaloblasts and normoblasts are present. Malarial parasites or pigment may be seen. During the fever there is marked leucocytosis, with polymorphonuclear and mononuclear increase, but when the fever disappears there is leucopenia, with a mononuclear increase.

The Urine.—The urine is dark red to brownish-yellow in colour, becoming sometimes black, like stout, the reddish tinge not being seen until it is diluted, when it shows with the spectroscope the absorption bands of oxy- or methæmoglobin—the latter only if the urine has stood some time. The reaction is faintly alkaline, and the specific gravity is often less than normal. A considerable amount of sediment falls when the urine is left to stand. This sediment is composed of dark brown granular material, which is the débris of the broken-down red cells, very few of which remain intact. Hæmatoidin crystals are sometimes met with. On boiling the urine, and then allowing it to stand for some time, a bright purple colour develops (Plehn's reaction). If some of the urine is made alkaline with potash and then boiled, a purple colour, due to hæmochromogen, is produced (Stephens and Christophers' reaction). The urine resists decomposition for some time.

The presence of urobilin can be detected by acidulating with a little acetic acid, extracting with amyl alcohol, and examining with a spectroscope, when a broad band to the red side of F will be seen. Bile pigments are seldom present, and may be recognized by Gmelin's or Maréchal's reactions. There is a considerable amount of albumen present in the form of serum albumen, serum globulin, and nucleo-albumen. Phosphates are said to be diminished. The hæmosozic value is higher than that of the red corpuscles of the blood.

Symptomatology.—Usually the patient has resided six months or longer in one of the regions mentioned above, and naturally has had attacks of malarial fever, and has taken quinine.

Prodromata.—Prodromata may be almost entirely absent, but usually the patient complains of lassitude, pains all over the body, loss of appetite, restlessness at night, and an entire lack of energy during the day, and a yellowish tinge may be noted in the conjunctivæ or skin for a day or so.

Attack.—Suddenly the patient feels chilly, and shivering fits may occur, accompanied by headache, severe pains in the back and legs, and an intense feeling of weakness and nausea, which, as a rule, quickly ends in retching and then vomiting, first of food, and then of green bile. The tongue is coated with a dirty-yellowish fur, and there is much thirst and constipation, the fæces at first being dark-coloured, and often scybalous.

The liver and spleen are enlarged and tender; the skin is hot and dry, and if not already tinged yellow, rapidly becomes so, deepening in tint as time goes on. It is said that itching is sometimes felt, but we have never noted this. The conjunctivæ are tinged yellow, like the skin. The temperature rises quickly to 103° or 104° F., and the pulse is regular, rapid, small, and compressible. At first the urine may appear normal, but sooner or later the characteristic stout-like colour appears, with pains in the back and burning sensations in the urethra. On the other hand, this may be the first feature of the attack, and causes the patient to send at once for the doctor, though he may not at the time feel ill, or it may occur at the height of the fever, as Kelsch points out.

The mind may be clear or the patient may be brought to the hospital quite unconscious, and may remain so for days, or delirium may set in. After a few hours perspiration appears, and the temperature remits to about 100° F., the urine clears, and a mild case may recover, while in a severe case, instead of the remission, hyperpyrexia, coma, and death may ensue.

Usually, however, after the remission the temperature again rises (post-hæmoglobinuric fever), and the shiverings, vomitings, and pains return, while diarrhœa, with motions full of bile, and sometimes also with blood or hæmoglobin, comes on. A motion with hæmoglobin may present a most striking appearance, being mainly green in colour, with a reddish deposit on the surface.

This second paroxysm may be the last, or it may be succeeded by several others, after which the patient may recover. On the other hand, he may die during these attacks from exhaustion, or from hyperpyrexia and coma, or from anuria and uræmia.

Convalescence.—After the attacks the patient is exceedingly weak, and convalescence is protracted, and is liable to be complicated at any time with anuria, leading to fatal uræmia.

Varieties.—Kelsch and Kiener recognize two distinct types—a mild and a severe, of which the latter is subdivided into three—viz., the ordinary severe, the fulminating with a rapidly fatal issue, and the uræmic type.

Complications.—The most usual complication is the passage of hæmoglobin or blood *per anum*, giving rise to 'dysenteric motions,' as they are often called. Muco-pus is, however, generally absent. Inflammation of the tonsils and salivary glands has been noted.

Sequelæ.—There is nearly always grave anæmia and much weakness as the result of an attack, with often stomach and intestinal derangements, but of all, the most serious is nephritis, leading to uræmia.

Diagnosis.—Blackwater fever is easily recognized, as a rule, the diagnosis being based on the *hæmoglobinuria with high fever and jaundice,* and the severity of the symptoms.

The differential diagnosis has to be made from yellow fever, in which, however, there is never hæmoglobinuria. Acute yellow atrophy of the liver and Weil's disease are easily distinguished by the urine, which does not contain hæmoglobin, and by the presence of the peculiar spirochæte in the blood and urine of the latter disease.

Quinine hæmoglobinuria is not a serious disease, and can be readily prevented and cured, and, moreover, is directly associated with a dose of quinine. Malarial hæmoglobinuria closely resembles blackwater fever, but is definitely associated with subtertian parasites as a rule, and much more rarely with other forms of malarial parasites.

Prognosis.—The mortality in our experience varies greatly, being very high in some epidemics and low in others. The mortalities given by Skelton are as follows: F. Plehn, 4 per cent.; A. Plehn, 6·8 per cent.; Stendel, 16 to 17 per cent.; Koch, 21 per cent.; Bérenger-Féraud, 23 to 24 per cent.; Schellong, 42 per cent.: Reynolds, 50 per cent.

Bad signs are:—

1. Persistent vomiting.
2. Hiccough.
3. Profuse diarrhœa.
4. High fever.
5. Sudden decrease in the tension and increase in the frequency of the pulse.
6. Diminution or cessation of urine.
7. Coma.

Good signs are:—

1. Little gastro-intestinal disturbance.
2. Low temperature.
3. Good pulse.
4. Clear mind.

It is usually said that a person should not return to the tropics after suffering from blackwater fever, but many people do return, and appear to remain in excellent health. Of course, there is the great risk of further attacks.

Treatment.—This may be considered under the following:—

1. During the attack.
2. After the attack.
3. Remarks.

1. During the Attack.—The treatment during the attack may be considered under the headings (*a*) Recommended Therapy, (*b*) General Treatment, (*c*) Diet, (*d*) Symptomatic Treatment.

Therapy Recommended.—We recommend the Sternberg-Hearsey treatment in cases of true blackwater fever, as distinguished from quinine hæmoglobinuria and malarial hæmoglobinuria.

This treatment consists in administering

Liquor hydrargyri perchloridi	30 minims.
Sodium bicarbonate	10 grains.
Water	to 1 ounce.

every two to four hours during the first twenty-four hours, and then every three hours until the urine clears. (For details as to the Sternberg method see Chapter XLII.)

General Treatment.—In treating the disease, the important features to be remembered are that the patients are often infected with malaria; that they suffer from a great blood destruction, and therefore from great weakness; that, as a result of the blood destruction, a severe strain is thrown on the liver and kidneys, and that the latter are apt to be damaged by the hæmoglobin. In fact, some people think that the hæmolysis takes place in the kidney, but in any case there is danger of blocking of the renal tubules, of nephritis, anuria, and uræmia. Lastly, the disease is apt to relapse.

From the very commencement, the patient must be put to rest in bed, and have careful nursing. A most important matter is to flush out the kidneys, and this should be done by introducing water into the body in some way. If the patient can take liquids by the mouth, use soda-water, albumen-water, whey, cold or warm tea, barley-water, or toast-water, in quantity. If vomiting is such that liquids cannot be retained by the stomach, use rectal enemata of warm physiological saline solution (0·9 per cent. of common salt in water) or *sterile* subcutaneous injections (temperature 98·4° F. or 37° C.) of a mixture such as the following:—

Calcium chloride	4–5 grammes.
Sodium chloride	10 grammes.
Distilled water	1,000 c.c.

One hundred to two hundred cubic centimetres of this mixture, ***properly sterilized,*** may be used two or three times a day as a subcutaneous injection in bad cases.

Adam Patrick recommends the intravenous injection of a 1 per cent sterile sodium chloride solution. He has injected as much as 3 pints at one time. Bayliss' Solution, containing 6 per cent gum acacia and 0·9 per cent sodium chloride, may also be used.

Diet.—The diet must be fluid, preferably in the form of whey, milk, chicken-broth, albumen-water, and Benger's food; but strong meat-extracts should be avoided.

If the vomiting is troublesome, and there is no diarrhœa, rectal feeding might be tried. Plenty of aerated water should be allowed.

The condition of the stomach, liver, and kidneys may counter-indicate stimulants at times, but there is no doubt of the value of champagne and brandy when they can be administered.

Symptomatic Treatment.—*Vomiting* may be relieved by sips of iced or cooled soda-water or champagne. If these simple remedies fail, apply a mustard-leaf to the pit of the stomach. Tincture of iodine in a strength of 1 to 2 drops in an ounce of cinnamon water, and administered orally several times a day, may be useful. If this fails, hypodermics of morphine must be tried, but it must be admitted that we do not like to administer this drug in blackwater fever unless compelled, and prefer to combine atropine with it, and even then to give as little as possible. *Constipation* may be combated by means of calomel in repeated small doses, helped if necessary by enemata. *Diarrhœa* should not be too rapidly stopped, but if it is a pressing symptom, weakening and disturbing the patient, then tannic acid in 15 grain doses, tannalbin in 15 grain doses, or bismuth subnitrate in 10-20 grain doses, may be administered by the mouth, or enemata of tannic acid given by the rectum if there is also much vomiting.

The *heart's action* should be carefully watched, and may require support by hypodermic injections of digitalin or caffeine. Calcium lactate, having a tonic effect upon the heart, and being also useful for other reasons in this disease, may be given in 10 grain doses twice or three times a day, or in the form of the injection mentioned above. Extract of the pituitary gland has been recommended in cases of cardiac failure.

Malarial parasites, when present in the blood, require treatment by intramuscular injections of *quinine bihydrochloride* (p. 1188), preceded by a dose or two of calcium lactate, but the sulphate or bisulphate of quinine are contraindicated, and should not be employed.

Pain in the back should be treated by hot fomentations, and if these fail and the symptoms be urgent, by morphine given subcutaneously.

Anuria must be met by vapour baths, before which a hypodermic injection of pilocarpine may be given. If this fails, dry or wet cupping of the lumbar renal area must be tried, and must be helped by oxygen inhalations if available and by free purgation.

Headache may be relieved by cool applications to the head, but special drugs must not be given.

2. AFTER THE ATTACK.—If the patient survive the attack of true blackwater fever, which is often fatal, he should be allowed a long convalescence, with a change to a temperate climate if possible. During this time he will require good, wholesome, nourishing food and slowly graduated exercise.

One attack of 'blackwater fever' *per se* should not necessarily lead to the permanent invaliding of the patient from the tropics, though he should be warned that he returns thereto at his own risk. If, however, permanent damage to any organ is also present, this should be the deciding factor in stating that a return will be dangerous.

3. REMARKS.—Such is the outline of the treatment which we advise, but other authors have different views, and one or two of these may be briefly mentioned:—

Dr. O'Sullivan-Beare strongly recommends the decoction or the fluid extract of the root of *Cassia beareana* Holmes; the latter can be obtained from T. Christy and Sons, Old Swan Lane, Upper Thames Street, London, and should be administered in 1 fluid drachm, well diluted with water, every two hours at first, and afterwards at longer intervals. We have no experience of this drug, but its introducer praises it highly, stating that it relieves all the symptoms quickly. Skelton says he has never seen it do any good, but that it does no harm. So well is the disease known in West Africa that several native remedies exist. With regard to other drugs, atoxyl is said to be useless. Cantlie has used turpentine in mild attacks. Nightingale recommends sodium dimethylarsenate administered in 1-grain doses thrice daily until the temperature is below normal for twenty-four hours. It is stated to soothe the gastric irritation and to clear the urine. Cholesterin in doses of 1 gramme has been given at intervals of four hours until two to three or four doses have been administered. It is given in suspension in thick milk, or as intramuscular injections in olive oil, and has been advocated on account of its antihæmolytic action.

Prophylaxis.—Very little can be said with regard to the prophylaxis, as the knowledge of the ætiology is incomplete. As blackwater fever generally develops in persons who have suffered from malaria, quinine prophylaxis should be carried out in the manner already described in the chapter on Malaria (Chapter XL., p. 1204), attacks of malaria being treated by quinine tannate in small repeated doses, or the drug should be preceded by a dose of calcium lactate.

CHAPTER XLII

YELLOW FEVER

Synonyms—History—Climatology—Ætiology—Pathology—Symptomatology —Diagnosis—Prognosis—Treatment—Prophylaxis—References.

Synonyms.—Bilious Remittent fever, Acclimatizing fever, Inflammatory fever, Febris Flava, Pestis Americana, Typhus Icteroides. *French :* Fièvre Jaune. *Italian :* Febbre Gialla, Febbre Amarilla. *German :* Gelbfieber. In addition, there are a large number of local names, such as Bulam fever (Grenada); Kendal's disease (Barbados); Pest of Havana (Cuba); Maladie de Siam (Martinique); Febre remittente biliosa dos bezos quentes (Brazil); Febre amarello dos acclimatados (Brazil); Magdalena fever (Columbia).

Definition.—An acute specific non-contagious fever of unknown causation characterized usually by two paroxysms of fever, separated by a remission or intermission, and accompanied with albuminuria, jaundice, and hæmorrhages, with usually a normal number of leucocytes and polymorphonuclear leucocytes. It is spread by the agency of *Stegomyia calopus* Meigen, 1818 (synonym, *S. fasciata* Fabricius, 1805, *non* O. F. Müller, 1764).

History.—Yellow fever is believed to have originally been a disease of the Antilles, and to have attacked the troops of Christopher Columbus in 1495 in the Isle of Spain (St. Domingo), from which it was carried by the Spaniards to the mainland of America. The endemic home of the disease at the present time is the east coast of Mexico, where it was reported in 1509 at Vera Cruz, and Central America from Cape Tampies to Cape Gracias à Dios, and the Greater and Lesser Antilles. From this area it can spread by ships to various parts of the world, where it may become epidemic.

The first clearly written description of yellow fever is that by P. du Tertre, in Guadeloupe, in 1635, but it soon became well known from the epidemic in Cuba in 1648-49: Jamaica, 1655; San Domingo, 1656; Martinique, 1688; and Vera Cruz, 1690. In 1698 it was recognized that the disease was being carried from place to place by ships, and a quarantine ordinance was brought into force, which lasted from 1709 till 1790, when the extensive wars of the period caused it to be ineffective, with the result that between 1791 and 1815 most extensive epidemics took place, and gave ample opportunity for the study of the disease. In 1794 Drysdale, of Baltimore, in 1797 and 1805 Rush, in Philadelphia, and in 1802 Vaughan, in Wilmington, drew attention to the large numbers of mosquitoes and other insects which abounded in their respective towns during yellow-fever epidemics, though rare in preceding years. With regard to bilious remittent fever, a good account of this disease was given in 1842 by Burton in the first volume of the *British Medical Journal* (then called the *Provincial Medical Journal*). In 1848 Nott, of Mobile, accused some insect or mosquito of being the possible carrier of yellow fever. In 1876 Dowell, of Galveston, showed that mosquitoes and yellow fever obeyed the same natural laws, and in 1878 it was demonstrated in Mobile that quarantine of the patients, together with sulphur fumigation, could control the epidemic. But it was not till 1881 that Charles Finlay, of Havana, directly attributed the spread of the disease to the mosquito. In 1882 Gererd, having caused a mosquito to suck the blood of a patient on the fourth day of the fever, then allowed it at once to bite his hand, with the result that he developed in due course a mild attack of yellow fever. The credit of having supported the mosquito theory for many years in numerous publications belongs to Finlay.

In 1883 Freire, of Rio de Janeiro, thought that he had discovered the cause of the disease in the shape of a micrococcus, and later C. Valle, C. Finlay, and Gibier each described specific bacteria. Sternberg studied the disease for years, but could find no definite bacterial or other cause. He, however, in a certain number of cases, came across a bacillus, which he called ' X.' In 1897 Sanarelli announced that he had found a bacterium (*Bacillus icteroides*) which he believed to be the cause of the disease, and, further, he prepared a serum for its treatment. Sanarelli's findings were at first confirmed by a large number of observers.

In 1900 Reed and Carroll announced that *Bacillus X* belonged to the colon group of bacteria, and *B. icteroides* to the hog-cholera group, and was probably identical with *B. choleræ suis*. In our experience *B. icteroides* is not identical with *B. choleræ suis*, but is a distinct species, although it plays no part in the ætiology of the malady, and is merely the cause of a secondary infection. In the same year Reed, Carroll, Agramonte, and Lazear proved that the disease could be produced by the subcutaneous injection of infected blood into a non-immune person; that the disease was not contagious, and was only spread by the bites of *Stegomyia calopus*. The agency of the mosquito was speedily confirmed by Guiteras, Ribas and Lutz, Marchoux, Salimbeni and Simond, Parker, Beyer and Pothier, and later by Rosenau, Parker, Francis and Beyer.

In 1903 Parker, Beyer, and Pothier concluded that the ætiological cause was *Myxococcidium stegomyiæ*, found in infected mosquitoes, which they believed to be an animal parasite closely resembling a *Coccidium*. Carroll, however, refuted this, as did Marchoux, Salimbeni, and Simond, and finally Rosenau, Parker, Francis, and Beyer clearly proved that *M. stegomyiæ* was a yeast normally found in mosquitoes.

In 1905 Rosenau, Francis and Beyer showed that the disease could be communicated by the inoculation of infected blood filtered through the closest-grained Pasteur-Chamberland B filter which they could obtain, and therefore came to the conclusion that the causal agent of the disease must be of ultramicroscopic size.

In 1909 Seidelin described the presence of minute bodies (*Paraplasma flavigenum*) in the red cells of persons suffering from yellow fever, but these are not believed to have anything to do with yellow fever. Low and Wenyon have shown that Seidelin's bodies are common in the blood of young guinea-pigs.

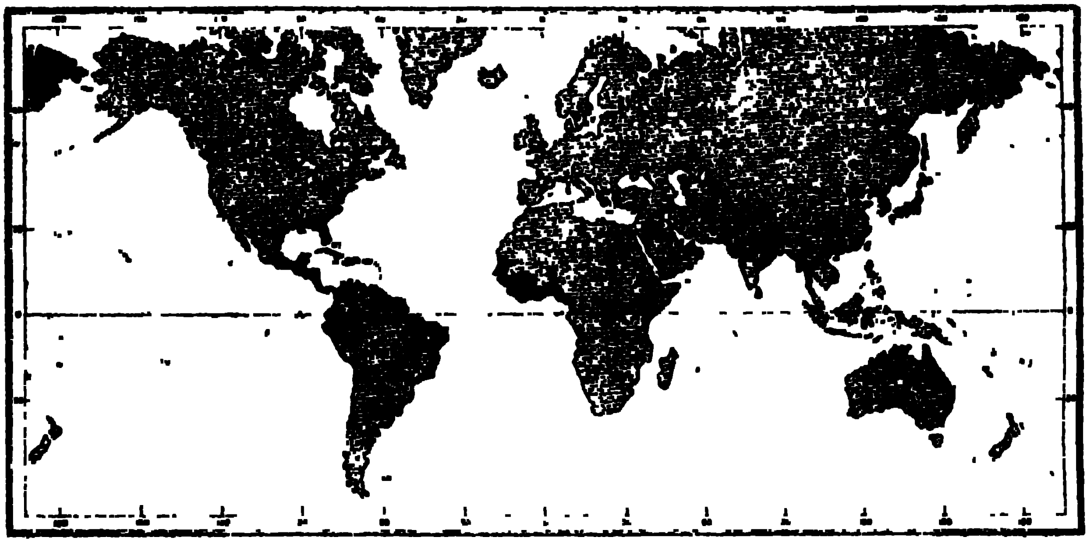

FIG. 628.—MAP OF THE DISTRIBUTION OF YELLOW FEVER. (After Newstead.)

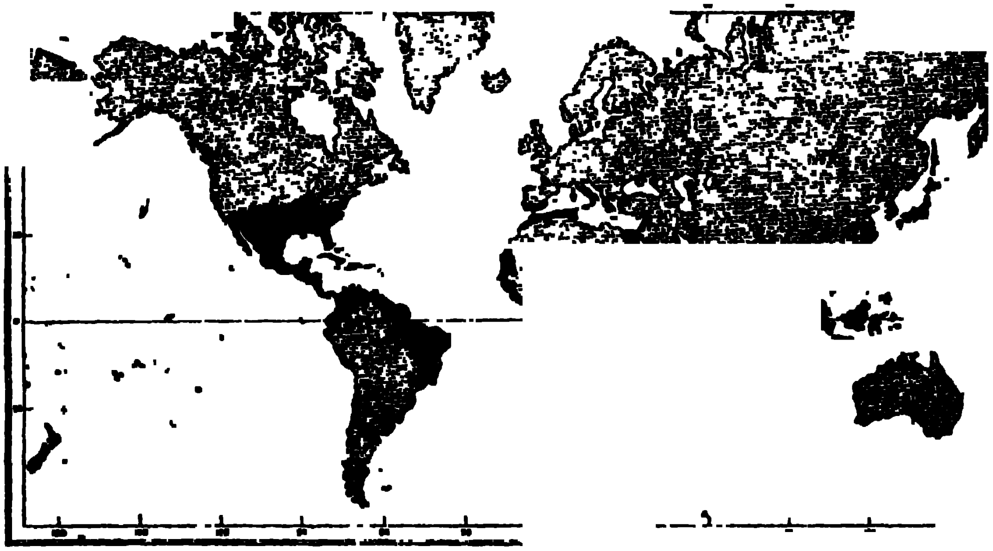

FIG. 629.—THE DISTRIBUTION OF *Stegomyia calopus*. (After Newstead.)

The theory of the propagation of the disease by *Stegomyia calopus* has been put to the practical test of prophylaxis with most excellent results in Havana, Texas, Mexico, and New Orleans, and in the works of the Panama Canal. The late Sir Rubert Boyce did excellent work in drawing attention to the yellow fever of West Africa, where it is extremely deadly at times, and which is probably a secondary endemic centre.

It is impossible to close this history without drawing the reader's attention to the great benefit conferred upon mankind by the labours of Reed, Carroll, Agramonte, and Lazcar, the last named dying from yellow fever following an experimental bite of an infected mosquito.

Climatology.—As already stated, the endemic area includes a portion of the Atlantic coasts of Mexico and Central and South America, as well as the Antilles. Some of the more important endemic centres at the present time are Guatemala, Spanish Honduras, Nicaragua, Costa Rica, Salvador, French Guiana, Dutch Guiana, along the Rivers Magdalena, Orinoco, and Amazon, and in Ecuador. There is evidence that the Cape Verde Islands were infected in 1510-15, and that the Gulf of Benin received its yellow fever from this source in 1520, and it is possible that it has been endemic on the West Coast of Africa from that date. Boyce was of the opinion that it has been a disease of Africa from time immemorable, but, though these early historical points cannot satisfactorily be settled, there is more evidence that the true home is Central America, and that Africa is a secondary endemic area, in which very serious outbreaks have been recorded in the past, and where the disease is at times epidemic.

From the endemic centre the disease can spread by the agency of ships until it reaches 46° 56′ N. (Quebec) and 34° 54′ S. (Monte Video), which correspond to the isotherm of 60° F. (16° C.) for the mean temperature of the hottest month of the year. At its northern limits the disease is generally very mild, but at its southern limits it may be very severe.

The areas most usually affected are the Atlantic coasts of North America, as far north as Charleston (32° 46′ N.), and of South America as far south as Rio de Janeiro (22° 54′ S.). Another region commonly affected is the West Coast of Africa from Senegambia to Saint Paul de Loando.

Europe has frequently been attacked—*e.g.*, England (Swansea) in 1865, France in 1861, Spain and Portugal in the eighteenth and nineteenth centuries, the last infection being in Madrid in 1878, and Italy (Leghorn) in 1804.

The disease has apparently more than once reached the Pacific, for it spread in 1740 to Guayaquil, in Ecuador, and in 1854 to Peru.

The distribution corresponds with that of *Stegomyia calopus*, and the fact that the disease is endemic in warm climates and more marked in the hot season, while it disappears in the winter of temperate climates, reappearing in the summer, coincides with the habits of the mosquito. Further, the facts that it is carried by infected ships and that it may affect low-lying regions near the coast, particularly ports, in which the dwelling-houses are especially attacked, are explicable by its mosquito transmission.

It appears to us that the fever associated with black vomit, found among children in 'Grande terre,' Guadeloupe, must either be a form of yellow fever or closely allied to it, though possibly some cases may be confused with the

vomiting sickness of Jamaica, in which black vomit is absent (p. 1695). At the same time it is interesting to note the general similarity between pappataci fever, dengue, and yellow fever, which appear to form a group of closely allied diseases.

Yellow fever has been recorded by Hudellet at Dinguira, Mahina, Ouida, between Kayes and the Niger in the Sudan, while cases have been recorded in Java.

Ætiology.—The causal agent exists in the blood of an infected person, as can be proved by the fact that the subcutaneous inoculation of 0·1 c.c. of the infected blood into non-immune persons produces attacks of the disease, but it cannot be spread to man by post mortem wounds. This causal agent appears to be, at least in one of its stages, of exceedingly small size, for diluted blood filtered through a Pasteur Chamberland B bougie can still cause the disease if inoculated intravenously into a non immune.

According to Seidelin it is a small protozoon (*Paraplasma flavigenum* Seidelin, 1909) found in the red blood cells, but the parasitic forms described by the author are now considered to be artefacts.

It is obviously a living organism, and not a chemical substance, because of the time it takes to develop in man and the mosquito, for the incubation period in man is usually three days. The mosquito, in order to become infected, must bite a patient during the first three days of his illness, and then fourteen days must elapse before the infected mosquito can transmit the disease.

The proof of the transmission of the disease by *Stegomyia calopus* was worked out by Reed, Carroll, Agramonte, and Lazear, by constructing a gnat-proof building divided into two gnat-proof compartments, into the first of which infected mosquitoes were liberated and allowed to bite a non immune, while other non-immunes slept in the second compartment. The man in the first compartment developed an attack of yellow fever, while the others did not.

Non immunes living in gnat proof houses, with articles of clothing and bedding soiled with urine, faeces, black vomit, etc., from cases of yellow fever, did not contract the disease, though after this experiment was finished some were infected by means of the bites of infected mosquitoes, thus proving that they were not immune.

Marchoux and Simond extended this knowledge by showing that a *Stegomyia* can live for some thirty days, and lay seven batches of eggs. Those laid after the twelve days' incubation by an infected mosquito are also infected, and can transmit the contagium vivum to a second generation of mosquitoes, but these cannot infect non-immunes until fourteen days after hatching as imagines.

The new generation of *Stegomyia* were fed upon glucose, and were made to bite a recent non-immune arrival in Brazil, but no infection followed. A week later the same mosquito was allowed to bite the same person, who then developed a typical attack of yellow fever, from which he subsequently recovered and was found to be immune.

This is believed to indicate that a mosquito requires a feed of blood before it can produce infection.

It is also stated that before a stegomyia can lay eggs she must have a feed of blood, the eggs being laid three days later, after which she is said to feed only at night, while before this she feeds during the day and during the night.

From this it is argued that any stegomyia which bites in the day-time can have only immature parasites, and therefore cannot produce an infection.

A mosquito can produce yellow fever some fifty-seven days after infection, which appears to become more virulent the longer it remains in the insect, especially if the air temperature is 27° to 28° C.

Further, the contagium vivum can apparently only exist in man and *Stegomyia calopus*, though it is true that a chimpanzee, after an incubation of three days, suffered from a typical attack of yellow fever, induced by experimental mosquito-bites, as was shown by Thomas in 1907. No other mosquito so far has been proved to carry the infection. It appears, also, that the development in the mosquito depends to some extent upon the air temperature, as in the case of the malarial parasite.

Thomas has succeeded in producing a reaction in a chimpanzee five days after infection by the bite of an infected *Stegomyia*, and in guinea-pigs from four and a half to thirteen days after being bitten by infected *Stegomyia*. It must be remembered that in yellow fever epidemics it is stated that dogs and fowls are supposed to be ill but from what cause is unknown. Manson has suggested that the disease may be kept up by animals.

The ætiology may therefore be summarized by saying that the causation is an animal parasite, living in the blood stream of man and in the body of *Stegomyia calopus* Meigen, 1818 (*S. fasciata* Fabricius, 1805, *non* O. F. Muller, 1764), by the bites of which it can be transmitted to man and the chimpanzee. The blood of the infected man is transmissive only during the first three to four days. *Stegomyia calopus* begins to be infective fourteen days after the transmissive feed, and remains infective for at least another forty-three days, and it has been claimed that it can pass on the infection to its young, which require a feed of blood before the virus becomes infective. During this non-infective period they bite during the daytime, but do not after their first feed and the deposition of their first eggs. It is possible that other species of *Stegomyia*, in the future, may be found to be carriers as well as *S. calopus*.

Unfortunately, according to Theobald, it is necessary to change the old name *Stegomyia fasciata* Fabricius, 1805, to *S. frater* Desvoidy, 1827, or to *S. calopus* Meigen 1818 though there is some doubt as to whether the latter, which is, of course, the older term, really applies to the insect we know as *S. fasciata*. The reason for this change is because the term *fasciata* was used by O. F. Müller in 1764 (not by de Villers, often wrongly spelt Villiers) for a *Culex* distinct from *S. fasciata* Fabricius, 1805. More recently there seems to be some doubt as to the correctness of the new term—that is, *S. calopus*—and a return to the old term, *S. fasciata*, may be necessary.

Spirochæte.—In 1909 Stimson, reported the presence of a spirochæte in yellow fever (*S. interrogans* Stimson, 1909), but no importance was given to this observation. Recently Noguchi has cultivated from the blood of several cases a spirochæte somewhat similar to *S. icterohæmorrhagiæ*, and has named it *Leptospira icteroides*.

Pathology.—In yellow fever the cells of the liver swell, and, pressing upon the bile capillaries, obstruct the flow of bile and cause a hepatogenous jaundice, characterized by yellow staining of the skin and tissues, and by the presence of bile in the urine. Further, the swelling blocks the intralobular capillaries, causing congestion of all the viscera drained by the portal vein, but especially of the pyloric end of the stomach and the duodenum, because of the arrangement of the veins from those parts. This stagnation of the blood may allow a secondary bacterial infection to take place, which shows its effect on the intestine and spleen.

The liver cells degenerate so extensively in bad cases as to cause the urea function to be considerably lessened in activity, and thereby a condition of ammonæmia comes about, which produces most serious toxic effects upon the brain and other organs. In addition, the disease in some way seriously affects the endothelial lining of the blood capillaries, producing hæmorrhages in various parts of the body. If these leading features of the pathology are borne in mind, the post-mortem appearances and the symptomatology will be easily understood.

An attack generally confers a lasting immunity upon a person, and second attacks are rare, and it appears that the so-called racial immunity of people living in endemic regions is really an acquired immunity, due to mild attacks in childhood. Relative immunity can be acquired by inoculation of infected blood heated to 55° C. for five minutes. Further, it is found that the serum of a convalescent has some protective power.

The Blood.—There is no marked alteration in the numbers or appearance of the erythrocytes, even in fatal cases. A few normoblasts are said to be present at times. On the other hand, there is a decided loss of hæmoglobin, though this is rarely much reduced in the first three or four days; and hæmoglobinæmia is said to occur in fatal cases before death. But this does not appear to coincide with the fall of specific gravity, which may be present without loss of hæmoglobin.

The leucocytes do not appear to be distinctly increased in numbers, varying from 3,200 to 20,000 per cubic millimetre, the increase, when present, being largely caused by polymorphonuclear leucocytes. The coagulation of the blood is diminished, and ammoniæmia is thought to be present in bad cases.

The Urine.—Albumen appears early—as a rule, on the second day—and increases in quantity remarkably, especially in severe cases. During convalescence it may disappear, or may last for months. Bile is present about the fifth or sixth day, and red blood cells may also occur, though leucocytes are rather rare. Casts are present—first hyaline, then granular, and finally epithelial. Urea is diminished in bad cases, and the diazo-reaction is believed to be absent in uncomplicated cases.

The Vomit.—The vomit is often distinguished as white, red, and black. The white is acid, colourless or bile-stained, and is composed largely of mucus. The red vomit contains bright blood, while the black is acid, containing hydrochloric acid, epithelial cells, red corpuscles, fat, débris, and micro-organisms, its colour being due to the presence of hæmoglobin, turned to acid hæmatin by the hydrochloric acid.

Morbid Anatomy.—The skin is yellow from bile-pigment, and blotched with post-mortem lividity and hæmorrhages. The mucosa of the tongue is fissured, and the mouth may be covered with blood. The liver is yellowish or brownish in colour, marked by hæmorrhages. The cells are swollen and in a state of advanced fatty degeneration. The gall-bladder contains inspissated bile, sometimes mixed with blood. The spleen is normal in size, but may be congested and soft. The stomach and intestines may be full of blood, usually in the form of a black homogeneous tarry fluid containing black particles, and the mucosa of the stomach, especially that of the pylorus and duodenum, is usually much swollen, and the mesenteric glands may sometimes be enlarged. The kidneys are, as a rule, normal in size, and show signs of some congestion. Bowman's capsules are said to be dilated, but this is not constant. The cells of the tubules show fatty degeneration, and the lumen may contain granular débris. The suprarenal capsules may be hyperæmic or show fatty degeneration, but neither of these is constant, and hyperæmia or fatty degeneration of the pituitary body and the thyroid gland have been described, but are not important. The bladder is usually empty. The heart shows ecchymoses, and effusions may be found in the pericardium. The lungs may be congested, and hæmorrhages may be found beneath the pleura. The uterine mucosa is congested, and there may be blood in the cavity. The meninges of the brain are congested, and hæmorrhagic spots may be seen.

Symptomatology *Incubation.* An exact knowledge of the length of the incubation period is of the utmost importance from a prophylactic point of view. Calculated from experimental mosquito bites, it varies from two days twenty-two hours to seven days five hours, but the latter figure was in a man who had had a mild attack. With regard to the former period, it is the shortest actual record, but some more doubtful figures, as low as two days one hour, are given. Excluding the man with the slight attack, the incubation period, as generally given by American observers, would be from two days twenty-two hours to six days two hours. Marchoux, Salimbeni, and Simond consider that the incubation may be as long as twelve days, and draw this conclusion from inoculation of modified blood serum, and also from natural infection. Carter's careful clinical records, however, give the incubation period as varying from three to five and three quarter days.

The average time appears to be about five days, but to be on the safe side at least six to seven days must be allowed.

The Fever.—The fever is divisible into two paroxysms, separated by a remission or intermission. The first attack is characterized by headache, pale, then flushed, face, injected eyes, and pains in the body, and after the second day albuminuria: while the second attack shows the jaundice from which the disease obtains its name, and the hæmorrhages, of which black vomit and black motions form such ominous signs.

Onset.—Prodromata are usually absent, but general malaise may be felt for some little time previously. The attack begins with a sensation of coldness, with or without rigors, and with severe frontal headache, pains in the back and limbs, while the face, at first pale, becomes flushed and painful, the skin congested, the eyes brilliant and injected, and photophobia is often present The temperature rapidly rises to 103° F. or more: the respiration quickens and is laboured: the pulse is quick, full, and bounding, reaching to 100 or 120 per minute. The appetite is lost, and there is usually vomiting, associated with pain and tenderness in the region of the pylorus, and usually constipation. The urine is generally diminished, acid in reaction, with a high specific gravity, and albumen is present from the first or second day. Its passage may cause a sensation of burning. During this stage there is often insomnia.

Intermission.—On the second to fourth day the remission sets in, the temperature either dropping with a crisis, accompanied by sweating, to normal, or remitting to about 100° F., the flush and pains disappearing. In the former case the disease ends and convalescence begins. More usually, however, after a few hours' remission, during which the patient feels much better and sleeps well, the temperature again rises to 104° or 105° F.: but a most characteristic feature, called 'Faget's sign,' now shows itself, in that the pulse does not increase in rapidity as the temperature rises. On the contrary, as days go on, the pulse-rate tends to become slower and slower, without regard to the temperature. This sign depends upon the severity of the case, being most noticeable in severe types, in which it may be only 70 to 60 per minute, though associated with a high temperature.

Second Attack.—During the second attack all the symptoms of the first paroxysm return, but the congestion of the skin is not so marked, and the yellow tint of jaundice appears for the first time, and deepens as the illness proceeds. The vomiting and tenderness in the stomach return, and are associated now with much thirst and prostration. The tongue is dry and furred, with red tip and edges. Hæmorrhages may now occur from the nose, mouth, or uterus, and the bad signs of black vomit and melæna may appear. The urine diminishes in quantity, and the albumen increases. In bad cases its excretion may totally cease. There is generally much restlessness, and often delirium.

Terminations.—Two courses are now possible. The first is that after three to four days' illness the temperature may decline, the urine increase in amount, the albumen diminish, and the vomiting gradually cease: while sweating may occur, and the patient, passing into a deep sleep, awakens on the road to convalescence. The second is that the temperature does not decline, the jaundice deepens, hæmorrhages appear under the skin, and from the regions indicated above, hiccough, subsultus tendinum, clammy sweats, anuria, coma, and convulsions lead to death, which may, however, take place before the full development of these symptoms by cardiac or respiratory failure.

Varieties.—Three varieties may be recognized, though some authors describe more. These are the mild, the severe, and the malignant. The mild type consists of simply the first paroxysm, in which the temperature does not rise above 102° F., the urine contains albumen, and the fever ceases by crisis on the second or third day. The severe type shows the characters given above as typical for the disease. The malignant type begins with high fever, 105° to 107° F., with violent vomiting and the early appearance of black vomit and melæna, when the patient quickly becomes delirious, and dies in the initial fever.

Complications.—Any pre-existing pathological condition is serious in yellow fever, but renal and cardiac affections are perhaps the worst. Gangrene, abscesses, congestion of the lungs, and intussusception are possible complications arising in the course of the disease.

Sequelæ.—Boils and abscesses, dysentery and hepatitis, are the common sequels, but usually convalescence is not complicated or protracted.

Prognosis.—The mortality is very variously given, usually 10 to 25 per cent. for the United States and Europe, and 45 to 80 per cent. for the endemic area and West Africa. The extremes are 0·5 to 94·5 per cent.

All cases of yellow fever must be considered serious, especially if complicated with pre-existing disease, and constant care must be taken to measure the daily quantity of urine passed, and to estimate the amount of albumen; for marked diminution of the urine, especially anuria, is a grave sign. High temperatures, black vomit, melæna and other hæmorrhages, and marked disturbance of the nervous system, are all bad omens.

According to Sternberg, if the temperature does not rise over 103° F. the prognosis is usually good.

Diagnosis.—The typical symptoms in an epidemic will hardly be mistaken for any other disease, but the mild early case is very difficult to recognize. The best signs for a positive diagnosis are the early albuminuria, the epigastric tenderness, and, later, the jaundice, with Faget's sign, and the black vomit.

Differential Diagnosis.—The most important diseases to differentiate in the first stage are dengue, subtertian malaria, blackwater fever, and relapsing fever. Dengue may be recognized by the absence of albuminuria, the preliminary rash, and leucopenia; subtertian malaria by the parasites in the blood, and in some cases the typical four-hourly temperature chart; blackwater fever by the hæmoglobin in the urine and the mononuclear increase; relapsing fever by the parasites in the blood and the leucocytosis.

Treatment.—There is no specific remedy known for yellow fever. The usual treatment, if the patient is seen on the first or second day, is to give repeated small doses of calomel until 3-5 grains have been administered, and then a draught of magnesium sulphate and sodium sulphate. Then employ Sternberg's mixture, which is:—

Sodium bicarbonate	150 grains.
Perchloride of mercury	⅓ grain.
Water	60 ounces.

This is given in three tablespoonful doses every hour.

General Treatment.—As the cause of the disease is unknown, the treatment must aim at the prevention of the spread of the infection, the rapid elimination of the toxins, and the alleviation of the symptoms. To prevent the spread of the disease, the patient's bedroom must be rendered gnat-proof. The excretion of the toxins must take place by the bowels, skin, and kidneys, and therefore it is necessary to encourage the action of all three. The action of the bowels can be maintained by enemata of 1 tablespoonful of sodium sulphate dissolved in a pint of warm water, and given morning and night.

When there is severe headache a hot mustard foot-bath may be given, which [illegible] relieve the head. After this the patient is warmly wrapped up in blankets, care must be taken that he is not oppressed by the clothing, for only those who have been seriously ill can appreciate how embarrassing the weight of heavy blankets is to the heart. It is hoped that by these means the action of the skin will be stimulated.

In order to dilute the toxins, and at the same time to stimulate the action of the kidneys, an alkaline treatment, with plenty of fluid, is required. This can be effected by administering 2 to 4 quarts of iced Célestins variety of Vichy water in the twenty-four hours, or the same quantity of any alkaline mineral water, to each pint of which 30 grains of sodium bicarbonate have been added; or by Sternberg's mixture as recommended above; or an effervescing drink can be made up of sodium bicarbonate and fresh lime-juice, but care should be taken that this is mixed in such quantities as to be neutral, and it may, if necessary, be combined with sodium sulphate. If this alkaline treatment cannot be given by the mouth, then the bicarbonate of soda must be administered as warm enemata.

Symptomatic Treatment.—As regards symptoms, if there is great pain, this can be relieved by a small dose of phenacetin, while severe lumbar pain may be relieved by hot fomentations; but if no urine is passing, the warm mustard bath will be better.

Vomiting is treated by sips of iced Vichy, iced champagne, a blister to the pit of the stomach, a dose of a mixture containing chloroform, or a hypodermic injection of morphia. If there is much fever, this must be treated by cool sponging and cool applications to the head.

Black vomit should be treated by the application of the ice-bag to the pit of the stomach, and hæmorrhages in general should be met with doses of calcium chloride or hypodermic injections of adrenalin or ergotin.

In these bad cases it is advised by some authors to rub olive oil into the skin in quantity, with a view of ladening the endothelial cells of the blood capillaries with fatty particles, and so protecting them against the action of the toxins.

Anuria requires treatment by hot fomentations to the loins, or cupping and hot-air baths and Carroll recommends the injection of 15 grains of urea, either hypodermically or by the rectum, with a view to stimulating renal activity, on the ground that in these bad cases the production of urea by the liver is not sufficient for that purpose.

Cardiac failure requires hypodermic injections of strychnine, camphor dissolved in ether or oil, or simply ether.

Diet.- No food should be given for two or three days, but only the alkaline drinks, and champagne if necessary, the idea being to relieve the stomach and prevent the accumulation of waste products in the system, and so to save the kidney from too much work

After this time, or if the temperature is below 102 F., milk and lime-water, toast water, and barley water may be given. With a view to saving tissue waste and getting fat into the circulation, pure frozen cream, cold white wine-jelly or lemon jelly, should be given, or olive oil administered by the mouth or rubbed into the skin, as indicated above.

After the temperature has been normal for some three days, chicken-broth, custard-pudding, blanc mange etc., can be tried, and a few days later the diet can be gradually increased.

Strong beef extracts and strong alcoholic stimulants should be avoided, the best stimulant being iced champagne in tablespoonful doses.

Prophylaxis.- Yellow fever is generally conveyed from one place to another by ships, but in order to produce an epidemic several factors are necessary viz., cases of the disease from which *Stegomyia calopus* may become infected, together with conditions of temperature, moisture, etc., suitable for the development of the germ in the mosquito, and also for the propagation of the mosquito itself, together with the presence of non-immune people for the mosquito to infect. It is also necessary to bear in mind that the incubation period is usually from three to six days, and therefore quarantine must be of at least five days, or, to be on the safe side, of six or seven days' duration. In order that the mosquito may become infected it must bite a patient during the first three days of the illness, and another fourteen days must elapse before it is able to infect non-immunes. Therefore an infected ship must be anchored at least a quarter of a mile from the shore and from other ships. The sick must be placed in mosquito-proof rooms, the crew quarantined for at least six to seven days, and the whole ship disinfected by a Clayton's disinfector, preferably between 9 a.m. and 3 p.m., while the mosquitoes are quiescent.

Dock-labourers working on suspected or disinfected ships should live in special gnat-proof buildings, and be under medical supervision.

With regard to an infected area, it must be remembered that *Stegomyia calopus* is essentially domestic in its habits, that it is active from 2 p.m. till early morning, but that it is quiescent between the hours of 9 a.m. and 2 p.m., when, therefore, visits can be made to infected areas without risk. Further, the mosquito is known to bite dead bodies and suck the blood, but this will seldom infect it, as a patient generally lives longer than the three days during which the disease can be communicated to the mosquito Lastly, it can pass through a screen with fifteen meshes, but not through one with twenty meshes to the inch.

The mosquito does not die after laying its eggs, but lives until it has laid seven batches *i.e.*, some thirty days. The eggs laid twelve days after infection are capable of carrying the infection into the second generation, which can spread the disease fourteen days after becoming imagines As the mosquito is believed to be non infective when it bites in the daytime, non immunes may visit an endemic area in the day with impunity, but must not stay late in the afternoon

When a person is moved from an infected room, disinfection should be begun at once. All cracks, openings, etc., should be closed with paper, and fumigation carried out, preferably by means of sulphur dioxide gas, or if there is an objection to this because of the damage it causes, pyrethrum may be used, but must be burned in the proportion of 1 pound to 1,000 cubic feet of air-space if the mosquitoes are to be merely stupefied, and 2 pounds if they are to be killed: or tobacco, 1 pound per 1,000 cubic feet, may be used.

In addition, if an epidemic is to be eradicated, cases must be at once notified to the central authority, and patients must be strictly treated in mosquito-proof rooms, and every person, immune or non immune, must use mosquito-curtains, while an anti-mosquito scheme on the lines mentioned under Malaria must be undertaken. Special care must, however, be taken to eradicate, after a careful survey, all the breeding-places, not forgetting those in old tins, cocoanut-shells, gutters, small pools, etc. In endemic areas, houses and public buildings should be rendered gnat proof Lastly, when an epidemic breaks out in any place, it may be taken for granted that the importation took place at least two to three weeks prior to the discovery, for this is the time required for the incubation of the germ in the mosquito and in man; and it may also be assumed that mild cases are probably being treated for influenza or malaria. Therefore a house-to-house visitation is almost necessary, in order to find out the extent of the outbreak.

Given a free hand and plenty of money, there should be no difficulty in dealing with a threatened epidemic, but the public must be won over to assist, and offenders must be fined for transgressions against sanitation, as is done by the Americans in Panama, the offences being the presence of mosquito larvæ, imperfect screening of the house, accumulation of water, etc.

The prophylactic measures may be summarized as follows:—

A. Where there is reason to believe that yellow fever is endemic.
(1) Segregation of non-immunes, partial or complete, town planning.
(2) Screening:—
  (*a*) The bed.
  (*b*) The veranda.
  (*c*) The house
(3) Systematic mosquito destruction:—
  (*a*) Removal of breeding places.
  (*b*) Screening of water cisterns.
  (*c*) Oiling.
  (*d*) Drainage.
  (*e*) Bush clearing.
(4) Education. Infliction of fines for transgressions
(5) Quarantine administration.
(6) Non-immunes only to visit endemic area in the daytime.

B. Where yellow fever has broken out.
(1) Removal of all non-immunes outside the infected area, and deflection of the traffic outside the infected area.
(2) Isolation of cases and suspected cases.
(3) Provision for isolation of contacts.
(4) Early notification.
(5) Fumigation.
(6) Emergency mosquito measures:—
  (*a*) Removal of receptacles.
  (*b*) Oiling.
  (*c*) Screening.
  (*d*) Drainage.
(7) Education:—
  (*a*) Lectures.
  (*b*) Meetings.
  (*c*) Pamphlets.
(8) General organization of the medical forces.

No anxiety need now be felt as to the spread of yellow fever to Asia though the Panama Canal has been opened, for it appears as though not merely yellow fever, but all infectious and contagious fevers are bound to be eradicated from the Canal zone under the able American rule.

CHAPTER XLIII

DENGUE AND ALLIED FEVERS

Dengue—Seven days' fever—Dengue-like fevers—References.

DENGUE.

Synonyms.—Febris Endemica cum Roseola, Exanthesis Athrosia, Knokkelkoorts Arthrodyme, Fièvre Rouge, and probably the 'seven days' fever.'

There are upwards of one hundred known synonyms for this fever, many of which refer to it as a form of rheumatism, or give it fanciful terms, such as 'breakbone' or 'breakheart,' 'broken wing' or 'giraffe fever.' It is sometimes called 'three days' fever,' a term by which pappataci fever is also known.

The word 'dengue' is said by Vambery to be of Arabic origin, and to mean weakness, but it might equally be of East African, Indian, or Spanish origin.

Definition. Dengue is a term covering one or more acute specific non-contagious fevers of unknown origin, but caused by a virus contained in the blood. It is characterized by two febrile paroxysms, separated by an intermission or remission, without jaundice, albuminuria, or hæmorrhages, and with a marked leucopenia, and a pulse which varies directly with the temperature. It is spread by the agency of *Stegomyia calopus* Meigen, 1818, and probably by *Culex fatigans* Wiedemann, 1828.

History.—It appears to have been first recognized at Batavia, in Java, in the year 1779, by Bylon, though it may have been noted by Pazzio previous to this in 1764-68 in an epidemic in Seville. It was soon discovered in other places, being found from 1779 to 1780 in Egypt, Arabia, Persia, and North America, and in 1784 in Spain, to which it appears to have come from the West Indies, and in 1818 in Peru. In 1824-28 it occurred all over the tropical and subtropical zones, and in 1830-70 it formed a series of large and small epidemics in the same regions. From 1871-73 there was an epidemic implicating East Africa, Egypt, Arabia, India, Burma, Indo-China, and China, and spreading later to America and North and West Africa—*i.e.*, practically to all the tropical regions. In 1876-88 it was epidemic in Hong Kong, Egypt, Syria, and the Mediterranean, and in the Fiji Islands in 1885, to which it was conveyed by a European suffering from the complaint. In 1889 it was especially prevalent in Asia Minor, Turkey, and Greece. From 1890 to 1895 there were outbreaks in Senegambia and Hong Kong, and in 1894 it was introduced into North Queensland. From 1895-96 there were epidemics in Bombay and in Charleston. In

1897-98 it was epidemic in Georgia, Florida, and Texas. In 1901 it occurred in Penang and Asia Minor; in 1902 in Hong Kong, Singapore, Madras, Rangoon, and Upper Burma. In 1906 it occurred in Saigong on a French warship, and recently it has been prevalent in Singapore, West Australia, and Ceylon. Manson says that an epidemic or pandemic takes place about once in twenty years.

The discovery of the disease, therefore, appears to have been first made by Pazzio and Bylon, and the first full clinical description given by Dickson in 1828.

The first attempt to find a causation for the disease was by McLaughlin in 1886, who found micrococci in the blood, but this was disproved by Klein, Wright, Crookshank, and Macfadyen. In 1903 Graham stated that he had observed small hyaline, unstainable rods or dots in the red blood corpuscles, which he considered to be protozoal parasites of the nature of Plasmodia. This discovery has been refuted by Carpenter and Sutton, Guiteras, Agramonte, Kiewiet de Jonge and Hahn, Still and Ashburn, and Craig. Graham fed *Culex fatigans* Wiedemann on patients suffering from dengue, and claimed to have found his parasites in these mosquitoes up to the fifth day after feeding. He did not find any oökinetes or oocysts, but he says he found spores in the cells of the salivary glands of the mosquitoes from forty eight hours to one month after they had fed on infected blood. Further, he states that he caused a typical attack of dengue by injecting subcutaneously a solution, in normal saline, of the salivary glands of a mosquito which had bitten a dengue fever patient twenty four hours previously. He only performed one experiment, because the illness caused was very severe, but he succeeded, after an incubation of four to six days, in infecting healthy people by the bites of mosquitoes (*Culex fatigans*) fed on dengue fever patients

Though Ashburn and Craig (in 1907) have not supported Graham by finding the parasite, they have supported him by proving that a typical attack of dengue can be produced by the intravenous inoculation of filtered and unfiltered blood from an infected patient, and that the disease can be, and usually is, transmitted by the bite of *Culex fatigans* Wiedemann.

In 1912 and 1913 Laloir drew attention to *Stegomyia calopus* as the carrier of dengue. Cleland, Bradley, and McDonald demonstrated that the virus of dengue fever was carried by *Stegomyia calopus*, in which it underwent development Archibald found that the same insect was the only possible carrier in certain parts of the Sudan. These observations support Legendre's earlier views with reference to Hanoi. The leucocytic formula has been carefully studied by Ashburn and Craig and by Archibald.

Climatology.—The history of the disease indicates roughly its geography, which lies mostly in the tropics, but can extend to the subtropical zones. Cases have been reported from Southern Europe. Its usual boundaries are 32° 47′ N. and 23° 23′ S., but during warm weather it may spread to 36° 10′ N., and even to

42° N. and 28° S. in exceptional cases. It is, therefore, a disease of tropical climates, and of warm weather in other climates. It appears to be favoured by low-lying lands near the sea, well supplied with water, and not to be found at high altitudes; but there are exceptions to this. It occurs in Australia, where it has appeared since 1885, and is common in the Anglo-Egyptian Sudan and along the Red Sea.

When the distribution of dengue is compared with that known for *Culex fatigans*, it will be seen that the two coincide most remarkably. In fact, at the present time it appears as though the geographical distribution depends upon the distribution of that insect, together with the importation or presence of infected persons.

Ætiology.—We are indebted to Graham and Ashburn and Craig, and to Cleland, Bradley, and McDonald, for our knowledge of the ætiology of this disease.

There appears to be no doubt that dengue fever is caused by some unknown living organism which requires over two days to increase so as to produce the symptoms of the disease when inoculated into human beings, and generally five to nine and a half days when produced by bites of an infected stegomyia.

Both Graham and Ardate have observed small bodies in the red blood-corpuscles, which are described as small, usually round, but sometimes elongated, bodies about one-fifth to one-third of the size of a red corpuscle. They divide up into minute granules, which become extra-corpuscular.

This organism exists in the blood, as can be shown by the intravenous injection of 20 c.c. of dengue fever blood producing typical attacks of the disease, the incubation usually being two to three days; but it is so small that it will pass through the pores of a filter which will retain *Micrococcus melitensis*, which is only 0·4 μ in diameter, as is demonstrated by the production of the disease by intravenous injections of filtered dengue fever blood, the incubation being two or three days, as before. It may also be present in the lymphatic glands, the gland juice being at times infective, as proved by experiments.

Blood is infective from two to eight days, but not after the fourteenth day, and the virus is said to be transmitted by the bites of *Culex fatigans*, which is thought to be an agent in the spread of the disease, but Cleland, Bradley, and McDonald's experiments have thrown considerable doubt on this. There may, however, be two distinct diseases, one caused by a stegomyia and one by a culex, the incubation period being about three days sixteen hours. It can also be transmitted by the bites of *Stegomyia calopus*, when, further, there is a natural immunity against the disease in some people, and also some degree of acquired immunity of unknown duration obtained by an attack.

The points in the ætiology which require further research are the nature of the organism and its chemical products; the changes, if any, which the parasite undergoes in the mosquito; the length of time during which the mosquito can carry the infection; whether any mosquito other than *Culex fatigans* and *Stegomyia calopus* can spread the disease; and how long the acquired immunity lasts in man. In conclusion, it may be said that there is no evidence of infection other than by the bite of mosquitoes, and there is no evidence that a monkey can be infected by inoculation.

Pathology.—There is but little that can be written on this subject, as the cause of the disease is unknown, and therefore, of course, its action cannot be explained.

Morbid Anatomy.—This appears restricted to the description of the complication which killed the person—viz., peritonitis or pleuritis.

Symptomatology.—The *incubation* period, judging from experimental infection by mosquito-bites, varies from three to six days in the case of culex, and five to nine and a half days in the case of stegomyia. Prodromata are usually absent, but general malaise may be felt during a period not exceeding three days before the onset.

The *attack* is usually sudden, and introduced by severe pain in some part of the body, or merely by the sensation of extreme fatigue, or by chilliness and shivering, or by deep flushing of the face. In children convulsions or delirium may usher in the illness. In any case the temperature rapidly rises, the pulse quickens, and the skin and mucosæ become markedly congested, especially about the face, mouth, and throat. The conjunctivæ are injected, the eyes watery, and sometimes vomiting and purging are also present. The disease now progresses for one, two, or three days, after which there is, as a rule, a remission or an intermission.

Course.—During this period the temperature rises to 103° to 106° F., and the pulse increases proportionately with the temperature to 90 to 120 per minute. Severe pains in the head, and especially in the eyeballs, are experienced, and, in addition, pains in different parts of the body, especially in the lumbar region and the legs. Often the joints are painful, usually without any sign of redness or swelling. This pain in the joints appears really to be due to the muscles in the neighbourhood, as the joint can often be passively moved without pain, while active movement induces almost agony. There are, however, rare cases in which the joints are affected, as is shown by redness and swelling. As regards the alimentary canal, the tongue is moist, but becomes covered with a white-creamy fur. There is no appetite, nausea and vomiting are not uncommon, and constipation or diarrhœa may be present. Enlargement of the cervical and axillary glands is present to the extent of 30 per cent. to 70 per cent. of the cases of some epidemics. The glands remain enlarged for some time, and may be tender on pressure. The juice of these glands has reproduced the disease in two out of three cases. The circulatory system is not affected, except that fainting occurs at times, while a sensation of præcordial discomfort or of suffocation may be complained of. Insomnia and delirium are not infrequent, but meningitis and neuritis must be uncommon if they occur at all, though hyperæsthesia of the skin may be observed. The skin shows the congestion already mentioned, which is not always present, being at times replaced by the opposite extreme of pallor. Jaundice, if it occurs, is rare. Hæmorrhages are rare, and will be mentioned as a complication. The changes in the blood have been carefully worked out by Ashburn and Craig. The erythrocytes are usually normal in appearance and number, but a few poikilocytes may be seen, while the hæmoglobin and colour-index are also normal. Leucopenia is so constant as to be of diagnostic importance, varying from 4,860 to 1,200, the average being 3,800 per cubic millimetre. The leucocytes are normal in appearance, but there is an increase of the large mononuclears and eosinophiles, and a decrease in the polymorphonuclear leucocytes. The urine appears to be usually quite normal, except that it is high-coloured, but may contain a minute trace of albumen, and in severe cases Guiteras says the diazo-reaction can be obtained.

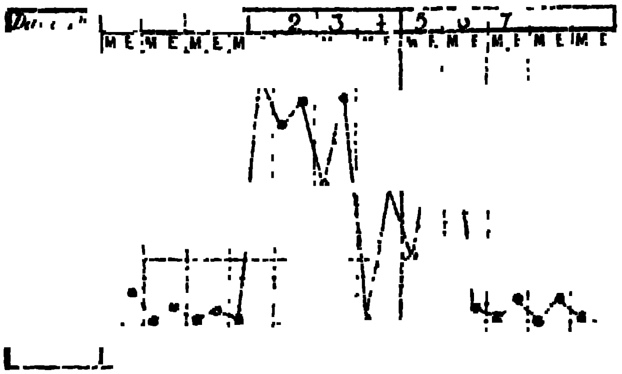

FIG. 630.—TYPICAL TEMPERATURE CHART OF DENGUE FEVER.

Intermission.—On the third day the temperature usually falls, but rarely reaches to normal. This fall may be accompanied by the usual signs of a crisis—namely, profuse perspiration, the passage of much urine, violent diarrhœa, and bleeding from the nose—but in many cases these signs may be absent. The patient now feels better, except for slight pains, and a genuine intermission in the disease is established. In other cases, however, this intermission may be entirely wanting, and the temperature may only remit, remaining at 100° to 102° F.

Second Attack.—The intermission or generally remission lasts until the fifth day of the illness, when the temperature rises to some point usually below 103° F., and at the same time a rash appears on the palms and backs of the hands, and rapidly spreads to the arms, the trunk, and the legs. This rash may be of two types—a measly eruption of small, circular, dark red maculo-papules, which almost entirely disappear on pressure, or a scarlatiniform eruption of close-set bright red points, which may coalesce and form large red patches. Eruptions intermediate in appearance between these two types may, however, be present, and occasionally only an abortive or no eruption at all occurs.

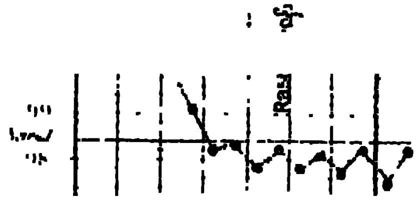

FIG. 631.—THE ATYPICAL TEMPERATURE CHART OF DENGUE FEVER.

This rise of temperature may last from a few hours to a day, and generally declines by crisis, with or without perspiration, on the sixth day. The skin eruption usually lasts from two to eight days, after which occasionally there is a desquamation, which may continue for two to three weeks.

The typical disease shows a first attack, a remission or intermission, and a second attack, though the two attacks may become merged together. The typical rash may be absent, and sometimes the disease is so mild that it ends on the third day with the first crisis.

Convalescence may be quick and permanent, but, on the other hand, it may be protracted and complicated with sequelæ. Immunity is said to be complete twenty-four days after recovery from a typical attack.

Varieties.—It is now generally agreed that seven days' fever is merely a variety of dengue fever, and therefore for comparison we attach a description of it to this chapter.

Megaw distinguishes the following varieties:—

1. *The Evanescent Type*, with only a short slight attack of fever, and corresponds with one variety of the old *febricula*, and cannot be recognized except during an epidemic of dengue fever.

2. *The Interrupted Fever Type.*—This is the three days' fever, followed after one or two days of apyrexia with another attack, and is typical dengue fever. True intermission is, however, rare, a fever of the saddle-back type being much commoner.

3. *The Saddle-Back Type.*—This is the so-called seven days' fever.

4. *The Continued Fever Type.*—This is rare, and is characterized by a lack of the usual remission or intermission of the fever.

Complications.—The rarity of the symptoms of hæmorrhage may perhaps justify its mention as a complication. It takes place from the mucosæ, as already mentioned, of the nose, stomach, intestines, and uterus. Hyperpyrexia may occur as a complication, but is rare, and pleurisy, pericarditis, orchitis, endocarditis, and meningitis sometimes complicate the disease and alter its characteristics. We have seen enteric develop in three typical cases of dengue, and appendicitis in two cases.

Sequelæ.—The most important sequelæ are the pains in the joints and muscles, which worry patients considerably. This polyarthritis affects joints of all kinds, both small and large, and is associated with swellings, so that the condition is like rheumatism, but salicylates are useless. The severe type is rare, but is very distressing, and may last six to eight weeks or longer. It is not uncommon in a milder form, with pain in various joints and slight swelling, and in this condition may last for months.

Relapses are said to take place, but Ashburn and Craig doubt whether any occur a short time after an attack, as the persons who were supposed to relapse, in their experience, really suffered from malarial fever; for, as a matter of fact, there is an acquired immunity for some little time after an attack which prevents such relapses.

Reinfections.—These are not uncommon, and each attack may be quite typical, being associated with the rash.

Diagnosis.—This is based on the sudden onset with extremely severe muscular pain, the remission or intermission in the course of the fever on the third or fourth day, the rash generally appearing on the third to the sixth day. The diseases most likely to be mistaken for dengue are yellow fever, malaria, influenza, scarlet fever, measles, rheumatic fever, smallpox, tonsillitis, typhus, and pappataci fever.

Yellow fever is recognized by its slower pulse, jaundice, albumen in the urine, and hæmatemesis; *malaria* by its blood parasites; *influenza* by the absence, as a rule, of any eruptions and the presence of catarrhal symptoms; *scarlet fever* by the presence of the sore throat with enlarged cervical glands; *measles* by the catarrhal symptoms and the absence of the severe pains; *rheumatic fever* by the swelling of the joints; *smallpox* may be with difficulty recognized until the eruption comes out; and *tonsillitis* may be recognized by examining the throat. In the tropics, where *enteric* is frequently atypical and often begins suddenly, there may be difficulty during the first few days in distinguishing the two diseases. The very severe pains are, however, rare in enteric, and the course of the fever will clear the diagnosis. From *typhus* it may be diagnosed by the leucopenia. From *pappataci fever* it may be distinguished by the presence of the rash and the frequent rise of the temperature on the fourth to fifth day.

Prognosis.—This is quite good, as the mortality is usually nil, but in Australia it caused 1 death in 1,000 cases, especially in those under five and over sixty years of age.

Treatment.—No rational treatment can be given, as we do not know what the nature of the cause will prove to be. Symptoms must, however, be relieved. The fever and headache may be combated with cool sponging and cool applications; the pains by hypodermic injections of morphia or doses of Dover's powder: this will also relieve the nervous symptoms, which otherwise will require bromides. Antipyrin, phenacetin, and aspirin, may be administered with care, and the bowels should be opened by calomel. The diet must be low, and stimulants should not be given.

Prophylaxis.—Protection against mosquitoes, as described under Malaria, excluding, of course, quinine prophylaxis, is the correct method of preventing the disease.

SEVEN DAYS' FEVER.

Remarks.—In our opinion the seven days' fever is dengue or a variety of it. We have come to this conclusion after having had the opportunity of studying epidemics of dengue and of the so called seven days' fever in various countries.

History.—This disease was described by Rogers in 1905-08 as a sporadic fever of Indian seaport towns. It is probably identical with Crombie's simple continued fever, and, according to many observers, including ourselves, is a form of dengue.

Climatology.—So far, in India and Ceylon it has been found in towns in low-lying districts near the sea, and is believed not to spread inland. In Calcutta it occurs from May to September, and is very common in Colombo during the same months.

Ætiology.—Rogers found a motile bacillus related to the coli bacillus in the blood, which he thinks may possibly be the cause of the disease. It resembles the *Bacillus coli communis* in size and shape, and possesses flagella; is decolourized by Gram; produces a diffuse haziness in broth; slowly liquefies gelatine; grows on agar like *B. coli*; does not produce gas in glucose agar; nor gas, nor acid, in dextrose, lævulose, and maltose broths; nor does it ferment arabinose, galactose, saccharose, lactose, inulin, salicin, erythrite, mannite, or dulcite. It is agglutinated in 1 in 20 and 1 in 40 dilutions of the serum of seven days' fever patients. These observations have not been confirmed. Clayton suggests that the disease is carried by mosquitoes. The fever is commonly found among Europeans, and especially among people having to do with shipping, and also in new-comers.

Pathology.—The morbid anatomy is unknown, as the mortality is nil.

Symptomatology.—The incubation period is unknown, and no prodromal symptoms have been recorded. The invasion is sudden, with a rapid rise of temperature to 102° or 105° F., but the pulse is not as quick as it should be, compared with the temperature.

The face is flushed and the palpebral conjunctivæ injected, and some rose-coloured spots may appear on the skin. Pain is felt in the back and, less commonly, in the limbs. After the initial rise there is usually a gradual marked remission of the temperature for two to three days, when the fever again rises, producing the typical saddle-back remission. After the second rise the temperature gradually or quickly falls to normal, and the disease ends about the seventh to eighth day. There is generally frontal headache, and the tongue is furred on the dorsum, while the edges are red. Nausea and vomiting are not common; the bowels are usually normal, though constipation or diarrhœa may occur. The abdomen is often distended, and may be painful. The liver is usually normal, but may in a few cases be slightly enlarged, and the spleen is at times enlarged. The respiratory and circulatory organs are normal, except that the pulse is often slow as compared with the temperature.

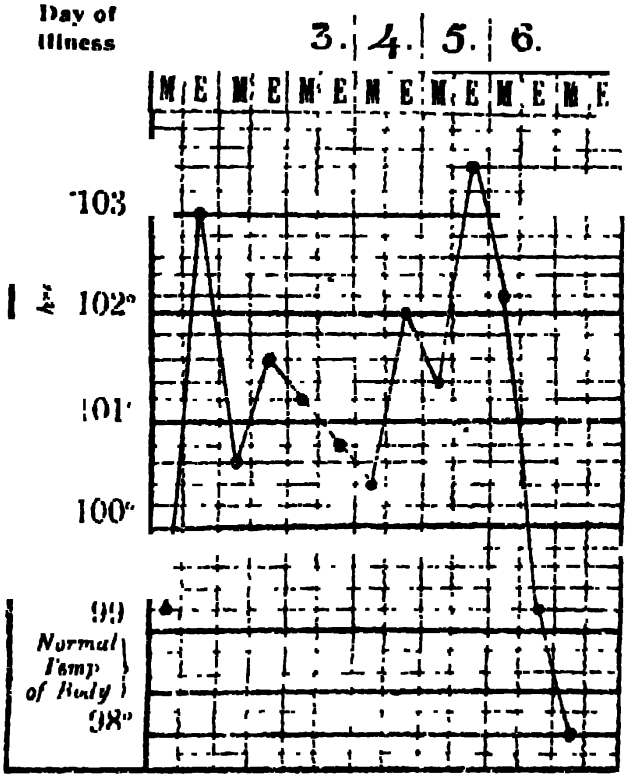

FIG. 632.—TEMPERATURE CHART OF A CASE OF SEVEN DAYS' FEVER.

The blood shows a slight reduction of the erythrocytes and a marked leucopenia—2,000 to 4,000 per c.c. The polymorphonuclear leucocytes are reduced, and the lymphocytes and mononuclears are increased. Nothing abnormal is found in the urine, except the usual appearance of febrile urine.

Rashes are frequent. The most common is a mottling or a diffuse erythema of the extensor surfaces of the forearms on the fourth to sixth day, which may fade before the temperature falls.

There are no complications or sequelæ, and the prognosis is excellent, as the mortality is nil. Mild recurrences in following years may be met with, but relapses in the same year, though rare, do occur, as we have met with such a case. Convalescence is rapid.

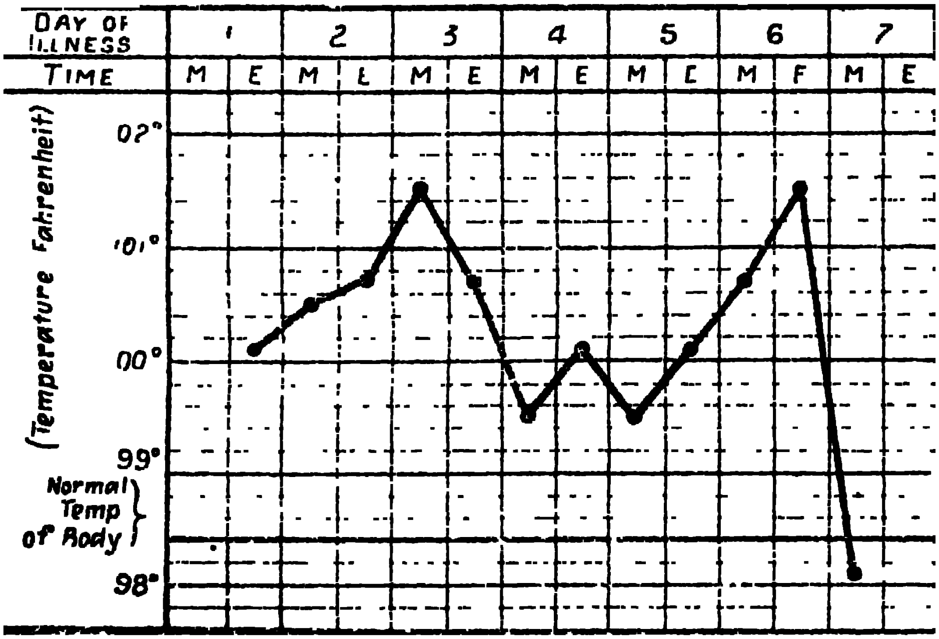

FIG. 633.—TEMPERATURE CHART OF A CASE OF SEVEN DAYS' FEVER.

Diagnosis.—It can be distinguished from malaria by the absence of parasites, and the slow pulse with high fever; from influenza by the absence of respiratory symptoms.

Treatment.—This is purely symptomatic.

DENGUE-LIKE FEVERS.

Synonym.—Climatic fevers.

Under this heading come the fever of the Antilles, the fever of the Red Sea, the six days' fever of Asia, the fever of Massowah, the six to eight days' fever of Aden described by Smith and Loughman, the six days' fever of the Canal zone in Panama described by Deeks, and the pseudo-dengue fever of Cochin China, which are all closely allied to dengue fever, lasting about seven days, and being associated with pains in different parts of the body, and having, in brief, the symptoms described above for seven days' fever or for dengue fever.

VAN DER SCHEER'S FEVER.

Synonym.—Five days' fever.

Definition.—A fever usually lasting for five days, and associated with an eruption of red macules and papules about the size of a pin's head, occurring on the trunk. It may be a form of dengue.

Remarks.—This fever, first described by van der Scheer, has also been investigated by Neeb, but its nature is at present not understood.

Symptomatology.—The illness begins suddenly with severe headache and backache, the temperature rising to 104° to 105° F. in the evening, but remitting considerably in the morning. Sometimes there is bilious vomiting and delirium. On the third day the eruption appears as macules or papules about the size of a pin's head on the chest, which spread to the back and abdomen. After five days' remittent fever the crisis comes on the sixth or seventh day, when the temperature rapidly falls below normal. This fall is accompanied by moderate sweating. In more severe cases the crisis is absent, and, cardiac failure setting in, the patient dies cyanosed.

Some days after the crisis there is a furfuraceous desquamation associated with pruritus on the palms of the hands and soles of the feet, and at the same time there is a considerable loss of hair and a bitter taste in the mouth.

Diagnosis.—It can be distinguished from malaria, relapsing fever, etc., by the absence of parasites in the blood, and from measles by the absence of the catarrhal symptoms, from scarlet fever by the absence of a sore throat, and from typical dengue fever by the temperature tracing.

Treatment.—The treatment is purely symptomatic, but it is recommended that injections of caffeine be administered on the sixth day to prevent a possible attack of cardiac failure.

IM-PYENG.

According to Landis and Matignon, there exists in Corea a fever called by the inhabitants Im-Pyeng. It is most frequently met with in the country districts from February or March to July, when it is most common among the poor, but affects all classes of society. It would appear to us to be allied to dengue fever.

Ætiology.—The causation is unknown, but it is regarded as contagious by the inhabitants of Corea. Matignon considered that it resembled relapsing fever, but was unable to find a *Spiroschaudinnia* in the blood.

Symptomatology.—The disease begins with headache, backache, or vague pains, which may become violent, while the temperature may rise to over 104° F. in the evening, but remits considerably in the morning, rising again in the evening to about 102° F., and again remitting considerably in the morning, and this fever may be accompanied with delirium. The fever continues for some seven to ten days, but usually after the sixth or seventh day the fever declines, and reaches normal in twenty-four to thirty six hours, this decline being associated with a profuse perspiration.

Sequelæ.—The patient is left with both general and cardiac weakness after an attack.

Treatment.—Quinine sulphate in association with antipyrin is the treatment usually adopted.

CHAPTER XLIV

PAPPATACI FEVER

Synonyms—Definition—History—Climatology—Ætiology—Pathology—Morbid anatomy—Symptomatology—Diagnosis—Prognosis—Treatment—Prophylaxis—References.

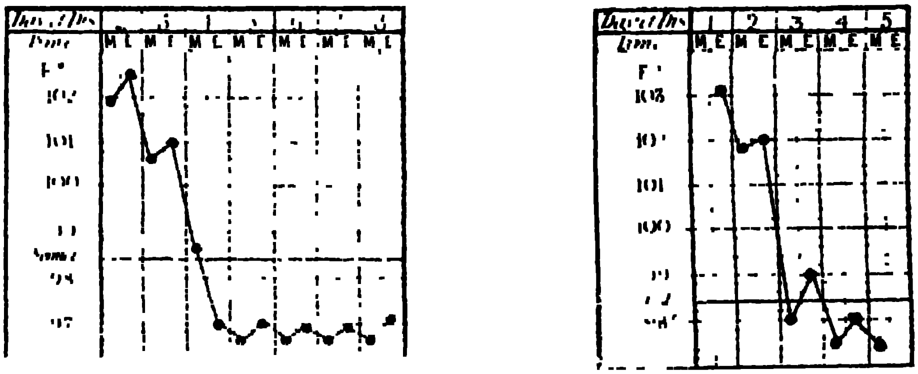
Synonyms.—Three days' fever, Phlebotomus fever, Sandfly fever, Summer fever. *French:* Fièvre des trois jours, Fièvre de Pick, Fièvre de Pym. *Italian:* Febbre gastrica, Febbre estiva, Febbre climatica, Influenza estiva, Influenza malarica, Mal della secca, Febbre dei tre giorni. *German:* Hundskrankheit, Sommerfieber, Endemischer Magenkatarrh. *Latin:* Febricula *pro parte*, Gastro-enteritis endemica, Gastro enteritis climatica.

Definition.—An acute specific fever of unknown causation, lasting three days, and characterized by nervous symptoms, pains in various parts of the body, and gastro intestinal disturbance, and spread by the agency of *Phlebotomus papatasii* Scopoli, 1786.

History.—In 1804 Pym described a fever of three days' duration as occurring in the Mediterranean basin, and this was confirmed by Burnett in 1816. From that time constant references may be found to this complaint in the English Army reports concerning Malta, where it was sometimes called 'summer fever.' In 1855-56 there was a considerable number of cases in that island, due to the passage of the troops *en route* to the Crimea. The fever was also described by Cicoli in 1871-75 in Pola, by Pick in 1887, by Karlinski in 1889, by Taussig, who was the first to suspect *P. papatasii*, in 1905, and in the same year by Panec. In 1903 McCarrison was the first observer to differentiate the disease, which he did in Chitral, when he suspected the sandfly as the causal agent. In 1907 it was noticed that although undulant fever had almost disappeared from Malta there were no less than 340 admissions for 'simple continued fever' into the Army hospitals, and in this year Gerrard and Marratt drew attention to this fever. In 1909 Doerr, Franz, and Taussig published their classical account of the ætiology and symptomatology of the disease, thus placing it upon a sound basis, and in the succeeding year Birt confirmed and extended these discoveries, and in the same year Tiraboschi found it in South America, and Phillips in Cairo. In 1911-12 Miorcec and Laplanchi found it in Crete, Niclot in Oran, Sergent in Biskra, Léger and Séquinaud in Corsica, and Wall described it again in Chitral. In 1915 Castellani found it in Serbia and Macedonia and showed that the so-called Skoplji or Uskub fever is pappataci fever. It occurs in Khartum.

Climatology.—It is found in all the countries bordering on the Mediterranean and Adriatic Seas, and it is known in India, Egypt, South America, and in South Africa (Cairs). It is possible that it may be found to be cosmopolitan in its distribution.

In temperate climates it only occurs in the summer months, and, when studied epidemiologically, it is found to be correlated with the distribution of *Phlebotomus papatasii*. How the infection is maintained during the winter months is not understood, as the imagines do not live through the winter, and as a relapse after a long period is unknown. Doerr believes that the female flies transmit the infection to their progeny, which in turn restart the disease during the succeeding summer. It is, however, by no means certain that the infective agent disappears from the blood when it ceases to be infective on inoculation



Figs. 634 and 635.—Temperature Charts of Pappataci Fever.

Ætiology. The causation of the fever is quite unknown, but the researches of Doerr, fully confirmed by Birt and others, have proved that a virus exists in the blood of patients suffering from the disease; that this virus is infective during the first day, and up to the end of the second day of the fever, but not later; that it is filterable through a Pasteur-Chamberland candle F; that *Phlebotomus papatasii* Scopoli, 1786, is the carrier of the disease, but does not become infective at once after feeding, but, on the contrary, is not infective under a week, after which it can convey the infection. This proves that the organism undergoes development in the fly. How long the fly remains infective is not known with certainty, as it usually dies after ten days' captivity, but it is probable that the disease is transmissible to young broods of flies. The incubation period of the experimental cases varied from three days sixteen hours to seven days, and a few of these cases showed only the gastro-intestinal symptoms, without any sign of fever. Animals have so far not been infected with fever except one small monkey by Tedeschi and Napolitani. Chalmers and O'Farrell have also infected a monkey by intravenous inoculation of human infected blood. It may be noted that phlebotomus can bite in the daytime and not merely at night.

Pathology.—Antibodies appear to be generated during an attack, as Doerr has shown that the serum from convalescents may neutralize infective serum; moreover, this action may be demonstrated during a period varying from one week to two years after an attack. An attack of fever confers a relative immunity, as relapses are seen, but reinfections are believed never to occur, and the natives of an endemic region are believed to be immune, possibly because there has been a previous attack during childhood.

Morbid Anatomy.—In the few post-mortems which have been performed, the signs exhibited have been those of the complication from which the patient died, as the disease *per se* is not fatal.

Symptomatology—*Incubation.*—The incubation varies from three to seven days. Prodromal symptoms in the form of malaise, vague pains, discomfort, and weariness, are generally present in India, but rare in Europe and Africa.

Attack.—The onset is sudden, with a slight rigor or a feeling of chilliness and severe frontal headache, lumbar and body pains. The conjunctivæ are injected and the cheeks slightly flushed. In a fairly large number of cases the flushing of the face and neck is extremely well marked, almost amounting to an erythematous rash. A peculiar feature of this symptom has been described by Castellani—viz., the flushing is persistent, lasting eight to fifteen days after the fever is over, and fades away so slowly that in many cases it is not difficult to diagnose the disease in persons convalescent therefrom. The skin is hot and dry, and the temperature rapidly rises, reaching 104° F., or rarely 105° F., in twenty-four hours. The pulse may reach 100 to 116, but is often unduly slow. The patient is very irritable, and intolerant to sounds. Movements of the eyes are painful, the conjunctivæ are injected, and often show a red band running from the cornea across the sclera. Sleep is impossible at times, but at other times the patient may be very drowsy. The tongue is coated on the dorsum with a white or brown fur, and the edges may be red. The appetite is lost and the sense of taste destroyed, but vomiting is uncommon, though there is pain in the epigastrium and sometimes diarrhœa. The mouth and throat are congested and irritable, and the gums may show a tendency to bleed, and there may be a little bronchitis. The cough is generally dry, with thick, tenacious, muco-purulent expectoration. The tonsils may be enlarged and the uvula congested, but this is not constant. Not only is there the congestion of the tonsils and pharynx, but the mucosa of the soft palate presents a peculiar appearance, showing small hyperæmic roundish spots. The eruption is sharply limited by a line of demarcation between the soft and hard palates. This appearance is not peculiar to the disease, being found in certain cases of relapsing fever, typhus, and malaria. It is rare in typhoid. The liver and spleen are normal. Vertigo and faintness may be present, and pains in the joints, especially in the elbow and knee, as well as in the bones and muscles, and burning sensations in the palms and soles. Cramps are not uncommon. Excitation is frequent, and delirium occasionally seen.

The blood shows a leucopenia—4,000 to 5,000 leucocytes per cubic millimetre—and the differential count is as follows:—

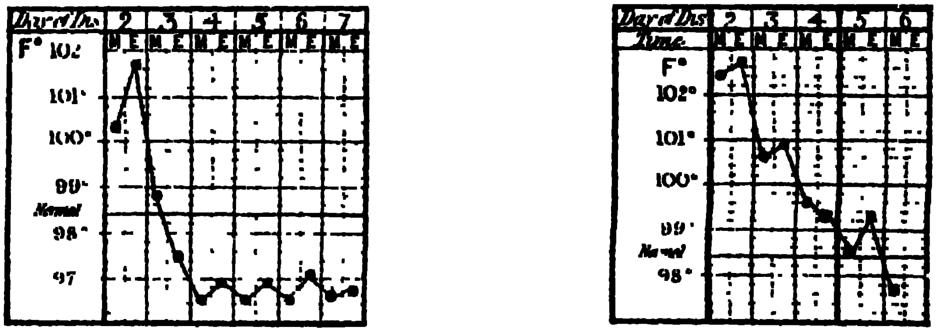
Polymorphonuclears	61·7
Lymphocytes	21·3
Mononuclears	14·0
Eosinophiles	2·7

The blood-pressure is normal during the attack, but somewhat diminished during convalescence.

The urine is diminished in quantity, but is of normal colour, specific gravity, and acid reaction, and does not contain albumen, except rarely, and then only a trace. Ehrlich's diazo-reaction is negative.

The skin is usually dry throughout, but profuse sweating may occur, and erythemata of a morbilliform or a multiform character may be seen, as well as a few roseolæ, but are very rare. A skin change, which starts at the commencement, is a delicate subcuticular mottling of the chest and abdomen, 'Cutis marmorata.'

Course.—In thirty-six to forty-eight hours the temperature falls to normal, but may show a terminal rise. This fall is often accompanied with epistaxis, more rarely with sweating, vomiting, or diarrhœa. When the temperature falls the symptoms abate, but much weakness is felt, the convalescence being prolonged. A post-critical rise is not very rare, and occasionally there may be a low irregular fever lasting for about a week and even longer.



FIGS. 636 AND 637.—TEMPERATURE CHARTS OF PAPPATACI FEVER.

Diagnosis.—In a country where sand-flies exist the disease may be diagnosed by (1) the sudden onset of the fever, ending on the third day without any roseolar-like rash; (2) rheumatoid pains all over the body, very well marked; (3) no enlargement of the spleen; (4) persistent erythematous flushing of face and neck after defervescence in 40-50 per cent. of cases—so-called Castellani's sign. There is, however, no certain sign for diagnosis except human inoculation, and as the incubation is so long the fever will have declared its character before the inoculated person develops the attack. Cuti- and ophthalmo-reactions have failed to be demonstrated. The *differential diagnosis* from malaria can be established by failing to find the parasite in the blood, and by the absence of enlargement of the spleen; from typhoid fever by the sudden onset; from influenza by the absence or mildness of catarrhal symptoms, the relative slowness of the pulse, and the leucopenia, but both diseases may exist together; from sunstroke by the absence of the severe symptoms, nervous symptoms, and the lower temperature; from dengue fever it can only be distinguished by the fever ending the third day, and by the absence of the rash. In countries where pappataci fever and typhus are endemic the diagnosis at the onset between these two fevers may be extremely difficult. Examine the blood: in pappataci there is generally leucopenia; in typhus no leucopenia, frequently leucocytosis.

Varieties.—An afebrile variety, with only headache and body pains, is described, as well as an abortive form lasting two days. Relapses and true reinfections may also occur.

Complications. -The complications are bronchitis and phlebitis.

Sequelæ.- Pains in the bones, neuritis, and a peculiar loss of memory may be sequelæ.

Prognosis.—This is good, as no one has been known to die of the uncomplicated complaint.

Treatment.—The treatment is purely symptomatic, and consists in sending the patient to bed, in administering a saline purgative, and following this by aspirin in 5 to 15 grain doses given three times a day. This treatment is said not merely to relieve the pains, but to render the attack milder. Pyramidon also promptly relieves the pains, while it has been recommended that the phlebotomus bite should be painted with tincture of iodine.

Franz and Kolar recommend the subcutaneous or intravenous injections of colloidal silver, but this hardly appears necessary in such a mild fever. Atoxyl has been found to be useless, and quinine to be harmful.

During convalescence a change of air and an iron tonic may be recommended.

Prophylaxis. - -The only obvious means of prophylaxis consists in isolating the sick and protecting them against the phlebotomus by means of mosquito curtains of a sufficiently fine mesh. It must be remembered that the little fly bites mostly in darkness, and chiefly in houses.

As regards ordinary prophylaxis, a fine mosquito curtain, together with the use of camphor, is to be tried. Fumigation by burning pyrethrum may also be tried.

CHAPTER XLV

THE AFRICAN TRYPANOSOMIASES

General remarks—The sleeping sicknesses—The trypanosome fevers—References.

GENERAL REMARKS.

THE human African trypanosomiases include two different clinical conditions—viz.—

A. The *sleeping sicknesses* characterized by the fact that we definitely know that the preliminary fever leads to meningo-encephalitis and meningo-myelitis.

B. The *trypanosome fevers* characterized by the fact that we do *not* know that in these cases the disease will end in meningo-encephalitis and meningo-myelitis.

Before Castellani discovered a trypanosome in sleeping sickness, Ford and Dutton had demonstrated that 'Gambia fever' was due to a trypanosome. After this discovery this disease was named 'trypanosome fever,' and was considered to be quite distinct from sleeping sickness. After Castellani had found a trypanosome in sleeping sickness the two diseases, trypanosome fever and sleeping sickness, were at the time judged to be covered by the one name 'sleeping sickness.' Recently, however, *Lanfranchi's laboratory infection* with a trypanosome has lasted for more than seven years, and there is no sign of meningo-encephalitis, as may be judged *inter alia* by the excellent papers which the distinguished professor produces. In fact, judging by the symptoms exhibited by Lanfranchi, which resemble those found in the trypanosomiases of animals, it seems very doubtful whether he will ever show signs of what we clinically call 'sleeping sickness.' Further, the organism with which he is affected appears to be of the *Evansi type*, a form known to be in his laboratory when infection took place.

Under these circumstances, it appears to us to be useful to return to the old name *trypanosome fever* for infections of man and animals with those pathogenic trypanosomes which produce fever and do not end in meningo-myelitis. At present those known in man are the case of Professor Lanfranchi and the infection with a variety of the *Vivax* type described by Macfie, both of which, in our opinion, should remain under this denomination until it is proved that they belong to the sleeping sickness group.

THE SLEEPING SICKNESSES.

Synonyms.—Sleeping dropsy, Negro lethargy, Morbus dormitivus. *French:* Maladie du Sommeil. *Portuguese:* Doença de Sonno. *Italian:* Malattia del Sonno, Letargia dei Negri. *German:* Afrikanische Schlafkrankheit, Trypanosomen Fieber. Native names are very numerous—Lalangola, Láá La-negulo, N'tansi, Mongota, Kónje Márree, Kaodzera, N'dulu, Tula Manugina, Nelavare, Dadane, Toruahebue, etc.

Definition.—The sleeping sicknesses are chronic specific fevers caused by the trypanosomes *Castellanella gambiensis* Dutton, 1902; *Castellanella castellanii* Kruse, 1903, spread by *Glossina palpalis*; and *Castellanella rhodesiensis* Stephens and Fantham, 1910, spread by *Glossina morsitans*, characterized by an inflammatory condition of the lymphatic system leading to a meningo-encephalitis which shows itself as dulness of the intellect, apathy, and lethargy, associated with tremors and a peculiar gait, and unless treated ending fatally.

Remarks.—This chapter should be read in conjunction with Chapter XIX. (p. 380), in which we have outlined a new classification of the trypanosomes with the view of crystallizing the knowledge obtained up to date with regard to these parasites. In so doing we have been compelled to introduce new terms, which we have made as few as possible by utilizing those found in the literature with which we are acquainted. Two of these new terms occur in this chapter, because we have gone more fully into the trypanosomes of man than into those of animals, because this is a work on tropical medicine and not upon trypanosomes, and because those of man are the forms which have been most satisfactorily studied.

Chalmers has introduced the name *Castellanella* as the generic name for the group of trypanosomes which includes the organisms of sleeping sickness, because *Castellanella castellanii* (Kruse, 1903)—synonym, *Trypanosoma castellanii* Kruse, 1903– is the organism upon which practically all the work in connection with sleeping sickness was done prior to the discovery of *C. rhodesiensis*, which is quite distinct from the other two forms.

This is a point not generally recognized, nor is it realized that though *C. castellanii* and *C. gambiensis* are morphologically alike, they may be very different if studied carefully from a pathological and serological point of view, as there is a suspicion that the well-known difference in type between the milder form of the disease as seen in portions of the West Coast of Africa and the severer as seen in Uganda may not be due to acquired partial immunity, but to a difference in the two organisms.

In order to emphasize the necessity for further work with regard to *C. gambiensis*, we have isolated it from *C. castellanii*.

We would also point out that in the few papers in which comparisons have been made with regard to the pathological effects of *C. castellanii* as found in sleeping sickness and *C. gambiensis* as found in trypanosome fever, they both refer to *C. castellanii* obtained from cases in Uganda showing at the time signs of sleeping sickness or simply symptoms of trypanosome fever.

It appears to us that *Castellanella gambiensis* as seen on the West Coast of Africa, and as originally described by Dutton and Todd, requires more study, and we are supported in this by Macfie's work with regard to *C. nigeriensis*, which we believe to be the same organism, and by the observations of Yorke and Blacklock at Sierra Leone.

To summarize, we believe that though *C. gambiensis* and *C. castellanii* are morphologically similar, the clinical difference between the milder form of the disease as seen on the West Coast of Africa and the terribly severe form found in Uganda is such as to demand the separation of these two forms until it is proved that they are really identical from a pathogenicity and serological point of view.

History.—The earliest mention of sleeping sickness so far discovered is by John Atkins, in his little book entitled 'The Navy Surgeon,' published in 1734, in the appendix to which he describes 'the sleeping distemper,' common among the negroes on the Guinea Coast among whom he had travelled in 1721. In 1803 Winterbottom gave an interesting account of the disease as he met with it on the West Coast of Africa near Sierra Leone. His description is quite understandable, and he draws attention to the presence of the enlarged glands of the neck, the association of which with the disease was so well understood that slave-traders would not buy slaves who had enlarged glands.

In 1808 Moreau de Jonnès described the disease in negro slaves in the Antilles. In 1849 Clarke on the Gold Coast, Davis and Daniell on the Guinea Coast, and Ferreira, came across it at St. Thomas. During the next twenty years a number of observers described sleeping sickness, among whom it is important to note that Guérin met with it in 1869 in Martinique in negro slaves who had been imported from Africa. In 1876 Corre gave a good description of the disease as he knew it in Senegal.

In 1891 the first case was brought to London, and was studied by Sir Stephen Mackenzie; and in 1900 two more cases were brought to London, this time under the care of Sir Patrick Manson. The morbid anatomy of these cases was carefully studied by Dr. Mott, who has done so much to clear up the pathology of this disorder.

In 1901 Forde and Dutton found a trypanosome *T. gambiense* (*C. gambiensis*) Dutton, 1902, in the blood of a patient suffering from a peculiar type of fever on the Gambia (Gambia fever, Dutton's disease), which was never thought by them to be connected with sleeping sickness. In 1902-03 Castellani in Uganda found a trypanosome in the cerebro-spinal fluid of persons suffering from sleeping sickness, and in 1903 reported that it was the ætiological basis of the disease. It was named *Trypanosoma castellanii* by Kruse in 1903, and on it most of the work with regard to sleeping sickness has been done prior to the discovery of Stephens and Fantham's organism. Low and Castellani gave a clinical account of the disorder which is largely followed in this chapter, which, therefore, contains a clinical account of the illness produced by *C. castellanii*. Low and Castellani called attention to two constant symptoms which had not been remarked by previous observers, the fever and the peculiar tremors; and Christy published many interesting epidemiological features concerning the disease. In 1903 Sir David Bruce and Nabarro showed that the trypanosome was spread by *Glossina palpalis* Robineau-Desvoidy, a conclusion already reached by Sambon and Brumpt on epidemiological grounds. From 1903-05 much clinical, experimental, and epidemiological work was done by Dutton, Todd, and Christy, the Commissions of the Royal Society and various Governments, and by the members of the Liverpool School of Tropical Medicine. Kleine, in a series of important researches, has experimentally shown that *C. castellanii* undergoes a cycle of development in *G. palpalis*—a fact which has been fully confirmed and extended by Sir David and Lady Bruce, Hamerton and Mackie, and Miss Robertson, as well as Fraser and Duke.

Koch, Laveran, Mesnil, Minchin, Blanchard, Greig, Gray, Tulloch, Kinghorn, Montgomery, Martin, Pittaluga, Lebœuf, and Roubaud, have all studied the disease and its epidemiology, and an International Conference was held in 1907 in London, and a Bureau for the study of the disease founded. This bureau for some time issued monthly bulletins, which are most valuable to the student of the disease: but recently it has become converted into the Bureau of Tropical Diseases.

In 1910 Stephens and Fantham created a new species of trypanosome (*C. rhodesiensis* Stephens and Fantham, 1910) for the parasites found in cases of sleeping sickness in the Luangeva Valley in Rhodesia, because the trophonucleus of a certain percentage of short forms was situate either close to, or even on the aflagellar side of, the kinetonucleus. In 1912 Kinghorn and Yorke showed that this trypanosome was transmissible by *G. morsitans* Westwood, 1850; and in the same year these observers pointed out the importance of the meteorological conditions on the development of the trypanosome in the fly. Further work has been done by Sanderson, Murray, Shircore, and others. As regards the history of the treatment, arsenic was long ago considered beneficial for the trypanosomiases of animals, Livingstone being the first to apply the drug to a horse for the purpose of treating nagana. Since then it has been used for the same purpose by several persons, notably by Lingard (1893) for surra and by Bruce (1896) for nagana, while Laveran and Mesnil introduced sodium arseniate in 1902 for the same disease, E. J. Moore and Chichester advocated the use of hypodermic injections of arsenic, and Thomas and Breinl of the same of sodium arseniate. In the meanwhile Manson had treated several cases of sleeping sickness with arsenic (liquor arsenicalis); and Ehrlich and Shiga had treated various experimental trypanosomiases with colouring compounds belonging to the benzo-purpurin group, of which trypan-red is the best known. Laveran and Mesnil also did some valuable researches on the subject. Thomas, in 1905, first brought the drug 'atoxyl' to the notice of the profession as a means of treatment of experimental trypanosome affections; and Kopke, in 1906, tried it in human beings affected with sleeping sickness.

The beneficial action of atoxyl in sleeping sickness was further confirmed by Broden, van Campenhout, Manson, Koch, and many others. In 1907 Ehrlich and his pupils, Franke and Roehl, discovered the very important fact that trypanosomes may, after a time, become atoxyl-resistant. Ehrlich therefore suggested mixed or alternating treatment with various preparations, and the same suggestion, though based on different grounds, was made by Moore, Nierenstein, and Todd. Plimmer and Thomas introduced tartar emetic, which has been found to be very beneficial, especially if associated with the atoxyl treatment.

Geography and Epidemiology.—The disease was first noticed on the West Coast of Africa at Sierra Leone, but was soon found to extend far southwards, and was also noted to be imported from this endemic area at times to the West Indies, where, however, it soon died out, becoming neither epidemic nor endemic. This fact clearly proved that, though the disease may be introduced by man along channels of intercommunication into a strange country, some other factor is necessary before it can spread from the infected new-comer to the inhabitants. This factor we now know to be a tsetse-fly.

In 1882 the disease had a geographical distribution from Senegal to Loando, and also to the islands of the Gulf of Guinea. Gradually, as civilization spread, it became known that the disease was not confined [illegible] coast but extended far [illegible] in 1898 was known to be at Jebba, on the Upper Niger, and at the Stanley Falls, on the Upper Congo. In the meanwhile Stanley had travelled across Africa with a large number of Congolese followers, and had relieved Emin Pasha and his people at Wadelai, on the Victoria Nile. These followers of Emin Pasha, together with some of Stanley's expedition, who had settled in the country about Kavali, to the west of the Albert Nyanza, were brought by Sir F. Lugard, for political reasons, to Busoga and Uganda. Christy and Hodges believe that the disease was carried from the Congo by Stanley's men, and that they and Emin Pasha's people brought the disease with them into Busoga and Uganda when they were moved from Kavali. But the fact is clear that when, in 1900, the Cooks first noticed the disease in Uganda, it was widespread, and had been there for some time, and it seems probable that Busoga was infected in 1896. Certainly, in 1901, Mengo, the Sese Islands, and the western shores of the Victoria Nyanza, were infected, and the disease spread in 1902 to the eastern shores and to late German East Africa.

In 1904-05 Dutton and Todd found that it had become widely disseminated throughout the Congo Free State, spreading by human agency along trade routes, and expressed the opinion that before long it would pass from the Congo into Eastern Rhodesia. Since then sleeping sickness has been found in that country, though, the trypanosome found in Rhodesia being a different species, it is more probable that the disease has been endemic there, and not recognized for a long time. It appears also to be spreading northwards from Uganda, for Greig, in 1904, found it at Wadelai, on the Victoria Nile, but not as high as Nimuli. It invaded the Lado earlier than 1908, and in 1909 the disease was recognized definitely in the Bahr-el-Ghazal Province of the Sudan.

Therefore the distribution of the disease at the present time may be said to extend along the West Coast of Africa; from St. Louis, in Senegal, to Mossamedes, in Angola; from the coast to Timbuktu on the Niger; through the whole of the Congo into Uganda and Rhodesia; from Uganda and Busoga southwards to late German East Africa; and northwards into the Bahr-el-Ghazal Province. The discovery of the tsetse-fly in Arabia makes it possible that the disease may some day still farther extend its area.

There does not appear to be any seasonal influence.

Ætiology.—From the present state of our knowledge it would appear that from a clinical and ætiological point of view there are three types of sleeping sickness, which may be differentiated as follows:—

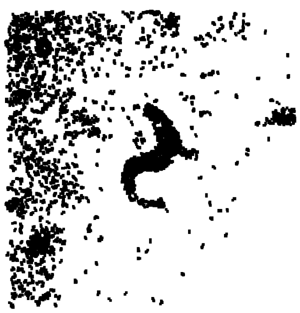

FIG. 638.—TRYPANOSOMA IN CEREBRO-SPINAL FLUID.

Preparation from the cerebro-spinal fluid of a case of sleeping sickness.

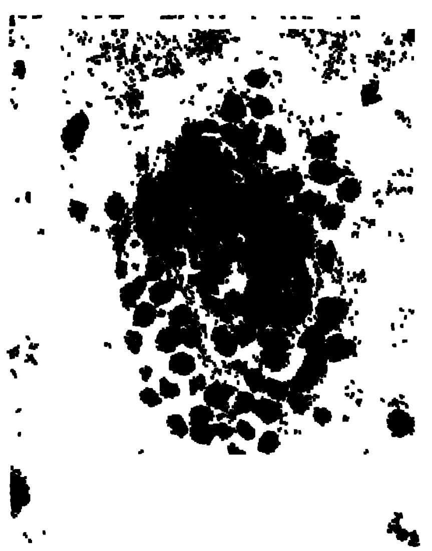

FIG. 638A.—LYMPHOCYTIC ACCUMULATION AROUND A VESSEL IN THE BRAIN.

I. *The Equatorial type*, caused by *Castellanella castellanii* and spread by *Glossina palpalis*.

II. *The Southern type*, caused by *Castellanella rhodesiensis* and spread by *Glossina morsitans*.

III. *The North-Western type*, caused by *Castellanella gambiensis* (synonym, *C. nigeriensis*) and spread by some as yet not clearly differentiated tsetse-fly, which may or may not be *Glossina palpalis*, and which Dutton suggested might possibly be *G. lachinoides*.

For description of the parasites, see p. 417.

Duke's researches made it possible that there is a vertebrate reservoir for *C. castellanii* in the antelope, because he found a trypanosome very like this organism in these animals, and because some boys working on an uninhabited island in Lake Victoria became infected with sleeping sickness. We feel, however, that the proof is not quite absolute with regard to this point.

Yorke and Blacklock with regard to *C. gambiensis* find that man is the principal vertebrate reservoir, with a possible secondary reservoir in domestic cattle.

With regard to *C. rhodesiensis*, as long as the view held that this was identical with *C. brucei* there was no difficulty in believing that the vertebrate reservoir was in such animals as the hartebeest, water-hogs, and domestic dogs; but with the human, crossed immunity, and serological experiments detailed on page 426, it again becomes evident that these two trypanosomes are distinct, and therefore the question as to the existence of *C. rhodesiensis* in game animals must again be considered as *sub judice*. The confusion has arisen by trusting too implicitly to only morphological characters, and ignoring serological tests.

In Chapters XIX., p. 388, and XXXV., p. 878, we have considered the tsetse in relationship to its carriage of these organisms, and in Chapter XXXIII., p. 837, we have described these flies. *C. castellanii* is spread by the agency of *Glossina palpalis* and *C. rhodesiensis* by *Glossina morsitans*, but it is not proved by actual experiment what fly carries *C. gambiensis*. It is *assumed* that it is *Glossina palpalis*, but the subject obviously requires careful study.

The tsetse flies obtain the trypanosomes by sucking infective human blood containing the organisms, which undergo development in the bodies of the flies. In due time (*vide* Chapter XIX.) the young trypanosomes in short form appear in the salivary glands of the tsetse-fly, and from these organs they pass into man when the fly next feeds upon him.

The fly appears to be the definitive host of the trypanosome, but there is no evidence that the infection is passed on to the succeeding generation.

From a practical point of view the bite of the infected tsetse is the most important method of infection, but less important methods, such as sexual intercourse, are possible and must be remembered.

With regard to *predisposing causes*, race, sex, and age have not been proved to have any influence, though the last two have been thought to be predisposing causes.

Occupation, however, has a considerable influence, for persons who live near the shores or work along the shores of lakes and streams, such as fishermen, are more liable than others to contract the disease, because of the habits of the fly, while porters marching through fly-zones are also liable to be attacked.

Pathology.—The trypanosome either enters the lymph-stream directly after the bite of the fly, and is blocked in the lymphatic glands, which it inflames, and through which it passes to the blood-stream and cerebro-spinal fluid, or, less probably, it enters the blood-stream first, and escapes by rupture of a capillary into a lymph-gland. But the polyadenitis is not the only change induced, for the lymphatic tissues of the intestine (solitary or agminated glands) are also inflamed, and the heart and other organs infiltrated with lymphocytes. This stage is marked by fever, but sooner or later, as a result of this lymphatic disease, changes are induced in the membranes and substances of the brain and spinal cord (chronic meningo-encephalitis and meningo-myelitis), especially along the course of the vessels, which result in the proliferation of the neuroglia and in a lymphocytic accumulation around the vessels. These two processes compress the vessels, and lessen the supply of blood to the cells of the brain and spinal cord, in which, as the result of malnutrition, changes ensue, which produce the typical symptoms of the cerebral stage of the disease, which is often called 'sleeping sickness.' The trypanosome apparently cannot pass through the placenta, as infected women give birth to healthy babies.

Towards the end secondary infections with bacteria may take place, the most constant of these being due to streptococci and the pneumococcus, which probably shorten the life of the patient.

Cerebro-Spinal Fluid. - The cerebro-spinal fluid was first studied by Castellani, and it may be noted here that it was during his researches on the leucocytic formula that he discovered trypanosomes for the first time in sleeping sickness. More recent researches are those by Broden and Rodham and others. During the first stage of the disease it is usually of normal appearance and clear, while on centrifugalization there is practically no sediment, though occasionally a few small mononuclear cells may be present, and trypanosomes are, as a rule, absent.

In the sleeping sickness stage it is often slightly turbid, and contains an amount of serum albumen and serum globulin: and on centrifugalization some sediment is obtained, consisting of a few cells, which are mostly mononuclear leucocytes, endothelial-like and vacuolated cells, while trypanosomes are almost constantly present, and also often aflagellate, roundish, or oval forms, with one or two chromatin masses, as described by one of us in 1903. These may probably be compared to the so-called latent forms described in the spleen by Breinl and others, though Laveran and other authorities consider them to be degenerated or fragmented forms.

Morbid Anatomy and Histopathology.- The macroscopical changes found post mortem are principally in the central nervous system and in the lymphatic glands, but pathological changes brought about by complications may also be noted.

The body is usually emaciated and anæmic, rigor mortis is well marked, and the skin may be normal, or dry and desquamating, or may show pustular eruptions on the hands and forearms, or ulcers on the feet which are generally due to jiggers (*Dermatophilus penetrans*). Enlargement of the lymphatic glands of the neck and groins is generally easily seen. On opening the brain-case, it will be noted that the under surface of the scalp is pale, that the dura mater may or may not be adherent to the bone, that the cerebro-spinal fluid is increased in quantity, and the gyri of the brain are often flattened. On careful examination, the pia arachnoid will be found to be thickened in places, and may or may not be adherent to the grey matter. The brain substance, which is generally firmer than normal, but may be soft and œdematous, is usually congested, and the fluid in the ventricles is increased.

With regard to the spinal cord, it will be seen that there is an increase of fluid, which, if examined with the microscope after centrifugalization, generally shows leucocytes and trypanosomes. The cauda equina may be found at times surrounded by gelatinous tissue. The cord itself is often congested, and hæmorrhages have been described.

The lymphatic glands of the submaxillary region, anterior and posterior triangles, around the bronchi, of the mesentery, behind the peritoneum, as well as those of the inguinal and femoral regions, may one or all be enlarged, congested, and even hæmorrhagic. At times abscesses are found in these glands, but they are due to secondary infection. The abdominal cavity often contains some straw-coloured fluid, and the pericardial fluid may also be excessive. There may be some increase in size of the lymph-follicles and Peyer's patches of the small intestine. The lungs may show signs of pneumonia and other complications. The other organs are usually not markedly affected.

The microscopical examination of the organs has been performed with the greatest care by Mott and Breinl and the members of the Portuguese Commission (Bettencourt, Kopke, Rezeide, and Maude).

The utmost care must be taken to distinguish between the lesions due to the trypanosomes and those caused by terminal infections such as the diplococci, streptococci, and colon bacilli; for these infections may give rise to chromatolysis in the nerve cells and degeneration in the nerve fibres of the brain (pons and medulla) and spinal cord (especially in the posterior and lateral columns), and perhaps in the peripheral nerves, which have nothing to do with the disease in question. With this proviso the microscopical examination is characterized by a round-celled infiltration surrounding the vessels of the pia arachnoid of the brain and spinal cord. This infiltration, first described by Mott, is best seen in the membranes, where there is an accumulation of cerebro-spinal fluid, and in the brain, around the vessels of the medulla, pons, cerebellum, and those entering the base. The process appears to begin with a growth in size, and then a proliferation of the neuroglia elements, which has been minutely described by Eisath, and is found, not merely around vessels, which show a small-celled infiltration, but around those which do not. Round cells are found later in the meshes of this proliferated glia.

These cells are (*a*) lymphocytes; (*b*) peculiar cells called the 'plasma cells of Marschalkó,' characterized by the nucleus becoming situated at one end of the cell, and staining blue with methylene blue and eosine, while a clear halo separates it from the cytoplasm, which stains pink; (*c*) 'morula cells of Mott,' which are large round or oval cells with an excentric blue nucleus and a cytoplasm containing a clear eosinophile area; (*d*) a few mononuclear leucocytes; (*e*) a few polymorphonuclear leucocytes. The cells of Marschalkó are considered by Mott to be derived from lymphocytes, and the morula cells to be degenerated cells of Marschalkó. Mott considers that the lymphocytes are probably formed by proliferation of the endothelial cells of the perivascular lymphatic space. According to Breinl, a layer of blood cells may be found external to the round cells, and hæmorrhages may be found in the cord. The ependyma of the lateral ventricle also shows a proliferation and dense fibrous formation at times. With regard to the parenchymatous elements, Mott considers that there may be increase in neuroglial nuclei and lymphocytes in the perineural spaces, while there is atrophy of the dendrons and diminution of the Nissl bodies, and alteration in the nucleus, which becomes large, clear, and excentric. These changes are most marked in the cerebral cortex and medulla, and less so in the spinal cord. The cells of the posterior spinal ganglion, however, show chromatolysis. The central canal of the spinal cord may be dilated, but is more generally occluded by proliferation of the cells of the ependyma. It is interesting to note that Mott did not find any of these changes in the brain and spinal cord of a cured case of trypanosomiasis, who died several years later of cystic disease.

The histological lesions of the encephalitis found in sleeping sickness closely resemble those of general paralysis and encephalitis lethargica (nona).

The next series of characteristic changes are in the lymphatic glands, in which trypanosomes are often found. These changes begin with a conversion of the lymphocytes into cells of Marschalkó, and these, again, into morula cells. The endothelial cells of the lymph sinus proliferate and take on a phagocytic action, containing lymphocytes, red blood cells, and chromatin particles. At the same time the gland becomes intensely congested, and the fibrous tissue of the capsule and septa proliferates, so that they and the walls of the lymph sinuses and of the vessels become thickened.

A lymph nodule therefore appears to be surrounded by a fine connective meshwork, containing few lymphocytes, but many red corpuscles and phagocytes. As time goes on, the inflammation in the gland subsides, and it becomes less vascular, firm, and hard, and full of dense fibrous tissue. Secondary infection, however, may occur with the formation of abscesses.

Microscopically, the lungs may be found to be hyperæmic, even when normal, to the naked eye, while the complication of pneumonia will give rise to the usual appearances. The heart shows small-celled infiltration in all its layers, with sometimes hæmorrhages. Vianna has noted in animals infected with *C. castellanii* cysts in the muscles similar to those of *S. cruzi*, and appears to have found them also in the muscular and nervous tissues from a case of sleeping sickness. The liver and spleen may show thickening of the capsule, while the latter is very congested, and its trabeculæ are increased in thickness. In natives signs of chronic malaria are almost constantly present in the spleen and liver. The bone-marrow may be very cellular, with congested vessels and hæmorrhages.

Stevenson and others have found trypanosomes scattered through the brain substance in no special relation to the capillaries and smaller bloodvessels in animals inoculated with *Castellanella gambiensis* (*nigeriensis*) and other trypanosomes.

Symptomatology.—The course of the disease may be roughly divided into three stages—the incubation, the febrile, called also glandular stage, and the cerebral stage.

Incubation.—The duration of the incubation period is not certainly known in man, but may be considerably shorter than was believed by the old authors: probably in most cases it does not exceed two or three weeks, and, according to Martin and Lebœuf's observations in Europeans, it may be even less than ten days. On the other hand, some infected individuals may not show any sign of disease for months, and, it is said, even five or six years. The bite of the infected *Glossina* gives rise, as a rule, only to very slight local irritation, which quickly subsides, and is often overlooked by the patient.

Febrile or Glandular Stage.—The onset of the disease is characterized by attacks of fever almost constantly associated in Europeans with an erythematous eruption. This fever lasts about a week, and disappears, to recur again later for the same or much longer periods. It is generally of an intermittent or remittent type. During an attack the pulse-rate and the respirations are increased, and there is often enlargement of the liver and spleen, though how much of this may be due to recurrent malaria is not known; the pulse often remain rapid during the apyrexial periods. Neuralgic pains and headache may also be complained of.

FIG. 639.—NEGRO PATIENT IN THE LATE STAGE OF SLEEPING SICKNESS.

An erythematous eruption is often found on Europeans. It begins, as a rule, with badly defined, pinkish patches, which clear in the centre until a ring is produced; if a portion of the ring fades a crescent may be produced. This circinate eruption may appear on any part of the body, but is especially frequent on the trunk; in some cases, instead of rings, solid infiltrated patches, the size of a half-crown or larger, are present. Rubeloid spots and a mottled appearance of the skin are not rare. A vesiculo-papular eruption has also been described, but is rare in our experience. Dermatographia is common in Europeans. In full-blooded negroes the erythematous eruption may not be noticeable; in them very often a dry, scaly condition of the skin is found. These various eruptions are called *Trypanides*. Patches of localized œdema may be seen in some cases.

The most typical sign of the disease in this stage is enlargement of one or more lymphatic glands, especially those of the neck, in the posterior triangle (Winterbottom's sign.) The enlarged glands are in this period generally fusiform, and of rather soft consistency. Another early symptom, noted by Kerandel, is a general, intense, deep hyperæsthesia. As repeated attacks of fever increase, the patient may become anæmic and asthenic, but the febrile condition may last for years, and, indeed, in this stage the disease may be cured.

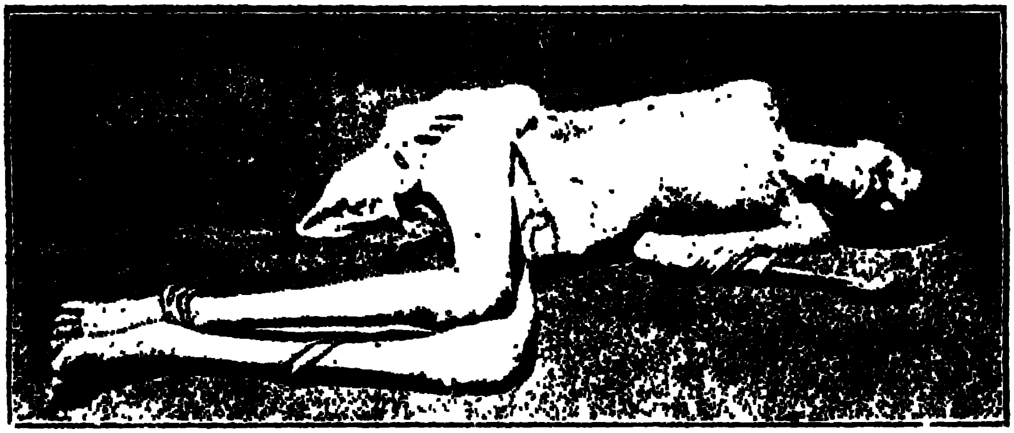

FIG. 640.—SLEEPING SICKNESS, LATE STAGE, IN ANGLO-EGYPTIAN SUDAN. (Photograph kindly lent by Colonel A. Balfour.)

The Cerebral Stage (the So-called Sleeping Sickness).—After the febrile stage has lasted some time (weeks or months), and even years, a change begins to appear in the habits and disposition of the patient. Previously bright, intelligent, and hard-working, he becomes apathetic, dull, with a disinclination for exertion, preferring to sit quietly or to lie down. He also becomes careless in his work and dirty in his habits, and at the same time a difficulty in walking begins to be noticed. In this condition the sleeping sickness stage of the disease may be said to have been properly entered. Typically, the patient is dull and apathetic, but can be easily roused, and answers questions rationally, without difficulty in speech. Sleep may be excessive, but is not the prominent symptom so often described, the condition being more one of lethargy, from which the patient can be easily roused. Fine tremors are noticed in the tongue at first, later in the hands and arms, and sometimes also in the legs, and even in the abdominal muscles. The tremor of the tongue and hands may be a very early symptom and may be present in the febrile stage. These tremors may occasionally be so severe that they cause the whole body to shake, and at times epileptiform fits, general or localized, may be seen. The gait is peculiar, there being apparently a difficulty in raising the feet, so that the patient shuffles along; but there is no paralysis as a rule, and the superficial reflexes are normal; the deep reflexes may be exaggerated and then lost; there is no clonus. There is inco-ordination in some cases, and Romberg's sign may be present. As the disease advances, rigidity appears, especially in the muscles of the neck and legs, which latter may assume the position of flexion of the thighs on the abdomen and the legs on the thighs. Babinski's sign is generally absent. Sensation is at first normal, but there may be hyperæsthesia in the region of the fifth nerve and other nerves, and at times the patient complains of headache. The pupils are equal, moderately contracted, and react to light and accommodation. There is nothing abnormal in the organs of special sense as a rule. There is usually fever, the temperature rising in the evening from 100° to 104° F., and falling to subnormal in the morning: but this may be varied in many ways: thus for a period the temperature may be almost normal or subnormal, while for some days before death it becomes, as a rule, permanently subnormal.

There are no special symptoms, such as rigors or sweating, associated with the rise of temperature. The pulse is quick (90 to 140), but it is independent of the temperature, being quick with a low temperature. It is regular, but small and very low in tension, and generally is imperceptible at the wrist for some time before death. The heart as a rule shows no abnormal symptoms, though systolic inorganic murmurs may be present. The respirations are regular and equal, but are increased in number, especially towards evening, varying from 20 to 30; before death they not uncommonly take on the Cheyne-Stokes type. Congestion and œdema, with patches of pneumonia, are not infrequently met with before death. The appetite is good, and may even be increased; digestion is usually satisfactory, but constipation may be marked, or there may be occasionally diarrhœa. The tongue is frequently flabby and covered with white fur; the fæces of native patients are typical of a vegetable diet, and show the usual parasites of a tropical country. The spleen and liver may be enlarged, which perhaps may partly be due to malaria.

The Blood.—The examination of the blood is complicated, because its condition is bound to be influenced by the secondary infections with other parasites, animal and vegetal.

With this understanding trypanosomiasis causes in a certain number of cases a gradual diminution of the red cells to 2,000,000 or less, with a corresponding decrease in the hæmoglobin; but it is to be noted that, as first observed by Low and Nabarro in several cases, the actual number of erythrocytes may be above normal. The red cells are usually normal in appearance, but normoblasts may be seen. The leucocytes are normal in number, as a rule, with an increase of mononuclear cells, while there may be a terminal polymorphonuclear increase before death.

In fresh preparations the red cells are not evenly distributed, nor do they form rouleaux, being generally clumped into masses. This phenomenon of *auto-agglutination* was first noticed by Kanthack, Durham, and Blandford in the lower animals inoculated with nagana; and in man in cases of sleeping sickness, by Dutton, Todd, and Christy, and may be of diagnostic value. The phenomenon of auto-erythrophagocytosis has occasionally been noted.

The chemical examination of the blood in trypanosome infections of animals has been performed by Takmioff and by Nierenstein, the latter of whom found, by Moore and Wilson's method of testing the alkalinity of the ash, that the acidity of the blood was increased, probably due to the formation of amido-acids, either secreted by the parasites or produced by their action upon the proteids of the serum. The acidity was tested by phenolphthalein and Congo red, and the alkalinity, which remained fairly constant, was tested by dimethyl-amido-azo-benzol.

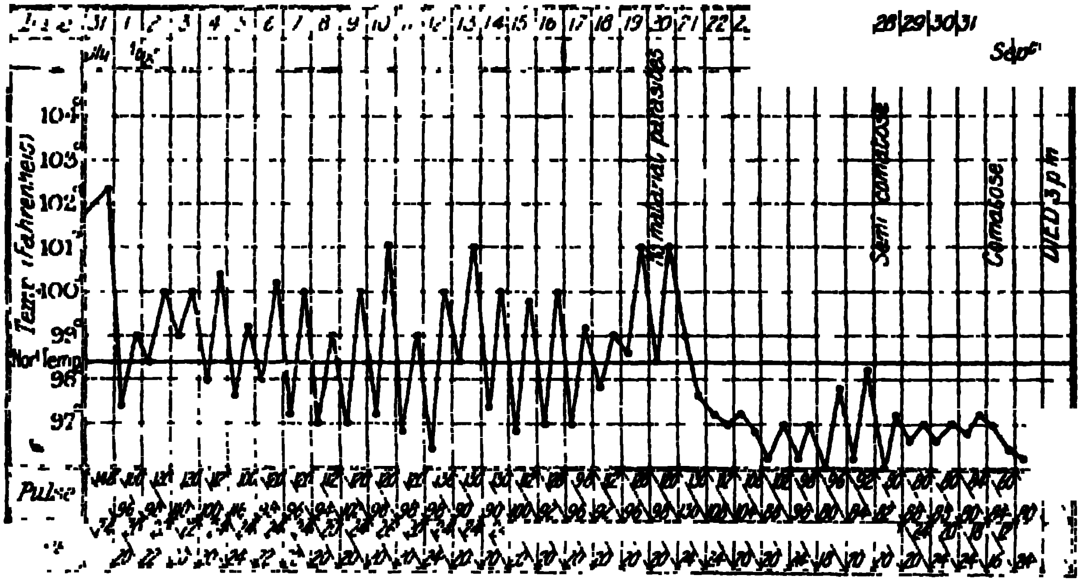

FIG. 641.—TEMPERATURE CHART OF A CASE OF SLEEPING SICKNESS. (From Low and Castellani Reports of the Royal Society on Sleeping Sickness.)

The animals were infected with *T. brucei* and *T. equiperdum*, but so far no observations have been made on human blood.

Urine.—No abnormality is found in the urine, but the reaction, amount of phosphates, etc., of course, varies with the food taken. In native patients it is very often alkaline.

Sexual desire and menstruation are normal at first, but later are lost. The lymphatic glands throughout the body, but especially those of the neck, and more especially those of the posterior triangle, are enlarged. It is to be noted, however, that in the last stages the lymph glands often undergo a process of fibrosis, becoming smaller and harder. The skin becomes dry and rough, but may be perfectly normal, though a papulo-pustular eruption may at times be noted on the backs of the hands and forearms. Nutrition suffers, and the patient generally becomes much emaciated.

As the disease progresses the muscular weakness and emaciation becomes worse and worse, the tremors more pronounced, the saliva dribbles from the mouth, the urine and fæces are passed involuntarily, and bedsores form, while the intelligence becomes more and more affected, and the patient passes into a state of coma, with a permanently subnormal temperature and an absence of pulse at the wrist, and in a short time is liberated from his sufferings by death. The duration of the cerebral or sleeping sickness stage varies from a few weeks to several months. Since the atoxyl treatment has become of general use, Hodges has noted that convulsive and mental symptoms are more prominent, and that death is often sudden, without being preceded by a period of coma.

Varieties.—When the disease is due to *C. rhodesiensis*, it generally runs a more rapid course, seldom exceeding four or five months. Lethargic symptoms may not appear, and the enlarged glands in the posterior triangle of the neck may be absent, while enlargement of the epitrochlear glands seems to be frequent. The disease caused by *C. gambiensis* appears to be of a milder type than that due to *C. castellanii*.

Complications.—The patient is often infected by parasites other than trypanosomes; thus, *Plasmodium* and *Laverania*, *Filaria*, *Schistosoma mansoni*, *Ancylostoma duodenale*, *Ascaris lumbricoides*, *Trichurus trichiura*, *Strongyloides stercoralis*, *Trichomonas intestinalis*, *T. vaginalis*, *Dermatophilus penetrans*, and *Loeschia* may all be found. The commonest complication during the last stage is a cerebro-spinal meningitis, due to streptococci, the pneumococcus, or the meningococcus.

Pneumonia, laryngitis, and œdema of the glottis are not rare, while iritis is seen at times, and symptoms of mania, delirium, and epilepsy may be observed.

Diagnosis.—In the first stage (febrile or glandular stage) the disease may be readily confused with malaria and other fevers, but in endemic areas the true nature of the malady may be often suspected on certain clinical data, the principal of which are the attacks of fever not influenced by quinine, the erythematous eruption in Europeans, the rapid pulse frequently present also during the apyrexial periods, the asthenia, the deep hyperæsthesia (Kerandel's symptom), the fine tremor of the tongue (Low-Castellani's symptom), the cervical polyadenitis (Winterbottom's symptom). During the sleeping sickness stage the clinical diagnosis is based, in addition to the above symptoms, on the drowsiness and apathetic appearance of the patient, on the remarkable wasting and debility, and the more marked, and occasionally generalized, tremors. The long course and, usually, absence of facial paralysis differentiates clinically sleeping sickness from encephalitis lethargica (nona). To make a definite diagnosis, the demonstration of *C. castellanii*, *C. gambiensis*, or *C. rhodesiensis* in the body of the patient is necessary. The following methods should be used:—

1. *Microscopical Examination of the Peripheral Blood from the Finger or Ear.*—This procedure is often a failure, even using thick films.

2. *Scarification of the Erythematous Eruption and Examination of Blood Films.*—This method is more useful than the first, but may fail.

3. *Nabarro's Method.*—Repeated centrifugalization of 10 c.c. of citrated blood, and examination of the third sediment. The results are good.

4. *Dutton-Todd's Method.*—Some citrated blood is centrifugalized in small tubes and the leucocytic layer examined for trypanosomes.

5. *Greig-Grey's Method.*—Aseptic puncture of the enlarged cervical glands with a sterile syringe. The gland-juice is examined for trypanosomes. This, from a practical point of view, is the most valuable method. To Mott belongs the credit of having first suggested the search for trypanosomes in the lymph glands as a diagnostic method. Balfour has devised a 'gland-holder,' which is useful in some cases.

6. *Castellani's Method.*—Centrifugalization for fifteen minutes of 10 c.c. of cerebro-spinal fluid, aseptically removed by means of lumbar puncture. The sediment is examined for trypanosomes by making fresh and stained preparations. The result is almost constantly positive in the sleeping-sickness stage, but negative, as a rule, in the first stage of the malady.

The technique to perform lumbar puncture is as follows: The patient may be given chloroform, but usually a local anæsthetic spray is sufficient. Lay the patient on the right or left side, flex the thighs on the abdomen. Then make the skin of the lumbar region aseptic, and, feeling with the tip of the finger the position of the laminæ, thrust the sterile needle between the laminæ of the third and fourth lumbar vertebræ, ½ inch from the median line, obliquely outwards and forwards into the canal. The fluid will escape, and can be collected in a sterile tube After withdrawing the needle, the area should be covered with an aseptic pad and bandage.

7. *Inoculation of Susceptible Animals.*—Ten c.c. or 20 c.c. of blood are aseptically removed from a vein and inoculated into susceptible animals, or 10 c.c. of cerebro-spinal fluid may be inoculated. The animals most suitable are monkeys, guinea-pigs, and dogs. The most suitable monkeys, according to Thiroux and d'Anfreville, are those of the species *Cercopithecus ruber*, while some other species—*e.g.*, *C. fuliginosus*—are almost refractory.

The following biological phenomena and reactions may sometimes be of diagnostic value:—

1. *Auto-Agglutination.*—In many cases of sleeping sickness, in wet preparations of blood examined microscopically with a low power, the red corpuscles are not evenly distributed, nor are they arranged in rouleaux, but are clumped together 'agglutinated'—in irregular masses. This appearance is not specific of trypanosomiasis, having been found in cases of filariasis, malaria, syphilis, and yaws.

2. *Complement Fixation.*—Levaditi and Muttermilch have applied the Bordet-Gengou reaction to trypanosome infections. According to them, the complement can be fixed by using as antigen an extract of trypanosomes separated from red cells.

3. *Levaditi and Muttermilch's Leucocytic Attachment Reaction.*—Levaditi and Muttermilch have shown that trypanosomes treated with the specific serum (heated at 55° C.) develop a property of becoming attached to leucocytes, and that this phenomenon is specific. The test may be used for identifying a trypanosome or for diagnosis, but, according to Laveran and Mesnil, is not very reliable in the case of *C. castellanii* infections.

Attempts have been made to evolve agglutination reactions, trypanolytic precipitin, and other biological tests for purposes of the diagnosis of sleeping sickness, but so far with little success.

Prognosis.—The prognosis is serious, but not quite so serious as it was before the introduction of atoxyl and the mixed atoxyl tartar emetic treatment. If the patient is in the early stage, and can be removed from the endemic area and put under good hygienic conditions and atoxyl treatment, the disease may be cured, or at least a marked improvement may be obtained. Great care, however, is necessary before saying that a patient is really cured, and at least two blood injections into susceptible animals should be performed before giving a decided opinion. If, however, the patient is compelled to live in the endemic area, and cannot be treated with atoxyl, the outlook is most hopeless. It is to be noted that there are several strains or varieties of different virulence. The Uganda and French Congo strains caused by *C. castellanii*, as noted by Laveran and Mesnil, cause a more acute type of the disease than the Gambia strain due to *C. gambiensis*, and *C. rhodesiensis* is in laboratory animals more virulent than *C. castellanii*, and the disease caused by it in man runs a more rapid course.

Treatment. - The only medicaments which have been so far found to be of any real value are, first, arsenic in the form of atoxyl, and, in a less degree, antimonium in the form of tartar emetic, the best method of treatment being a combined treatment with the two drugs.

Atoxyl.— We recommend 2 to 3 grains of atoxyl by intramuscular injection every third day for at least two years, or 0·3 gramme every fourth day for the same period, with 0·1 gramme for a child ten years old.

Borden and Rodhain's method is 7½ grains of atoxyl by intramuscular injection every fifth day. Koch recommended the subcutaneous injection of 7½ grains (½ gramme) on two successive days every ten days for two months, when the treatment is to be stopped until further symptoms develop, and when this occurs the treatment should be repeated. The drug can be obtained or imported from any chemist in sterile vials ready for hypodermic medication. The injection of atoxyl is occasionally followed by a febrile reaction, due, according to some observers, to the absorption of products of trypanolysis.

Atoxyl is sodium-*p*-aminophenyl arseniate— $NH_2C_6H_4AsO\begin{matrix}ONa\\OH\end{matrix}$ —and contains from 25·05 to 20·78 per cent. of arsenic, according to the amount of water of crystallization. Mono-acetylated atoxyl is  $CH_3CONHC_6H_5AsO\begin{matrix}ONa\\OH\end{matrix}$.

According to Mesnil and Nicolle's observations, and the more recent observations of Nierenstein, it is not the arsenic in these compounds which is to be looked upon as the effective agent, but the amido-group, which may possibly be the effective agent in trypan red, afridol blue, afridol violet, and parafuchsin, which do not contain arsenic, but possess amido-groups, and affect trypanosomes in a similar manner to atoxyl. According to Ehrlich, Levaditi, and Yamanouchi, atoxyl undergoes a reduction in the animal tissues. Ehrlich has prepared two derivatives of atoxyl, one of which, already mentioned (arseno-phenylglycin), is very effective in mice on atoxyl-resistant trypanosomes. Levaditi and Yamanouchi have also prepared an active derivative of atoxyl, which they call trypanotoxyl Nierenstein thinks that atoxyl is oxydized in the tissues, and it is only in the nascent state that it becomes efficacious

Soamin -Owing to the fact that large doses of atoxyl lead to such unpleasant results as optic atrophy, gastro-intestinal inflammation, and peripheral neuritis, other arsenical preparations have been recommended; and the firm Burroughs and Wellcome has introduced, under the trade name of ***soamin***, a preparation somewhat similar to atoxyl, but said to be less poisonous. It is given in the same doses as atoxyl, but the therapeutic results do not appear to have been very successful. *Soamin*, according to the published formula, is $C_2H_4NH_2AsO(OH)(ONa)5H_2O$.

Arseno-phenylglycin. Ehrlich has prepared a derivative of atoxyl, called ***arseno-phenylglycin***, which is from two to four times less toxic than atoxyl itself

This preparation has been tried by Ehrlich, Mesnil, Kerandel, and others upon lower animals experimentally infected with *C. castellanii*, and has been found to be very effective, being also a prophylactic. It has been used in man by Kleine in the same doses as atoxyl, but has now been abandoned.

Liquor Arsenicalis. -When for special reasons it is impossible to carry out the treatment by injections, arsenic may be given by the mouth in the form of Fowler's solution which must be given, well diluted in water or milk, in 5-minim doses and gradually increased to 15-minim doses.

Löffler and Ruh's neutral solution of arsenious acid (1 c.c. of which contains 1 centigramme of arsenious acid) may be given in doses of 2 c.c daily for three days, and then continued in doses of 1 c.c. per diem for several weeks, after which it must be temporarily discontinued, but must after a time be restarted, and in this manner continued for months, provided no ill-effects are produced.

Salvarsan and Neosalvarsan -Their action is less efficacious than atoxyl.

Atoxylate of Mercury - This preparation, introduced by Uhlenhuth, has given less satisfactory results than atoxyl.

Quinine Derivates - Morgenroth and Halberstaedter have shown that some quinine derivatives, such as hydroquinin, have a preventive and curative effect in certain experimental trypanosomiases.

Ipecacuanha Derivates —The emetine salts might be studied in regard to their possible action on trypanosomes.

Anarcotine. - -The use of this opium alkaloid has been suggested by Johnson.

Combined Therapy. As the result of the important observations of Ehrlich on the phenomenon of chemio-resistancy, which may be acquired by trypanosomes after a long use of the same drug, numerous combined treatments have been suggested. Of these, the most important are: (1) antimony and atoxyl; (2) mercury and atoxyl; (3) orpiment and atoxyl; (4) various dyes and atoxyl.

Antimony and Atoxyl Treatment. - Antimony salts, as well as phosphorus, were first suggested by Mesnil as likely to be of use in trypanosomiasis. To Plimmer and Thomas belongs the credit of having experimentally shown the powerful trypanocide action of antimony. In man the subcutaneous or intramuscular injections of solutions of the various salts of antimony (sodo-tartrate of antimony, sulphide of antimony and soda, etc) are very painful. Plimmer therefore suggests oil emulsions, Manson gives the drug by the mouth or by the rectum, and other authors by intravenous injection. Daniels and

Newham recommend the painless Martindale's injectio antimonii oxidi, 30 minims (= gr. $\frac{1}{20}$ antim. ox.) to be given subcutaneously once or twice daily. Apparently the trypanocide action of antimony is more powerful in the lower animals than in man, in whom the results are inferior to those given by atoxyl. A mixed antimony and atoxyl treatment is, however, of advantage in most cases, an atoxyl injection (3 grains) being given every third day, or 7½ grains every fifth day, and sodio-tartrate of antimony (Plimmer's salt) administered daily- 2 grains dissolved in a large quantity of water (2 pints) by the mouth or by the rectum. Tartar emetic, however, is best given by intravenous injections, using solutions of 1 in 100 or 1 in 1,000. The dose of the drug to be given is 5 to 10 centigrammes per injection. It is important that none of the fluid of the injection should escape into the surrounding tissues, as a violent inflammation may result. These injections should be administered monthly on ten consecutive days for a long period. The injection of salts of antimony may produce a marked fall in the blood-pressure, dyspnœa, and signs of collapse, and therefore Thiroux suggested that subcutaneous injections of caffein should precede ten or fifteen minutes their administration.

Basing his opinions upon the very successful treatment carried out by Captain Simson, R.A.M.C., at the Yei Sleeping Sickness Camp in the Mongalla Province of the Sudan, Captain Spence, R.A.M.C., is treating cases in the Bahr el-Ghazal Province as follows :-

A. Cases in the early stage :-

1. Six intravenous injections each of 6 centigrammes of *antimony* at three-day intervals.
2. Interval one month.
3. Twelve intramuscular injections each of 30 centigrammes of *atoxyl* at three-day intervals.
4. Interval one month.

5 and 6. Repeat 1–4.

7. Three months after last treatment the blood of the patient is inoculated into an animal. If the animal remains uninfected the patient is given a numbered disc and told to report every three months.

Total dosage: Atoxyl, 10·8 grammes in about one year; antimony 1·08 grammes.

B. Relapses and cases first seen in a late stage of the disease :-

1. Nine intramuscular injections each of 1 gramme of *atoxyl* at ten-day intervals.
2. Interval one month.
3. Nine intramuscular injections each of 1 gramme of *atoxyl* at twenty-day intervals.
4. Interval one month.
5. Nine intramuscular injections of *atoxyl* at thirty-day intervals.
6. Interval of three months.
7. Animal is inoculated as above.

Total dosage: 27 grammes of atoxyl in two years.

Cases in which no symptoms are noted and in which animal inoculations are negative are kept under close control for two years, after which they report every six months for two years and the result judged.

Mercury and Atoxyl.- Mercury was first introduced in 1902 for the treatment of sleeping sickness by Low and Castellani, using intravenous injection of Baccelli's sublimate solution (hydrargyri perchloridi, 0·10 gramme; sodii chloridi, 0·50 gramme; aquæ destillatæ, 100·00 c.c.; 1 to 4 c.c. per intravenous injection), in association with arsenic and quinine by the mouth. A fall of the temperature was observed in some cases, but the fatal course of the disease was not influenced. Moore, Nierenstein, and Todd have used mercury and atoxyl in combination or alternation, with the idea that mercury might act upon the latent form of the trypanosome, while atoxyl would influence the active form. In man this combined treatment has apparently not given any better results than atoxyl alone.

Orpiment and Atoxyl.—This combined treatment, consisting of atoxyl and an inorganic salt of arsenic such as orpiment, has been recommended by Laveran and Thiroux, and has been used in man with good results. The orpiment should be given in pills, in the dose of 2 grains of orpiment two or three times daily. The administration of orpiment frequently causes diarrhœa. Thiroux therefore incorporates in the orpiment pills some opium. Thiroux's formula is:—

Orpiment	20 grammes.
Extr. opii	0·40 gramme.
Gumm. Pulv. glyceriz.	q.s.

To be divided into 200 pills.

Various Dyes and Atoxyl.—Combined treatments of Mesnil's afridol and atoxyl, Ehrlich's parafuchsin and atoxyl, picric acid, safranin, trypaflavin and other dyes and atoxyl, have been suggested, but in man the results have not been so successful as in the lower animals.

Treatment of Natives. In the case of natives it is necessary to gather them into special sleeping sickness camps in order that treatment may be efficiently carried out. These camps should be in some fly-free area, and should be provided with a trained medical staff. Patients able to work should be employed to raise crops for their own consumption, to supplement the diet provided by the Government.

Symptomatic Treatment.—In addition to the atoxyl treatment or combined treatments, malaria and the intestinal parasites must be treated if present. The patient should, if possible, be removed from the area of infection and placed under good hygienic conditions and on good food, and no case should be considered to be cured until the injection of the blood, on more than one occasion, into susceptible animals fails to infect them.

Prophylaxis.—At the present time prophylaxis must be undertaken on the assumption that the disease is spread from place to place by man along channels of human intercommunication, and from man to man by *Glossina palpalis* and *G. morsitans*, and that at least in the case of *C. rhodesiensis* there are animals which act as reservoirs of the virus. With regard to these flies, further information is required as to their bionomics, though Bagshawe's and Hodges' researches, as well as those of Zupitza, Sander, Minchin, Kinghorn and Yorke, Carpenter, and others have thrown some light on the subject.

Before enumerating the principal prophylactic measures to be recommended, we wish to draw attention to the fact that these, as pointed out by Bagshawe, will be useless without the co-operation of the natives. This co-operation may be obtained by explaining to them at every possible opportunity the reason for the measure taken. In this missionaries and native chiefs may be of the greatest help. With this proviso we consider the following to be the principal prophylactic measures:—

Public Prophylaxis.—We advocate:—

1. The formation of a Central Executive International Board, with headquarters in either Paris or London.

2. The formation of an Executive Sleeping Sickness Commission in each political division of Africa in which the disease exists.

The different Governments should be invited to co-operate to prevent persons travelling from districts where the disease exists into non-infected regions, and medical posts of inspection should be established for the examination of natives. According to some authorities (Dutton, Todd), all natives presenting enlarged glands should be considered, from a practical point of view, as trypanosome carriers, and prevented from emigrating. This is, perhaps, going a little too far, inasmuch as, in our experience, and in that of Low, Bagshawe, Koch, Hodges, etc., numbers of natives have enlarged glands, though not suffering from trypanosomiasis; and, on the other hand, cases of trypanosomiasis occur in which there is no enlargement of the lymphatic glands. We admit, however, that gland palpation may be of some use in formulating an approximate idea of the extent of the dissemination of the disease.

The sick should be removed from the fly regions and segregated in places where the *Glossina palpalis* and *G. morsitans* are not found, or where the temperature and climatic conditions are unfavourable to the development of trypanosomes in the flies. They should be treated with atoxyl before being moved.

In the regions where the disease is due to *Castellanella castellanii*, which is mostly carried by *Glossina palpalis*, villages should be removed, if possible, from the fly zones: and the occupations carried on in fly zones, such as fishing, should be discouraged. This has been done in certain regions round the Victoria Nyanza Lake, but the result has not been completely successful, as infected flies were found to be plentiful three years after the measures had been carried out. The waste land became full of game and wild animals, some of which are probable reservoirs of the infection. Duke, in fact, has found *C. castellanii* in two marsh antelopes or situtunga (*Tragelaphus spekei*), and believes this observation to be confirmed by the infection of two boys working on an uninhabited island in Lake Victoria.

Clearing of the bush along the water's edge for 100 yards, and round a village for 300 yards, at least, is to be advised.

European bungalows should be segregated from native quarters. Houses should be rendered gnat-proof, and natives bringing water from streams should not be allowed to enter the house, as they are liable to be surrounded by tsetse-flies which have followed them. Indeed, some authorities look upon the bath-room as a source of European infection.

Destruction of the Animals on which the Fly feeds.—Koch recommended the destruction of the crocodiles by poison, and by collecting and destroying their eggs. Unfortunately, the crocodile is not the only animal on which the fly feeds. The blood of many other vertebrate animals is palatable to the fly, and therefore this method of prophylaxis is without much practical importance.

Destruction of the Vertebrate Reservoir.—Many authorities have supported the idea of exterminating the big game, because they may be the vertebrate reservoir, but this requires further proof, and is therefore at present too radical a measure.

Destruction of the Pupæ.—Minchin has suggested the breeding of the jungle-fowl to destroy the pupæ, which, as discovered by Bagshawe, are found in the turf among the roots of banana and other trees. Balfour and others have suggested trapping the adult flies in various ways. Further information, however, is necessary on the enemies of the pupæ and adult tsetse-flies.

Personal Prophylaxis.—Natives in the fly zones should be encouraged to wear suitable clothing, and the reason explained to them. Europeans should be careful not to expose their legs and hands to be bitten. High boots, puttees, or leggings should be worn, and where the flies abound gloves and veils, though very uncomfortable, are of service. White clothes are better than dark ones, as it has been long observed that the tsetse-fly, as well as many other insects, have a preference for black or dark colours. The use of volatile substances such as citronella oil has been advised by some. Unfortunately, the odour of such substances is repellent to many persons.

Morgenroth and Halberstaedter have shown that certain derivates of quinine, in the lower animals, prevent an experimental trypanosome infection, and Bagshawe suggests that a daily dose of quinine may be useful in man.

Vaccination.—Attempts at vaccination have not yet entered a practical stage, as inoculation with dead or attenuated viruses have so far failed in the lower animals.

Summary of Prophylactic Measures.

I. General measures:
  1. Co-operation of various Governments, especially in controlling the movements of non-infected natives.
  2. Formation of medical posts of inspection at suitable places to prevent infected natives entering non-infected areas and *vice versa*.
  3. Segregation of the sick, if possible, in districts free from *Glossinæ*, or where the climatic conditions are unfavourable for the development of the trypanosome in the fly.
  4. Clearing of the bush near villages and along the water's edge, especially at landing-places, fords, and ferries.
  5. In certain cases—especially with regard to *C. rhodesiensis*—the destruction of large game, especially antelopes. (This is still *sub judice*.)

II. Personal measures:
  1. Avoidance of bites by wearing white clothing, high boots, puttees, and the putty pattern of leggings.
  2. Immediate disinfection of a bite by painting it with tincture of iodine or by applying a solution of formalin (1 in 40).

TRYPANOSOME FEVERS.

Definition.—The trypanosome fevers of man are caused by a monomorphic trypanosome allied to *Duttonella vivax* Ziemann, 1905, and to an unspecified germ allied to *Castellanella evansi*, and are characterized by milder symptoms and the absence of meningo-encephalitis as far as is known.

Remarks.—In Macfie's case of infection with a trypanosome allied to *T. vivax*, apart from slight fever there were no symptoms, and after a single injection of atoxyl the trypanosomes disappeared from the blood.

In Lanfranchi's case of accidental laboratory infection there have been irregular attacks of fever lasting seven years, and general debility associated with large patches of cutaneous œdema. But there has been neither mental symptoms nor tremor. He has been treated by atoxyl and tartar emetic.

It will thus be seen that the trypanosome fevers resemble mild infections in animals rather than human sleeping sickness.

Diagnosis.—This can only be made by finding the trypanosomes in the blood.

Prognosis.—This appears to be good *quoad vitam*.

Treatment.—The treatment is atoxyl administered as in sleeping sickness.

Prophylaxis.—Nothing can be said at the present time with regard to this.

CHAPTER XLVI

SOUTH AMERICAN TRYPANOSOMIASIS

Synonyms—Definition—History—Ætiology—Pathology—Symptomatology—Diagnosis—Treatment—Prophylaxis—References.

Synonyms.—Oppilação; Canguary (both indicate ankylostomiasis); *Schizsotrypanose* or *Douença* de Carlos Chagas, *Coreotrypanosis* (*coris* = bug); *Molestia* de Carlos Chagas, *Tripanozomiase braziliera*, *Tireoidite parasitaria*, *Molestia do barbeiro* (popular name), *Molestia* de Cruz e Chagas.

Definition.—South American trypanosomiasis is an acute or chronic specific disease caused by *Schizotrypanum cruzi* Chagas, 1909, and spread by the bug *Lamus megistus* (*Trialoma megista*) Burmeister, and perhaps other allied bugs.

History.—In February, 1909, Chagas reported that he had frequently found a new trypanosome, which he named *T. cruzi*, in the intestine of a species of Lamus, which occurred in the State of Minas in Brazil. He also reported that he was able to infect marmosets, dogs, cats, guinea-pigs, and rabbits by the bites of the infected insects, and also to grow the parasite on blood agar.

In May, 1909, he announced that he had made an investigation of the mines of the State of Minas, and found the Lamus in large numbers in the houses of the poorer inhabitants. He noticed that the bite was painful, and that the insect was very voracious, and also that it generally attacked people, especially children, at night, biting the face, from which fact the inhabitants called it 'barbeiro' or 'barber.'

He suspected this Lamus of causing a disease marked by extreme anæmia, which occurred especially among the children, and he was able to find in the blood of a two-year-old child during an attack of fever a trypanosome identical with *S. cruzi*, morphologically and biologically. Since then Chagas has not merely worked out the life-history of the trypanosome in man and in the Lamus, but he has also studied carefully the clinical and pathological aspects of the disease, while Vianna has reported upon the histopathology, Dias on the blood, and Guerreiro on the urine.

Chagas has also shown that in all probability the armadillo commonly called 'tatu,' and scientifically *Dasypus novemcinctus*, or less correctly *Tatusia novemcincta*, may be the reservoir for *Trypanosoma cruzi*, and that *Triatoma geniculata* (synonym, *Conor-*

hinus geniculatus) of the family Reduviidæ is one of the carriers of the same trypanosome. He also believes that *Triatoma infestans* and *T. sordida* may be carriers. It may be stated that *T. geniculata* lives in the burrows of the armadillo, the flesh of which is rather a delicacy.

With regard to the history of the discovery of a trypanosome in man in South America, Sambon informs us that in 1904 de Lacerda published a paper entitled 'Etiologia de Beri-Beri' in the *Brazil Medico*, in which he stated that he had found trypanosomes in films taken from the spinal cord of a case of beri-beri. We have been unable to obtain this paper, and therefore cannot verify the statement, nor can we say whether the disease, which de Lacerda was considering, was beri-beri or some other complaint. It would, however, be interesting to have this historical problem elucidated.

Climatology.—The disease is known among the poorer inhabitants of the State of Minas in Brazil, where it appears to attack the whole population, so that the children all become affected and either recover, die, or pass into the chronic stage.

Ætiology.—The disease is caused by *Schizotrypanum cruzi* Chagas, 1909. This trypanosome, which is remarkable because of the large size of its kinetonucleus, is capable of being transmitted by *Lamus megistus*, and perhaps by species belonging to other genera of the Reduviidæ—*e.g.*, *Triatoma*—to domestic animals and to man. The reservoir of the trypanosome appears to be an armadillo—*Dasypus novemcinctus*.

In the blood three forms are seen: the first with a large nucleus and loose chromatin and a terminal kinetonucleus; the second narrower, with an oval nucleus and dense chromatin; the third with a long nucleus. The parasite undergoes schizogony in the lungs, after which the merozoites enter the red blood cells and become trypanosomes again. Sporogony takes place in the bug *Lamus megistus*, the final forms being found in the salivary glands, from which they pass during the act of biting into the vertebrate. (For a description of the parasite and its life-history, see Chapter XIX., p. 427.)

Pathology.—The trypanosomes enter the cells of the various tissues and organs of the body, but especially those of the muscular system, and more particularly those of the muscles of the extremities and back. Inside these cells they assume Leishmania-like forms without flagella, but provided with trophonucleus and kinetonucleus. These forms divide by binary division, and so increasing in numbers, dilate the cell considerably. During this process there is no reaction upon the part of the surrounding tissue, but after a time the cell membrane ruptures, and the parasites which have already become flagellate inside the dilated remains of the cell, which is virtually a cyst, escape. With this escape of the parasites into the tissues the local inflammatory reaction appears, and with the appearance of the trypanosomes in the blood the general symptoms make themselves evident. Whether the parasites produce any toxins or not is unknown, but it is probable that they do so, because of the fatty degeneration described in the liver, as well as because of the other pathological features.

As a result of this activity on the part of the parasites and of the reaction on the part of the body, local pathological changes take place in different organs, and these are in general agreement with the symptoms exhibited by the particular case.

At present there is no evidence of any secondary infection being responsible for any of the essential pathological features of the disease.

Morbid Anatomy.—In an autopsy upon the body of a person dying from the acute phase of the infection, a certain amount of serous effusion is remarked upon opening the abdomen. The liver is seen to be enlarged, and to be in a state of fatty degeneration. The spleen is also enlarged, hyperæmic, and very soft, as are the mesenteric glands. On opening the chest serous effusion is seen in both pleural cavities, as well as in the pericardial sac. The pericardium shows signs of hæmorrhagic pericarditis, while the enlarged heart is in a condition of intense myocarditis. The lymphatic glands of the mediastinum are also swollen and hyperæmic. In the neck the thyroid gland is seen to be enlarged, as are the lymphatic glands. The dura mater is congested, and there is leptomeningitis and encephalomeningitis, and firm adhesions between the leptomeninges and the cerebral cortex. The liquor cerebro-spinalis is increased in amount. There is a generalized myxœdematous condition under the skin.

Histopathology.—As already stated, the most likely place to find the parasites is in the muscular system. In the heart they occupy the central undifferentiated protoplasmatic portion of the muscle cell, and growing therein, destroy the sarcoplasm, and convert the body of the cell into a parasitic cyst without affecting the processes. When this cyst ruptures, the now flagellate parasites escape into the intermuscular tissue, and give rise to patches of interstitial myocarditis. No changes are to be seen in the larger bloodvessels of the heart, nor can parasites be found associated with patches of pericarditis or endocarditis which may be present. In the skeletal muscles the parasites are mostly found in those of the extremities and the back. Here, again, the parasites grow in the centre of the muscle fibre (Fig. 114, p. 428).

In the central nervous system a similar process appears to take place. The parasites invade a neuroglia cell, which becomes converted into a parasitic cyst, on the rupture of which a patch of inflammatory reaction is produced. Parasites have never been seen to invade the nerve cells or the leucocytes of the central nervous system (*vide* Figs. 642 and 643).

A similar invasion of the medulla or cortex of the suprarenal capsule and inflammatory reaction can also be seen in the kidneys, the hypophysis, and the thyroid gland. In animals the parasites have been seen in the testicular tubules, but they have not been noted in the human ovary.

Symptomatology.—There are two principal varieties of the disease—the acute and the chronic.

In the *acute stage* the disease begins with a violent attack of fever in a young child or a new-comer into the district. This fever shows a morning remission and an evening rise, and is associated with a palpable increase in the thyroid gland, œdema of the face, in which characteristic crepitation can be felt by palpation, enlargement of the lymphatic glands in various regions of the body, but especially of the neck; and fugitive œdemas in different parts of the body—as, for example, the forehead and extremities. The spleen enlarges and becomes painful, and the liver also becomes enlarged, and there may be signs of meningitis, and also of albumen in the urine. After a time the attack of fever passes off, only to return after periodical intervals. During an attack the typical trypanosomes can be found in the blood, but during the apyrexial interval they are absent. After these attacks have lasted some time the child either dies, recovers, or passes into the chronic stage.

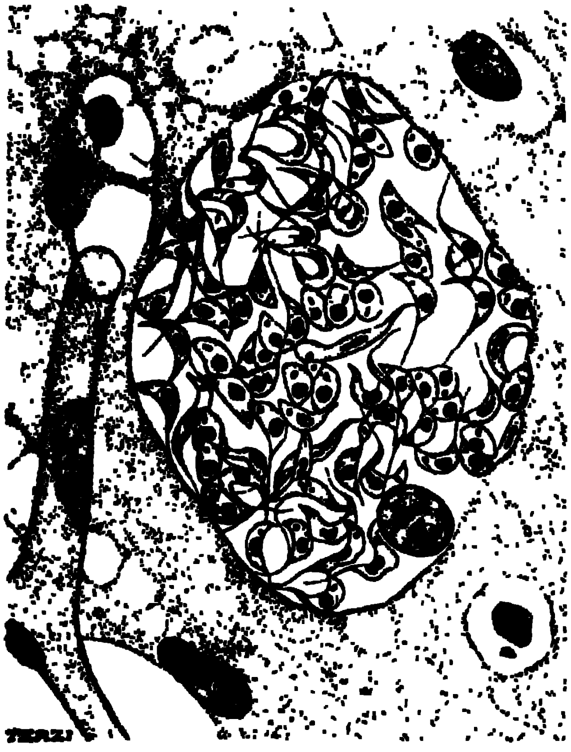

FIG. 642.—NEUROGLIA CELL OF BRAIN DISTENDED TO A CYST AND FILLED WITH *Trypanosoma cruzi*. (× 2,000.) (After Vianna.)

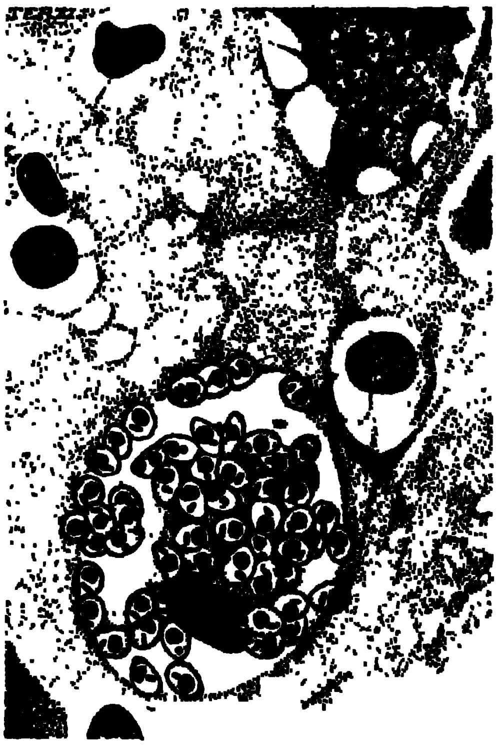

FIG. 643.—*Trypanosoma cruzi* IN A NEUROGLIA CELL OF THE BRAIN. (× 2,000.) (After Vianna.)

In this *chronic stage* the children show signs of marked thyroiditis and loss of hair, with hypertrophy of the lymphatic glands, a dull expression, a peculiar bluish-bronze pallor, tachycardia, and intestinal and nervous disorders, especially convulsions.

Chagas has classified the various symptoms of the chronic stage of the disease into five subvarieties:—

1. The pseudo-myxœdematous form.
2. The myxœdematous form.
3. The cardiac form.
4. The nervous form.
5. The chronic form with acute or subacute exacerbations.

1. *The Pseudo-Myxœdematous Form.*—In this subvariety of the chronic stage there is usually hypertrophy of the lateral lobes of the thyroid gland, more rarely a globular enlargement of the central lobe. This hypertrophy is usually well marked in quite young children, but is by no means evident in older children. In young children the face is thin and the skin of a peculiar light bronze colour, said to be quite different from the pallor of an anæmia. In older children the skin colour is violet-bronze. These colourations are believed to be associated with a parasitic invasion of the suprarenal capsule.

There is enlargement of the lymphatic glands in the neck, axillæ, and groins, while the parotid gland is also often hypertrophied.

In young children the liver and spleen may be found to be enlarged, but in older cases the abdominal signs are not well marked.

With regard to the circulatory system, there may be tachycardia, sinus irregularities, and an extra systole, and the blood-pressure may be lower. Convulsions have been noted, and at times slight fever, while the occurrence of conjunctivitis is also recorded.

2. *The Myxœdematous Form.*—In this form the thyroid gland is atrophied, and associated with the usual symptoms of myxœdema, such as the rough skin, loss of hair, and the presence of a firm œdema not pitting on pressure, together with an arrest of mental development in young children, or a mental degeneration in older persons. The lymphatic glands of various regions are enlarged, and there may be inflammatory eye affections.

3. *The Cardiac Form.*—In the cardiac form there is disturbance of the heart's action associated with arrhythmia, allarrhythmia, extra systole, or sinus irregularities. The greater number of the cases would be classed under Mackenzie's '*Rhythmus nodalis.*'

4. *The Nervous Form.*—Various brain and spinal cord symptoms are seen in this disease—*e.g.*, spastic paralysis in the legs, athetosis in the arms, aphasia, pseudo-bulbar paralysis, or suprabulbar paralysis. They are associated with the other symptoms of the disease.

5. *Acute or Subacute Exacerbations.*—The principal feature of this form is the preponderance of fever, and this may be due to exacerbations of an old infection or to new infections. This form is the cause of much mortality, and is separated from the acute form by the rarity of the parasites in the blood, and by the history of the long duration of the illness. As a rule it occurs in patients who show marked hypertrophy of the thyroid gland, and there may also be signs of suprarenal insufficiency.

Blood.—**The hæmatology has been investigated by Dias, who finds that the hæmoleucocytic formula has a great similarity to that found in African**

trypanosomiasis. As a rule, there is no globular anæmia, but there is a definite diminution in the hæmoglobin and in the specific gravity. The leucocytosis is slight in the acute and exceptional in the chronic cases. In acute cases there is a macrolymphocytosis.

Metabolism.—Guerreiro, from careful experiments associated with urine analysis, concludes that there is a true liver insufficiency in most forms of the disease, but not in the cardiac form unless associated with other symptoms.

Sequelæ.—Chagas considers that *infantilism* may be a sequel of the disease, especially as it is associated with hypothyroidism.

Diagnosis.—The diagnosis must be effected by finding the parasite in the blood during a febrile attack. The disease is most likely to be confounded with ankylostomiasis, from which it can be recognized by the absence of the typical ova in the fæces and the presence of *S. cruzi* in the blood, though, of course, both infections may occur together.

It might also be mistaken for malaria during the febrile attack, especially as there is splenic enlargement, but the absence of the malarial parasite and the presence of *S. cruzi* in the peripheral blood will enable a diagnosis to be made.

In the chronic stage it may be mistaken for goitre, especially when the myxœdematous or pseudo-myxœdematous symptoms are present, and the diagnosis will depend upon the discovery of the parasite or the history.

Prognosis.—The prognosis is most serious in the acute attacks and the acute or subacute exacerbations. The severer cardiac forms are also of grave import.

Treatment.—The indications for treatment are the same as those for African trypanosomiasis, associated with treatment for hypothyroidism.

Prophylaxis.—The prophylaxis must aim at the prevention of the Lamus biting man.

CHAPTER XLVII

THE KALA-AZARS AND PSEUDO-KALA-AZARS

General—Tropical kala-azar—Mediterranean Kala-azar—The pseudo-kala-azars—Tropical febrile splenomegaly—Toxoplasmosis—Krempf's splenomegaly—Tropical afebrile splenomegaly—References.

GENERAL.

THE present chapter is devoted to those fevers which are known as the kala-azars and those allied conditions, tropical febrile splenomegaly and tropical afebrile splenomegaly, which clinically resemble kala-azar, in one variety of which Castellani has obtained protozoal bodies from spleen which are classified, at present, in the genus *Toxoplasma*.

With regard to the kala-azars, of which Ross has pointed out that the correct name is 'kala-jwar'—*i.e.*, black or mortal sickness—we have already in Chapter XIX., p. 369, pointed out that we consider that tropical kala-azar should be treated, at all events at present, separately from Mediterranean kala-azar, and this we shall do in the present chapter, although the general tendency of modern thought is to consider the two diseases to be identical. We invite the reader's attention especially to the first half of Chapter XIX., in so far as it deals with the *Herpetomoninæ*, and especially to the experimental work of Fantham and Porter (p. 363), as having a direct bearing upon the unknown method of infection of man with the germs of kala-azar.

TROPICAL KALA-AZAR.

Synonyms.—Indian Kala-Azar, Kala-Jwar, Kala-Dukh, Sirkari disease, Sahib's disease, Dum-Dum fever, Non-malarial remittent fever, Cachectic fever, Tropical splenomegaly, Tropical Leishmaniasis, Internal Leishmaniasis,

Definition.—Tropical kala-azar is a subacute or chronic febrile disorder characterized by splenic and often hepatic enlargement, progressive wasting and anæmia, and caused by *Leishmania donovani* R. Ross, 1903. The method of infection is unknown.

History.—In 1869, when the district of the Garo hills was first occupied by the British, a disease believed to be a very severe form of malarial cachexia was found to be endemic. This disease the Garos called 'kala-azar,' which means the black fever, so named from the appearance of the victims. In 1875 it began to spread, and became epidemic, and by its high death-rate attracted attention. In 1882 the first account of the disease was published by Clarke from notes of 120 cases compiled by McNaught, the Civil Medical Officer of the district. In 1889, when it had spread into Assam, following the lines of human intercommunication, Giles investigated the epidemic, and concluded that it was ankylostomiasis. In 1894 Stephens, in his yearly report, stated that the disease, though allied to, was distinct from malaria. In 1897 Rogers reported that it was malarial, and this was further supported by Ross in 1899. In 1902 Bentley ascribed the disease to *Micrococcus melitensis*, on the basis of serum reactions.

Up to this point the history of the disease remarkably resembles the present history of blackwater fever. A change now comes over the ætiology, for, in 1900, Sir William Leishman found the parasites already described under the heading *Leishmania donovani* in films taken post mortem from the spleen of a soldier who died in Netley from fever contracted at Dum-Dum, but he did not publish this discovery till 1903. In July, 1903, Donovan observed the same parasite in blood obtained by splenic puncture performed during life. In 1904 Christophers published a valuable report on the parasite and the disease, and in the same year Rogers observed the development of the parasite into a flagellate organism when splenic blood was incubated at 22° C. in citrate of soda solution. In 1907 Patton showed that the parasite could be found in numbers lying in leucocytes in the peripheral blood, and, further, that it became flagellated in the alimentary canal of bugs.

In 1904 Neave in Omdurman discovered the existence of this disease in a child coming from the Bahr-el-Ghazal province of the Anglo-Egyptian Sudan, and in the same year Philips in Cairo discovered it in two adults coming from the Yemen district of Arabia. In 1907 Pirrie, who had been working in the Sudan, died in England from kala-azar. In 1908 Cummins discovered a case contracted at Singa on the Blue Nile; Carroll recorded a second case from the same district, while Black met with two other cases; Bousfield recorded seven cases from the province of Kassala and one from Mafaza, and Thomson and Marshall found forty-one new cases in children and adults along the Blue Nile towards Abyssinia, which forms an endemic zone, which has been carefully studied by Archibald. It corresponds to the Blue Nile, Sennar, and Kassala districts, while the infection in one case of a woman is regarded as coming from quite a different part of the Sudan—*i.e.*, from Um Ruaba near Talodi. Archibald has studied a small epidemic at Kurmok on the Abyssinian frontier. This Sudan kala-azar is peculiarly interesting because of its limited endemicity (as far as is known) and by the peculiar features shown by Archibald to be associated with its parasite.

In 1913 Gaspar Vianna introduced the intravenous injections of tartar emetic for the treatment of the American mucocutaneous

Leishmaniasis. According to Christopherson the drug was discovered by Basil Valentine in the sixteenth century, and accidentally caused the death of several monks, and thus acquired its name 'antimony'—*i.e.*, *anti-moine*, against the monk. In 1914 Castellani in Ceylon used this method combined with oral therapy for the treatment of tropical kala-azar. In 1915 Rogers treated cases in India in the same manner, and later in the same year Rogers and Hume administered this treatment to six cases of kala-azar in Europeans. Christopherson has successfully employed the same method in the Sudan; and this has now become the recognized method of treatment.

In addition to the above, much work has been done by the Indian investigators, such as Mackie, Cornwall, and others, as well as by Manson, Low, Statham, and others.

Climatology.—The disease is especially spread through the tropics, but is unknown in Tropical America and Oceania. It is found in the Sudan, Arabia, India and Ceylon, Burma, Indo-China, and China.

Ætiology.—Kala-azar is caused by a herpetomonad parasite called *Leishmania donovani* R. Ross, 1903, described on pp. 369-370, which lives especially in the endothelial cells of bloodvessels and lymphatics, and is especially numerous in the spleen, the liver, and the bone-marrow, but is also found in other organs, such as the lungs and the kidney. Especially must be mentioned its presence in the mesenteric lymphatic glands, and in ulcers of the intestinal mucosa.

It can also be found in mononuclear and polymorphonuclear leucocytes in the peripheral blood, but only occasionally, as at other times it is most difficult to find it in this situation. It also at times, but very rarely, lies in the hollow of the biconcave disc of a red blood cell, thus looking as though it was contained therein. The parasites have been cultured from the blood by using the N.N.N. medium.

They are most abundant in the blood towards the fatal end of the illness, and during fever or the presence of intestinal symptoms. They are said to have been found in the motions during an attack of kala-azar dysentery, and also in the scrapings from intestinal ulcers. They have also been found in papules and ulcers in the skin.

As they occur in the peripheral blood and in the skin, it is possible that they may pass into the alimentary canal of some blood-sucking arthropod, but these animals are often naturally infected with flagellate parasites of the leptomonad, crithidial, and trypanosomal types, and therefore the mere finding of a flagellate in the interior of a blood-sucking arthropod which has been fed upon a man or animal infected with *L. donovani* is worthless from an ætiological point of view.

As they occur in the peripheral blood and in the intestinal mucosa, they can equally escape in the fæces in the form of cysts, and thus get into water, from which they can be ingested by some aquatic arthropods, many of which naturally contain flagellates.

The work of Laveran and Franchini, of Fantham and Porter, has demonstrated that these natural arthropodal parasites can by ingestion or by inoculation produce a fatal illness resembling kala-azar in mammals. Archibald, experimenting with human kala-azar parasites in the Sudan, has shown that monkeys can be similarly infected by feeding with kala-azar material, and this, together with the curious endemicity of the disease in the Sudan, and with Laveran, Franchini, Fantham, and Porter's researches, make the possibility of water carriage of cysts from infected arthropods to man worthy of consideration.

From the above it will be clear that, though the parasite is known, the method of infection is still unknown, and the cultivation of the parasite into flagellate form clearly indicates that this is part of the life cycle.

The predisposing causes appear to depend upon, and be capable of explanation by, the habits of man. Thus the disease, when epidemic, always spreads relatively slowly along channels of human intercommunication, and apparently is directly due to the introduction of an infected human being into the district. It runs in families, in which children particularly suffer, while the class of people who are mainly affected are the poorer sections of the European and native communities. Season and sex appear to have no influence, but there is no doubt about the infection of the dwelling or perhaps its water-supply, nor of the capability of the disease spreading from one dwelling to another, or from one water-supply to another.

Pathology.—Introduced into the body, the parasite appears to enter the endothelial cells of a capillary bloodvessel or lymphatic, and to grow therein, and to increase in numbers by simple fission until a very large number—Leishman says upwards of 220—may be counted in one cell. The organs principally affected in this manner are the liver, spleen, bone-marrow, and lymphatic glands, and, to a less extent, the pancreas, kidneys, suprarenals, testicles, and lungs.

The parasites may now escape from the enclosing cell by rupture, and are then taken up by the leucocytes, particularly by the polymorphonuclears, but also by the mononuclears and rarely by the eosinophiles, by means of which they appear in the peripheral blood even in early cases, but are much more common late in the disease, especially if there is diarrhœa due to ulceration of the intestine, in which condition the polymorphonuclear leucocytes are increased in numbers in the peripheral blood, and many of them contain parasites. The further development has still to be worked out, as all that is definitely known is that in cultures the parasite becomes flagellate.

It would appear as though the parasite could produce some sort of toxin which causes the marked changes in the spleen, liver, and bone-marrow, as well as the ulceration of the skin and intestinal mucosa, because sometimes, and in an inconstant manner, it can produce a reaction on the part of the body, as is seen in the formation at times of agglutinins, specific precipitins, inconstant in presence and feeble in action, and useless from a diagnostic point of view, as is complement deviation. At the commencement of the infection there appears to be generally an attempt to produce an immunity, and it is this which produces the rare natural cure in man. It may be the cause of the refractory nature of certain animals to the disease and the limitation of infection in endemic communities. After the infection has obtained its hold on the body as a rule the struggle for immunity becomes less and less, and disappears eventually.

By some means or other the parasite irritates the organ it infects, causing marked changes in the spleen, liver, and bone-marrow, and also causing ulceration of the intestine and skin.

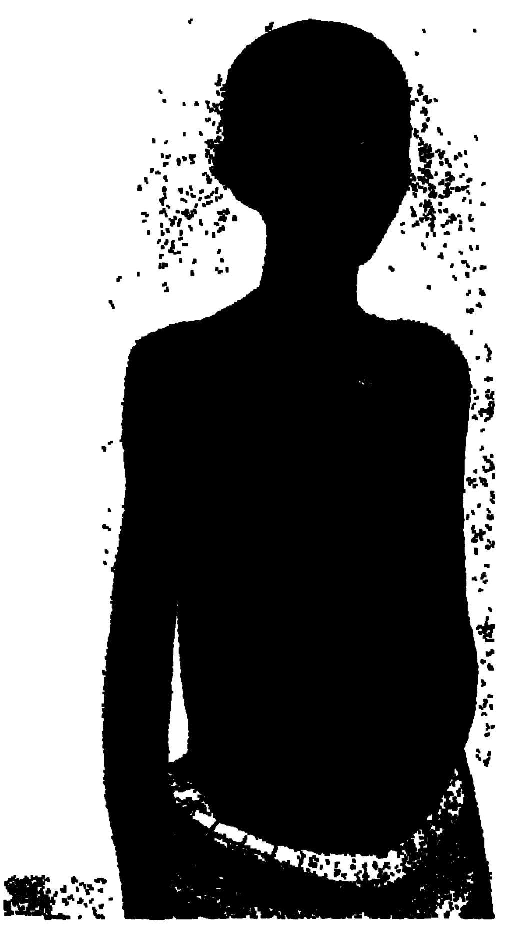

FIG. 644.—INDIAN KALA-AZAR.

The distension of the abdomen by the greatly enlarged spleen should be noted. (Photograph of a case in the Tropical Clinic, Colombo.)

The Blood.—The examination of the blood is most important because, firstly, the parasite may be found in a leucocyte if carefully looked for, even in the early stages of the disease: secondly, the leucocytic changes are of the utmost importance. There is marked anæmia—54·2 per cent. of Rogers' cases giving from 4,000,000 to 2,500,000 corpuscles per cubic millimetre—and the hæmoglobin is reduced in proportion to the erythrocytes, the colour-index being normal. There is a most marked leucopenia, and Rogers reports that in 42·1 per cent. of his cases the leucocytes were 1,000 or less, in 30·3 per cent. 1,000 to 2,000, and in 22·6 per cent. 2,000 to 3,000. The proportion of white to red, according to the same author, is less than 1 : 1,500 in 67·9 per cent., or, if inflammatory cases are excluded, in nearly 90 per cent. of the cases he examined. There is a reduction in the polymorphonuclear leucocytes and in the eosinophiles, and an increase in the mononuclear leucocytes and lymphocytes. The diminution of the polymorphonuclear leucocytes is thought to explain the tendency to bacterial infections. The coagulability of the blood is decreased, which explains the tendency to hæmorrhage, and renders occasionally splenic puncture dangerous. The alkalinity of the blood has been shown by Archibald to be diminished—a fact which may be of some secondary diagnostic importance.

The Urine.—The urine in our cases did not show anything abnormal.

Morbid Anatomy.—The body is much emaciated, and there is marked muscular atrophy, together with œdema, enlargement of the spleen, and often of the liver, ulceration of the skin and intestine, sometimes hæmorrhage in various places, and generally the presence of some complication. The spleen is greatly enlarged, firm, and deep red in colour, though it may at times show malarial pigment. The capsule and septa are thickened, and the whole organ is congested with blood, and contains numerous mononuclear cells and macrophages full of parasites.

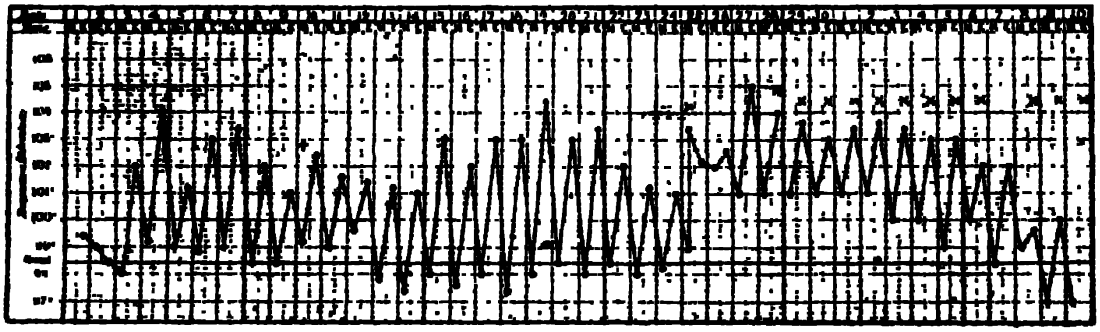

FIG. 645.—TEMPERATURE CHART OF KALA-AZAR FROM A SUDAN CASE. (After Christopherson.)

+, Leishman bodies found; ××××, injection of tartar emetic.

In the liver, which may or may not be enlarged, the most marked changes are in the intralobular capillaries, which are dilated and contain macrophages, derived from their endothelial wall, full of parasites, while the liver cells are atrophied and degenerated. Cirrhosis has been noted in some cases.

The bone-marrow contains numerous parasites in the usual cells, and, as in malaria, the yellow marrow is converted into red, and is soft and diffluent. The skin may show papules and ulcers, in which the parasites can be found, while the colon is often ulcerated, or shows the cicatrices of old ulcers.

Symptomatology—*Incubation.*—The incubation period appears to be very variable, and, indeed, it is difficult, in a chronic disease of this nature, to decide when it first begins. It is said to range from ten days to three weeks or several months.

Onset.—The onset may be heralded by a rigor, which may be repeated daily, and by an attack of irregular, high, remittent fever, which may early show two remissions per diem in a four-hourly temperature chart. This double remission is considered by Rogers to be almost diagnostic of the disease. Towards the end of the third to sixth week of the fever the temperature declines, and the initial stage of the disease may be said to have terminated. During this period, however, the spleen and liver will have enlarged, and may be both painful and tender. Headache is present at times, but is not severe. Nausea and vomiting are unusual, while the bowels are regular, and there is no abdominal distension. The pulse may be slow or quick.

The attack, however, may begin with a continuous fever, which shows two fluctuations in the twenty-four hours, which Rogers considers as almost diagnostic of the disease. In other cases the disease may begin with gastro-intestinal disturbances or with dysenteric symptoms, or quietly, without any marked initial stage, the patient gradually developing an enlarged liver and spleen, anæmia and weakness.

Course.—The course of the disease, after the decline of the temperature, is marked by what is called an apyrexial interval; but it appears that—in some cases, at all events—there is a slight daily rise of temperature, not exceeding 100° F. After some weeks this apyrexial interval ends in an attack of fever resembling the onset. Periods of apyrexia and pyrexia now alternate with one another, while the spleen, and sometimes the liver, enlarge. Anæmia commences and increases, while asthenia not merely appears, but deepens, until the wretched patient presents the typical appearance, which may be described as follows:—He is thin and wasted, with the abdomen much swollen and protuberant, the chest so thin that the ribs show clearly, the arms and legs wasted, the cheeks sunken, the nose sharp, and the ankles puffy, while the skin and tongue are often distinctly darker than they should be, the former being furfuraceous.

On examining the swollen abdomen, the enlarged spleen may be felt reaching almost to the pelvis, while the enlargement of the liver may be marked or may be absent. In this condition intestinal disturbances in the form of diarrhœa or dysenteric attacks are common, and may be due to the actual disease or to complication with true dysentery. Dyspeptic symptoms may also be present.

Hæmorrhages may occur from the nose, the gums, the stomach, the bowels, or under the skin. Papular eruptions are to be seen, especially on the thighs, and ulcers may be present. The weakened, emaciated patient may now die of asthenia, but more usually the long-drawn-out illness is brought to a close by some complication. The total duration varies from about seven months to two years, and generally ends fatally.

Complications.—It appears as though the reduction in the number of the polymorphonuclear leucocytes laid the patient open to invasion by pathogenic bacteria, for septic infections, such as cancrum oris, or lung infections—for example, pneumonia, phthisis, and pleurisy—or abdominal troubles of the nature of diarrhœa, dysentery, and cystitis, are not uncommonly met with, and may cause the death of the patient. Sometimes, after a severe attack of septicæmia or some other complication, the disease is found to be cured, but this is rare.

Diagnosis.—The only certain method of diagnosis is to find the parasite, and as Donovan and Patton have reported its frequent occurrence, even in early stages, in the peripheral blood, this should be possible, especially if aided by dilution with normal saline solution, and centrifugalization and examination of the leucocytes. In our experience, the search for the parasite in the leucocytes of the peripheral blood requires an extremely long time, and is often negative. If the parasites cannot be found in the blood, an attempt may be made to find them by the examination of the exudate obtained by exciting artificial pustulation of the skin by some irritant, as suggested by Cummins. Failing this, there is puncture of the spleen or of the liver, and withdrawal of blood, which can be examined by the microscope. The diagnostic puncture of the spleen in the tropics is, however, not to be undertaken lightly, because splenic enlargement due to leukæmia is by no means unknown, and puncture of the spleen in this disease, or, indeed, in that of chronic malaria, may lead to most unfortunate results. The blood of the peripheral circulation should therefore be examined to exclude leukæmia.

Certainly, the first thing to do is to examine the peripheral blood and exclude leukæmia. Secondly, the coagulability of the blood should be tested by Wright's method, and if found to be decreased, the puncture should not be performed. Thirdly, if the puncture is to be carried out, the liver should be chosen for exploration, not the spleen, particularly in the later stages, in which hæmorrhages are to be feared. In the early stages there may not be so much risk, but it must be done with the greatest care, aseptically, and the patient must be kept at rest for some time afterwards, the site of puncture being covered with an aseptic pad and a firm bandage. The syringe should be sterile, and *perfectly dry*. Rogers recommends that a dose of 30 grains of calcium chloride in a couple of ounces of water be administered directly after a puncture, in order to promote coagulability of the blood. Attempts at cultivation from the blood and inoculations into susceptible animals may also help, rats and monkeys being used by preference.

Differential Diagnosis.—In the early stages the diagnosis has to be principally made from acute malaria and typhoid, when the positive signs in favour of kala-azar are:—(1) Presence of the characteristic daily double remission of the fever; (2) absence of constitutional symptoms, proportional to the severity of the fever; (3) absence of malarial parasites and Widal's reaction, though, of course, the latter reaction is negative in true typhoid during the first week; (4) marked enlargement of the spleen; (5) great leucopenia, especially in relation to the erythrocytes, which, however, may also be found in typhoid and malaria; (6) increase in mononuclear leucocytes; (7) presence of *Leishmania donovani* in the leucocytes.

In advanced cases the diagnosis has to be made from malarial cachexia and ankylostomiasis by (1) the presence of *Leishmania donovani* in the leucocytes of the peripheral blood, or in the juice from the liver and spleen; (2) by the absence of the typical febrile attacks of subtertian or tertian fever: (3) by the absence during the febrile attack of malarial parasites; (4) by the absence of ancylostomes, or, if they are present, by the continuation of the symptoms after their expulsion. Mixed infections of kala-azar and malaria may occur.

Prognosis.—The prognosis is much less serious than before the introduction of the tartar emetic treatment. Formerly the mortality was about 98 per cent. It is true that some people recover after having nearly died from a complication, or, more rarely, without this episode, but why they recover is not known.

Leucocytosis and increase of the polymorphonuclears are considered to be good signs, while leucopenia and polymorphonuclear decrease are bad signs. Complications, of course, increase as a rule the gravity of the prognosis.

Treatment—*Essential Treatment.*—As soon as a diagnosis is made give *tartar emetic* either—

(*a*) Intravenously (this is the method to be preferred);
(*b*) Intramuscularly;
(*c*) Orally combined with (*a*) or (*b*).

Intravenously.—Give 2-10 cubic centimetres of a sterile 1 per cent. solution in warm normal saline solution daily for five to ten days, and then every other day, and finally twice a week. This is the best method of treatment.

Dose for Children.—This is as follows:—

INTRAVENOUS DOSAGE OF 1 PER CENT. TARTAR EMETIC.

Age.	*Dose.*	*Number.*
Under one year ..	¼-1 c.c.	One daily for seven days
One to five years	1-3 c.c	Ditto.
Five to ten years	1-5 c.c.	Ditto.
Ten to sixteen years	1½-8 c.c.	Ditto.

Important.—The sterilization of the tartar emetic solution must be made in flowing steam on two or three consecutive days, and must not be performed in an autoclave, in which the drug is liable to decomposition and may then cause serious symptoms. Some authorities advise using a solution merely filtered through a Chamberland filter. One of us has used a solution containing ½ per cent. carbolic, which in practice renders unnecessary a sterilization by heating.

Intramuscularly.—Intramuscular injections are painful and often become inflamed. The following solution may be used:—

Tartrate of antimony	8 grains.
Carbolic acid	10 minims.
Glycerine	3 drachms.
Bicarbonate of sodium	¼ grain.
Distilled water	1 ounce.

The dose is ½-1 cubic centimetre every other day injected intramuscularly into the gluteal region.

Martindale's formula may also be used:—

Antimonii oxidi	gr. $\frac{1}{60}$.
Glycerin. Aq. dest.	āā ♏xv.

One ampoule.

Combined.—Oral administration may be combined with intravenous or intramuscular injections. The following mixture may be given:—

Tartrate of antimony	5 grains.
Bicarbonate of sodium	30 grains.
Glycerine	1 ounce.
Chloroform water	1 ounce.
Water	to 3 ounces.

The dose is one to two teaspoonfuls in water three times a day.

Rogers regards sodium antimonyl tartrate, given intravenously, as being more efficacious than tartar emetic. Colloidal antimonial preparations have been recommended.

Symptomatic Treatment.—*Hæmorrhagic symptoms* may be treated by calcium lactate in 10-grain doses twice or three times a day. *Diarrhœa* may be combated by bismuth subnitrate in 10-12 grain doses, with or without 5-10 grains of salol, every four to six hours, as may be required. *Intestinal parasites* should be looked for and treated as prescribed in the chapters pertaining to the different forms. *The heart* must be watched and cardiac tonics or saline injections given if required (*vide* Treatment of Malaria, p. 1188).

General Treatment.—The patient should be kept in bed and well nursed during this treatment.

Diet.—The diet should be good and nourishing, but if there is much diarrhœa it is necessary to restrict it to milk, Benger's food and the like, soups, etc.

Prophylaxis.—As the method of infection is unknown, all that can be done is firstly to segregate the sick and carefully disinfect his motions, as well as protect him against blood-sucking arthropods. Secondly, to remove the healthy from the infected area, and to disinfect or destroy the clothing, furniture, and houses, while a complete change of the drinking-water supply is essential. If this latter cannot be done and the water-supply is a well, it may be sterilized by blowing in steam, as in the case of prophylaxis against the guinea-worm (p. 1971); or if this cannot be done, the simple boiling of all drinking-water should be carried out. It does not appear probable that infection comes about via unbroken skin.

MEDITERRANEAN KALA-AZAR.

Synonyms.—Infantile kala-azar, Infantile leishmaniasis, Mediterranean leishmaniasis, Febrile splenic anæmia (Fede), *Anæmia infantum a Leishmania* (Pianese), *Leishmania anæmia* (Jemma and di Cristina), *Marda tal biccia* (Malta), *Ponos* (Greece), *Malattia da mensa* (Sicily).

Definition.—Mediterranean kala-azar is a subacute or chronic specific disease due to *Leishmania infantum* Nicolle, and clinically closely resembling tropical kala-azar, but occurring in temperate or subtropical climates.

Historical.—Fede several years ago described in Italy a form of splenic anæmia among young children characterized by irregular fever, progressive anæmia, and a fatal ending. He considered it a disease by itself, separating it from the non-febrile type of splenic anæmia. In 1904 Laveran and Cathoire found a Leishmania in films from the spleen of a child who had died of an ill-defined disease in Tunisia. Pianese in 1905 called attention to the similarity of the symptoms of Fede's splenic anæmia with kala-azar, and described parasitic bodies in the spleen of the affected children morphologically identical with *Leishmania donovani.* Later Nicolle suggested for the disease the name of 'infantile kala-azar,' and completed the study of the parasite, which he called *Leishmania infantum.* Gabbi considers the disease to be identical with tropical kala-azar, having found it also among adults. A fuller account of the history will be found on p. 373.

Cristina and Caronia in 1915 applied to this complaint Vianna's tartar emetic treatment for American muco-cutaneous leishmaniasis.

Climatology.—The malady is met with in Southern Europe, in the northern regions of Africa, and perhaps Egypt. Future investigations will probably show that it is endemic in many countries.

Ætiology.- The malady is due to *Leishmania infantum* Nicolle. The description of this parasite will be found on p. 373. Nicolle has succeeded in reproducing the disease in monkeys, and less typically in dogs. He has also found that dogs may be spontaneously affected with a leishmania; in fact, in his opinion, the dog acts as a reservoir of *L. infantum,* and its ectoparasites, such as fleas, may possibly serve as the transmitting agents to human beings. These views have been tested experimentally by Basile, but to-day doubt is cast upon canine leishmaniasis being the same disease as that in man, and the flea infection of man is also considered to be doubtful.

The majority of the cases occur in young children of two to three years of age, among whom there is a slight preponderance of males. The disease sometimes occurs in more than one member of a family, and more often begins in the spring or early summer.

Pathology.--The pathology has been carefully studied by Pianese, who finds that the post-mortem lesions are similar to those observed in Indian kala-azar, the spleen and liver being greatly enlarged. Microscopically, there is great increase of the lymphoid tissue in the spleen and hypertrophy of the islands of Langerhans in the pancreas. In the bone-marrow there is hyperproduction of the myeloid and lymphoid tissues.

Symptomatology—*Onset.*—The disease begins in a very insidious manner, and is usually first noticed when the child has some disturbance of the alimentary canal, such as an attack of vomiting and diarrhœa, when the spleen may or may not be found to be enlarged; and as the child is anæmic and has a very irregular fever, the complaint is wont to be diagnosed as malaria, especially as some seizures are apt to come on suddenly, and to be associated with rigors.

The child becomes pale, ceases to be interested in its games, and suffers from attacks of diarrhœa, alternating with periods of constipation, from attacks of irregular fever separated by apyrexial intervals, and from epistaxis.

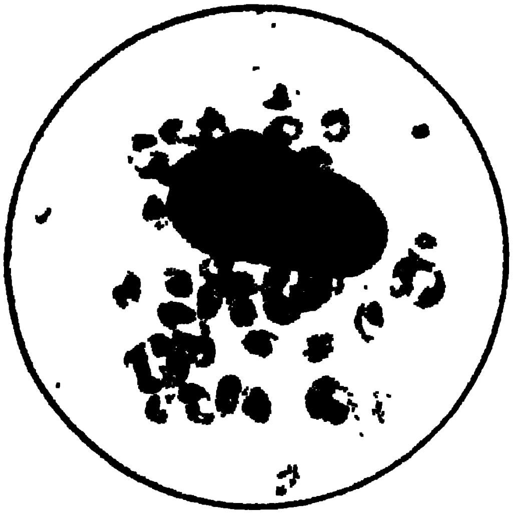

FIG. 646.—*Leishmania infantum* NICOLLE.

(After Marzinowsky.)

FIG. 647.—CHILD SUFFERING FROM INFANTILE KALA-AZAR.

(After Marzinowsky.)

Course.—After the above symptoms have lasted some time, the spleen begins to enlarge, and presently protrudes from under cover of the ribs; the attacks of fever become more marked; hæmorrhages from the nose and gums and into the skin are seen, and the diarrhœic or dysenteric attacks become pronounced. The child now wastes and becomes progressively anæmic: the face, conjunctiva, and whole body taking a peculiar white tinge, and the disease may be said to be fully established.

With regard to the special symptoms, the fever is very irregular, with exacerbations sometimes twice a day—in the morning and in the evening—and sometimes several times a day. High temperatures at times appear in cycles, or there may be sudden falls to subnormal temperatures.

The alimentary canal is always disturbed, but the appetite is preserved, and may even be increased, although the little patient is suffering from alternate attacks of diarrhœa and constipation; but this is not always so, and some observers have recorded anorexia. The motions may be very foul, containing undigested food, and at times blood and mucus. Ulcerative stomatitis, and even noma, may occur, and the last may appear on the face or on the genitalia. Noma appears to be not uncommon in Greece.

The spleen, as stated above, is always enlarged from the time of the full establishment of the symptoms, but this enlargement is not stationary. On the contrary, it steadily increases until an enormous size is sometimes reached, so that it fills the left side of the abdomen and projects across the median line into the right half, causing the abdomen to bulge and become prominent. On palpation it is found to move, and notches may be felt through the attenuated abdominal wall. It moves with the respiratory movements, and may be altered in position from side to side, and up and down by manipulation. There is not, however, any constant relationship between the progress of the disease and the size of the spleen. Jemma, Di Cristina, and Critien state that it diminishes with a persistent and profuse diarrhœa, especially during the last few days of life.

There is not always a concord between the temperature and the pulse-rate; on the contrary, the latter is almost constantly rapid, even during the apyrexial intervals, but may rise to 150 to 160 beats per minute during attacks of fever. Hæmic murmurs may occur over the heart, but are rare. The blood is pale, and shows a decrease in the number of erythrocytes (1,500,000 to 3,000,000), and in the hæmoglobin (below 50 per cent.), which, however, is reduced in proportion to the red corpuscles; and also in the leucocytes (1,500 to 3,000), though the leucocytic formula is mononuclear (70 to 80 per cent.), being especially composed of medium-sized cells. The mononuclears are increased at the expense of the polymorphonuclear cells, which make up the remaining 20 to 30 per cent. There is usually some poikilocytosis and anisocytosis, but nucleated cells are rare or absent. The opsonic index is diminished below that which is normal for a healthy child, and is especially low for *Bacillus coli communis*, which is held to be responsible for the frequency of the intestinal symptoms. Œdemas of the face, hands, genitalia, and feet, coming on suddenly and disappearing suddenly, are not unusual; they have a tendency to bilateral symmetry, but are influenced by the position of the patient, and may occur at any stage of the disease. At times they are painful and may show signs of inflammation.

The liver is very generally enlarged, but to a much less extent than the spleen. On palpation, its edge is felt to be smooth and hard, and is not tender.

As the spleen and liver enlarge, the abdomen also enlarges and becomes prominent, while the superficial veins may stand out distinctly, and there may be a slight degree of ascites at times.

The urine is usually normal, but there may be slight signs of albuminuria, or a decrease in the output of urea. The lymphatic glands are as a rule not enlarged.

The mental and physical activity of the child decreases as the disease progresses; it emaciates, and becomes extremely pallid, thereby assuming a prematurely aged appearance. The bones become evident, especially the ribs and shoulder-blades, and the child dies from exhaustion, often due to an attack of dysentery or diarrhœa. Spontaneous recovery may take place, but this is rare.

Complications.--Respiratory complications are not unusual. Bronchitis is common, while broncho-pneumonia and pleurisy may occur, as may a rapidly developing fatal dyspnœa, which is probably due to œdema of the glottis. Perhaps noma, as already mentioned, is a fairly common complication in Italy and Greece, and should come in this place as a complication rather than a symptom of the disease. Otitis media has been recorded not merely as a complication, but also as a cause of death. Ankylostomiasis associated with lipuria has been recorded as a complication.

Diagnosis.—The symptoms more or less closely resemble those of kala-azar, but differ in that this disease occurs in children and is inoculable into dogs, while kala-azar occurs mostly in young adults and is with difficulty inoculable into dogs. The temperature chart may resemble that of kala-azar, but is generally more irregular. The characteristic clinical symptoms of the disease are the enlarged spleen, the irregular fever, and the pallor occurring in a child. The essential feature in the diagnosis is the parasite, which may be obtained by splenic puncture, by liver puncture, by examination of the bone-marrow obtained by a modified trocar and cannula, as designed by Caccioppoli, to which a Potain's aspirator with a strong pump is attached: rarely by blood examination. Other methods are by vesication and examination of the fluid; and by lumbar puncture, if there are cerebral symptoms.

Having obtained the splenic or hepatic pulp, etc., the diagnosis may be made by microscopical examinations and by cultivation on the medium devised by Novy and McNeil, and modified by Nicolle, usually known as the N.N.N. medium (p. 377).

It has been suggested by Cochrane that removal of one of the post-cervical lymphatic glands might be adopted as a diagnostic method. The removed gland is cut, and a smear made, when numerous parasites may be seen. This method is said to be the most certain means of diagnosis. It is recommended that the glands be removed under the influence of a local anæsthetic.

Differential Diagnosis.—The differential diagnosis has to be made from kala-azar, undulant fever, enteric fever, malaria, other forms of splenic anæmia, and syphilis.

Kala-Azar.—This fever occurs in adults, and is characterized by the double daily rise of the temperature, and by the difficulty of successful inoculation into dogs. In this disease the spleen is not so markedly enlarged.

Undulant Fever.—In contrast to undulant fever, in infantile kala-azar the temperature is much less regular, never showing a typical undulating type; the enlargement of the spleen is much greater; the articular symptoms are lacking, and Wright's agglutination test is negative.

Enteric Fever.—From enteric, infantile kala-azar differs by the splenomegaly, by the irregular fever, by the absence of Widal's reaction.

Malaria. -The absence of the typical blood parasites, and the fact that quinine has no influence on the irregular fever, are points of diagnostic value.

Other Forms of Splenic Anæmia.- From the splenomedullary leukæmia, infantile kala-azar is distinguished by the leucopenia; from syphilitic splenomegaly, by the history and inutility of mercury and salvarsan; from the various types of infantile afebrile splenomegaly, by the fever and the presence of the parasite; from the splenomegaly found in rickety children, by the absence of deformity of the bones and by microscopical examination.

Prognosis.—The prognosis is much more favourable since the introduction of the tartar emetic treatment, the mortality having been reduced from 90 per cent. to less than 20 per cent.

Treatment.—This is the same as for tropical kala-azar (p. 1297).

Prophylaxis.—As canine leishmaniasis (p. 377) is now considered to be a separate disease, and as the flea is doubtful as an infective agent, prophylaxis cannot be advised until more is known as to the method of infection, but the suggestions made under the heading of Tropical Kala-Azar may perhaps be applicable, and in any case it is unnecessary to keep dogs and fleas in a house.

Basile has sufficiently indicated the possibilities of this method of infection being correct to make the simple methods of prophylaxis of such a fatal disease imperative even before the full proof of the researches has been obtained.

THE PSEUDO-KALA-AZARS.

These are febrile and afebrile diseases which resemble kala-azar in that they are associated with splenomegaly, anæmia, and often emaciation. They can be divided into:—

Tropical febrile splenomegaly.
Toxoplasmosis.
Krempf's splenomegaly.
Tropical afebrile splenomegaly.

TROPICAL FEBRILE SPLENOMEGALY.

Synonyms.—Tropical splenomegaly, Pseudo-kala-azar, Esplenomegalia tropical (Columbia), Wenku (Karonga), Gobora or Tebi (New Guinea).

Definition.—A chronic irregular febrile disorder of unknown causation, characterized by splenic hypertrophy and gastro-intestinal disturbance, followed by emaciation.

History.—A form of febrile splenomegaly resembling kala azar has been long known in the tropics; but the typical parasites of that infection cannot be found either during life or after death. Though well known, there is but little literature upon the subject. Woolley first gave an excellent account of the disease as seen in the Philippine Islands, and Day and Ferguson as seen in Egypt. We have repeatedly in local publications called attention to the disease in Ceylon. Gabbi has ably described the disease in Italy, and so has Leys, in 1917, from Karongo, and it is probably the same disease as that described by Breinl, in 1915, in New Guinea. In 1916 Spagnolio recorded cases from Calabria and Sicily.

In one form of this complaint (p. 1305) Castellani has found protozoal bodies, *Toxoplasma pyrogenes*, which may be causal (*vide* p. 490), but there may be many varieties of the disease.

Climatology.—The disease has been reported from India, Ceylon, China, the Philippines, Egypt, Arabia, Tunis, Algiers, the Belgian Congo, Italy, and South America.

Ætiology.—The causation of the disease is quite unknown. Gabbi suggests that it may be a filterable virus.

Pathology.—It is thought probable that the disease may be a primary infection of the alimentary canal, and that the fibrosis is secondary, but we would rather distinguish this from the ordinary forms of polyfibrosis, and would consider that the seat of the disorder was in the spleen and liver, and that the alimentary canal signs were secondary.

Morbid Anatomy.—On post-mortem examination, the body is seen to be emaciated as a rule, but there may be œdema of the feet and legs, and there may be ascites if the liver is seriously affected. Upon opening the abdomen, the principal object of interest is the extremely enlarged firm spleen. The liver may be enlarged and smooth, and does not show the hobnailed appearance of alcoholic cirrhosis, while the lymphatic glands in various regions of the body may be slightly enlarged. The intestines show signs of catarrhal or ulcerative enteritis. The bone-marrow is diffluent and pale in colour. Hæmorrhages may at times be found in different parts of the body. Microscopical examination reveals hyperplasia of the lymphoid elements of the spleen, associated with hyperplasia of the fibrous tissue, dilatation of the vascular sinuses, and sometimes hæmorrhages. The microscopic examination of the liver shows the usual appearances of monolobular and polylobular cirrhosis. The bone-marrow is seen to be congested and hæmorrhagic, and the hyaline cells are increased, while the granular cells are reduced.

Symptomatology.—The onset of the disease is quite gradual and unnoticed by the patient, although at times a history of diarrhœa, dysentery, or of attacks of fever may be obtained. Usually the patient comes to the hospital complaining of weakness and vague rheumatic pains, although he may come in the later stages because of the ascites. On examination, the patient is found to be more or less emaciated, and to have a large firm spleen projecting from under the ribs, and sometimes making a considerable protuberance of the thin abdominal wall. The amount of anæmia is usually not extreme, the average number of red corpuscles being between 2,500,000 and 3,500,000, while microcytes, megalocytes, and polychromatophilia are not unusual. The leucocytes are more or less normal. Frequently there is some fever of an irregular type, and there may be exacerbations, and at times there may be a double remission similar to that found in kala-azar; but there may be long periods of apyrexia. In addition, in a few cases there may be all the signs and symptoms of cirrhosis of the liver, with the abdomen distended from ascites.

By some authorities the disease has been subdivided into two stages—the first or splenic stage before, and the second or hepatic stage after, the hepatic cirrhosis. The first may last for many years, but the latter is much shorter, lasting a variable number of months, and ending fatally by the patient passing into a condition of coma, sometimes accompanied by jaundice. Death in the first stage is, in our experience, not rare, and may be due to hæmorrhages or exhaustion.

Complications.—Pregnancy is a serious complication, and may hasten the end, even after the child has been born. Ankylostomiasis and other parasitic diseases may occur along with tropical febrile splenomegaly.

Diagnosis.—The leading features of the disease are the great enlargement of the spleen, associated with wasting and irregular fever, in people in whom examination fails to reveal any obvious parasitic cause. Tropical febrile splenomegaly must be differentiated from kala-azar by the absence of *Leishmania donovani* in the spleen pulp as obtained by puncture. It can also be distinguished from chronic malaria by the absence of the typical parasites or pigment from the splenic juice, and from cirrhosis of the liver by the presence of the enlarged spleen. From leukæmia it is easily distinguished by the absence of a leucocytosis. From infantile kala-azar it may be distinguished by the absence of *Leishmania infantum*, as seen in the splenic juice. The disease can be distinguished from Banti's disease by the febrile attacks, and apparently splenic removal does not effect a cure.

Prognosis.—The illness is very chronic, but the prognosis is bad, as no cure is at present possible, and the patient tends to go from bad to worse.

Treatment.—Arsenical injections are the most valuable, and salvarsan may be tried. Removal from the endemic area is advisable.

Prophylaxis.—As the ætiology is unknown, nothing can be said under this heading.

TOXOPLASMOSIS.

In 1913 Castellani recorded a case of splenomegaly associated with fever of long standing and terminating fatally, in which he had found protozoal bodies which eventually received the name *Toxoplasma pyrogenes* Castellani, 1913 (*vide* p. 490).

Morbid Anatomy.—The body was much emaciated, and the principal feature was the greatly enlarged, smooth, not very hard spleen, which was reddish in colour. No malarial parasites could be found, but there were some light yellowish pigment granules, quite different from malarial pigment.

Toxoplasma Pyrogenes.—This was rarely found in the blood, but was abundant in the spleen. (For a description, see p. 490.)

Symptomatology.—The fever starts in youth and lasts many years, defying all treatment. In character it is intermittent, reaching 103° to 105° F. at times. The attacks of fever do not start with shivering, and the fall is not associated with sweating. The spleen is much enlarged and hard, while the liver is also enlarged, but neither organ is tender on pressure. All the other organs are normal, and there is no enlargement of the lymphatic glands.

Blood Counts.—The red blood-corpuscles in an advanced case number 2,000,000, the leucocytes 5,200 per c.mm. A few nucleated red cells are present, and basophilia and chromatophilia are marked. The leucocytic count is as follows:—Polymorphonuclear leucocytes, 50 per cent.; lymphocytes, 40 per cent.; large mononucleurs, 7 per cent.; eosinophiles, 3 per cent.; hæmoglobin, 30 per cent.

No malarial parasites could be found, and the serum reactions for typhoid, the paratyphoids, and Malta fever, were absent.

The urine sometimes contained a trace of albumen.

Course.—The case grew gradually worse, emaciation set in, and the patient died.

Treatment.— Quinine was given by the mouth and intramuscularly in doses of 30-60 grains a day without effect.

KREMPF'S SPLENOMEGALY.

In 1917 Krempf described a case of splenomegaly in a young Chinaman. He suffered from a malarial infection, and stated that in his village near Tientsin splenomegaly was frequently observed in both sexes and at all ages.

On making a splenic puncture, Krempf found bodies either enclosed in red cells or free in the plasma. They were only found in the spleen.

The red cells were deformed and contained a capsule 10 × 5 microns in size, inside which lay a vermicular sporont often curved like the letter U. Extracted from a red corpuscle, these bodies measured 20 × 1·5 microns.

These bodies were believed to be the sporonts of a hæmogregarine, and were named *Hæmogregarina hominis* Krempf, 1917. No further history of the case is given.

Recently Raubaud, examining the blood of a lady who had resided for two years in the Congo, observed that some red cells contained a hæmogregarina 9-11 μ by 2·8-3·5 μ, which differed from Krempf's parasite by having a crescenting, not vermicular shape. Raubaud has named it *Hæmogregarina inexpectata*. There was no fever, and no enlargement of the liver or spleen. The blood, however, showed a marked mononucleosis.

AFEBRILE SPLENOMEGALY.

Synonym.— Pseudo-Banti's disease.

Definition.—A chronic afebrile disorder characterized by splenomegaly and severe anæmia.

History.—There is no literature on the subject as far as we know.

Climatology.—We have observed it in tropical Africa, Ceylon, and India, and probably it will be found in many other places.

Symptomatology.—The disease begins insidiously in either children or adults, but usually the case is not observed until either the anæmia becomes well marked or the splenomegaly attracts attention. The symptoms are more or less severe anæmia and a painless firm enlargement of the spleen, without increase in size of the liver or other important signs. The blood shows the ordinary signs of a severe anæmia, but no parasites can be observed. There is no diarrhœa, and the mucosa of the mouth is not inflamed or ulcerated.

Diagnosis.—The disease can be differentiated from malaria by the absence of fever and of the absence of the parasites in the blood and spleen; from kala-azar by the absence of the parasites in the spleen; from forms of febrile splenomegaly by the absence of fever; from leucocythemia by the absence of the great increase of the white blood cells. From other forms of splenic anæmia it may be differentiated by the absence of any history or signs of rickets, syphilis, etc.

Prognosis.—Patients appear to live for years.

Treatment.—This is purely symptomatic, but arsenic may be administered.

Léger's Disease.

Léger has recorded a case, from Guiana, of prolonged fever with great enlargement of the liver, in which he found organisms of two types. Some were 3-5 μ in length by 1 μ in breadth, with a flagellum 3-5 μ long. Others were of oval shape, without any flagellum. Léger considers his parasite to differ from *Hæmocystozoon brasiliense* Franchini (p. 1468), as it never contained any pigment, and encysted forms were absent.

REFERENCES.

The most complete and valuable references may be found in the *Kala-Azar Bulletin* (1911-1912), which was published separately by the Bureau of Sleeping Sickness, but is now merged in the *Tropical Diseases Bulletin*, in which many references will be found. The most valuable single work is the excellent monograph of Laveran (1917). 'Leishmaniases,' Paris.

CHAPTER XLVIII

THE RELAPSING FEVERS

General—*Louse group:* European—North African—Indian—Manchurian—*Tick group:* Tropical African—Persian—American—References.

GENERAL.

The relapsing fevers are caused by various species of spirochætes, and may for purposes of description be arranged partly by their carrier and partly by their geography as follows:—

A. *Louse group:*—
  1. European relapsing fever.
  2. North African relapsing fever.
  3. Indian relapsing fever.
  4. Manchurian relapsing fever.

B. *Tick group:*—
  1. Tropical African relapsing fever.
  2. The tick fever of Miana, Persia.
  3. American relapsing fevers.

THE RELAPSING FEVER OF EUROPE.

Synonyms.—*English:* Recurrent fever, Five Days' fever, Spirillum fever, Five Days' fever with relapses, Typhus Recurrens, Seven Days' fever (not Rogers'), Icteric typhus, Remittent fever, Bilious typhoid, Epidemic remittent fever, Miliary fever, Relapsing fever. *French:* Fièvre à Rechute. *Italian:* Febbre Ricorrente. *German:* Rückfallfieber, Die Hungerpeste.

Definition.—An acute specific relapsing fever, caused by *Spiroschaudinnia recurrentis* Lebert, 1874, and spread from man to man by lice, *Pediculus corporis* de Geer, 1778, and by *P. humanus* Linnæus, 1758.

History.—Hippocrates was the first writer to describe an epidemic of relapsing fever in Thasos, but this knowledge was entirely lost, and the reference was not understood until after relapsing fever was properly defined. Strother and other observers refer to fevers with relapses in London and in Ireland in the eighteenth century. In 1826-27 there was an epidemic of fever in the United Kingdom, during which it was recognized that there were two distinct types of typhus—viz., a mild and a severe. In 1842 this mild type again appeared in Scotland, and, to a lesser extent, in England, and continued in the years 1843, 1846, and 1847. In 1843 Henderson of Edinburgh defined this mild type as a fever distinct from typhus, and about the same time it was recognized in Germany, and somewhat later in Russia.

In 1868 there was an epidemic in Berlin, when Obermeyer, one of Virchow's assistants, first saw a spirochæte in the blood of a patient; but he does not appear to have been very certain about this at the time, for he waited till the next epidemic in 1872, and even then did not publish his account till 1873. This spirochæte was named *S. recurrentis* by Lebert in 1874, and *S. obermeyeri* by Cohn in 1875, and was proved by Münch, of Moscow, to be the cause of the disease by the successful inoculation of blood containing the spirochætes into healthy human beings—an experiment which has since often been repeated accidentally at post-mortems. It has been inoculated with success by Metchnikoff and others into monkeys and mice. In 1888 Sakharoff suggested that this organism was a protozoon—a view which later met with great support.

In Russia, where the disease has been well known since 1863, there is a popular belief that it is spread by the bed-bug *Clinocoris lectularius* L., which belief was supported by Flügge in 1891. In 1897 Tictin found that he could infect monkeys by inoculation of the blood obtained by crushing bugs which had very recently been fed on a patient—*i.e.*, within forty-eight hours.

Spirochætes have been found in bugs during relapsing fever epidemics by Karlinski in 1902, and later by Schaudinn. Nuttall has successfully transmitted *S. recurrentis* from mouse to mouse by the bites of bugs. Dönitz's hypothesis, that *S. recurrentis* is conveyed by ticks, has not been supported by experiments.

The rôle of the louse in this disease has been studied by Koch and by Werner and Wiese in 1917, but requires the accurate study given to the North African type by Nicolle, Blaizot, and Conseil. It has also been studied by Toyoda, who has shown it to be closely related to the North African type by means of immunity experiments.

Climatology.—The disease is endemic in Russia, Ireland, Turkey, the Balkans, Denmark, Norway, Bohemia, and in some parts of Poland and Germany, while the same or a similar type is found in Lower Egypt, in Southern China, and perhaps in the Philippines. There, however, appears to be some doubt about the presence of the disease in these islands; the authority for the statement is McCrae, in Osler's 'System of Medicine.'

Ætiology.—This type of relapsing fever is caused by *S. recurrentis* Lebert, 1874, which is generally to be found in the peripheral blood during the attacks, but is usually absent in the apyrexial interval, though individuals may occasionally be found after prolonged search. (For description of the organism, see p. 443.)

This spirochæte is carried from the sick to the healthy by the agency of lice, *P. humanus* and *P. corporis* (see p. 917). The subject, however, requires further study on the lines of the North African type (*vide infra*). It is known that the human blood is infective during the pyrexial and apyrexial stages, and that the spirochætes reach the cœlom of the louse between the second and eighth day after the transmissive feed. It can also be spread by direct inoculations such as may take place accidentally in laboratories or at post-mortems.

The blood is not merely transmissive to the louse during the time when the spirochæte can be found therein, but also during the apyrexial interval. The louse may be infective for a few hours after a transmissive feed, and perhaps a few cases of human infection may be accounted for in this way, but this is not the usual method.

After a transmissive feed the spirochætes quickly disappear from the alimentary canal of the louse, and do not reappear in the cœlomic fluid until the eighth to ninth day after the feed; but before this the louse becomes infective from the third to fifteenth day, and usually on the sixth day the louse is most infective.

Infection is not conveyed by the louse bite, but by the parasite escaping from the body of the crushed louse and entering man through excoriations in the skin, generally made by scratching. One crushed louse is sufficient to produce the disease.

The incubation period under experimental conditions appears to be six to eight days.

The louse is not pathologically affected by the germ, of which it is the natural reservoir, the spirochæte being passed from one generation to the next succeeding generation, as has been shown by the discovery that the young of infected lice are themselves infective.

Pathology. -The presence of the spirochætes in the blood is associated with fever, which must be due to toxins produced by these organisms, though the severity of the symptoms bears no relationship to the number of the organisms found in the peripheral blood. The spirochætes disappear from the circulation when the temperature falls to normal. The disappearance of the parasites from the blood is brought about by the presence of antibodies (agglutinins and parasiticidal substances). In those cases, however, in which relapses occur, the blood remains infectious during the intervals. This is due to some parasites resisting the action of the antibodies. These resistant spirochætes after a time multiply again in large numbers, giving rise to the relapse. Levaditi and Roche have demonstrated that serum collected after a first attack destroyed the spirochætes which caused the attack, but had no effect whatever on the spirochætes which caused the second attack. The relapses, therefore, are caused by the survival of resistant types of spirochætes, and recovery depends upon the existence of protective substances in the blood. The immunity acquired after one or several attacks may last for some weeks or months. Animals can be hyperimmunized by repeated inoculations after recovery from the first attack. The serum of such hyperimmunized animals shows definite protective and curative properties.

Morbid Anatomy.—The principal pathological feature of the post-mortem is the enlargement of the liver and spleen, the latter organ reaching a weight of 1 to 2 kilogrammes at times. On section, the spleen is dark-coloured and soft, with enlarged follicles, and on microscopical examination shows congestion and a cellular increase. The liver is enlarged, and its lobules are poorly defined, while microscopically cloudy swelling and fatty infiltration may be seen, as well as leucocytic infiltration into the portal system. The kidneys are enlarged and congested, and microscopically show cloudy swelling and fatty degeneration of the cells, while the stomach shows signs of inflammation, and the heart is soft and flabby. The bronchi are generally congested, and contain frothy mucus, and the lungs show hypostasis. The brain may be congested, and all the organs may be stained yellow with bile.

Symptomatology.—*The incubation period* is said to vary between two and twelve days, but in accidental inoculations it is *about seven days*. During this period prodromal symptoms, in the form of slight malaise, may be felt.

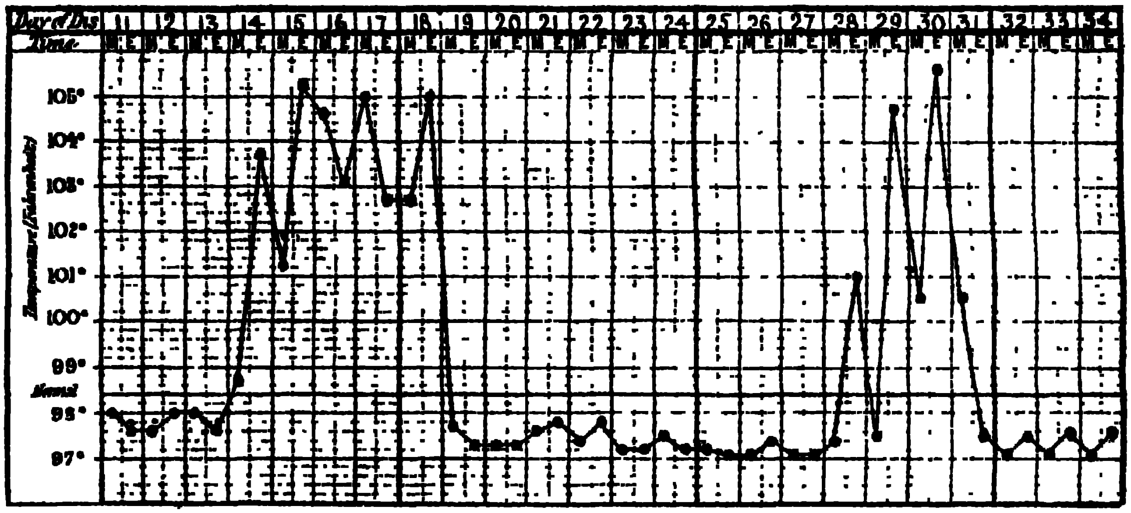

FIG. 648.—TEMPERATURE CHART OF THE RELAPSING FEVER OF EUROPE.

The onset is usually sudden, but it may be gradual, the patient suffering from rheumatic-like pains, headache, and constipation. When it begins suddenly, there are rigors, with severe frontal headache, pains in the back and limbs, epigastric pain and tenderness, associated with a sense of weakness. The face becomes flushed, the conjunctivæ injected, and the temperature rises to 103° to 104° F., with a pulse-rate of 110 to 120, quickened respirations, and sometimes nausea and vomiting.

The Course.—The temperature continues high until the sixth or seventh day, during which period the skin may be yellowish in colour, hot and damp from perspiration, with at times a rose-coloured macular eruption, disappearing on pressure, on the thorax, abdomen, and legs, which lasts for a day or so. The tongue is moist, red at the tip, and covered with a white fur. Vomiting of greenish-yellow matter may occur, but nausea is always present, and thirst is common; the bowels are usually constipated, and diarrhœa is more a complication than a feature of the disease. The liver is enlarged and tender, and so is the spleen, which may reach a considerable size. The heart sounds are normal, but the pulse-rate is quick, reaching 120 to 140, or even more, per minute; but it is not dicrotic. The erythrocytes and the hæmoglobin are reduced in amount, while a polymorphonuclear leucocytosis may be present. Spirochætes can be found in the blood, and occasionally can be seen engulfed by leucocytes. There is generally a troublesome cough, with scanty bronchitic expectoration, and râles, which can be heard over the chest and trachea. The respirations follow the pulse-rate, being increased to 48 to 50 per minute if the temperature is high. The pains in the muscles and joints continue, and sleeplessness may result, while a noisy delirium is not rare, but stupor is uncommon. The urine is febrile, and may contain a little albumen. About the sixth or seventh day the crisis, sometimes ushered in by a rigor, intervenes, with violent perspiration, or diarrhœa, with or without epistaxis, and with a sudden rapid fall of temperature, while the pulse and respirations also return to normal, and the patient falls into a deep sleep, and awakens much better.

The Intermission.—The intermission now begins, during which the temperature returns to normal. The spleen often remains enlarged, the temperature chart may show small rises, and the patient's strength slowly improves.

The Relapse.—The disease may now end; but this is exceptional, and more usually, about the fourteenth day from the first commencement of the illness, the *relapse* occurs, beginning with a rigor and symptoms resembling the attack, but often more severe, and, after lasting three or four days, terminating in a crisis, which generally ends the illness. Very rarely is there a *second relapse*, in which case the same symptoms occur, but much less severely, and a *third relapse* is most uncommon. *Convalescence* is sometimes slow.

Complications.—The complications are numerous, affecting the lungs in the form of bronchitis and pneumonia, or the alimentary canal as dysentery, diarrhœa, and hæmatemesis; while cerebral hæmorrhage, conjunctival hæmorrhage, iritis, and corneal ulcers, have all been recorded.

Abortion often complicates the first relapse in pregnant women.

Diagnosis.—In the first instance, before the relapsing character has appeared, the disease requires to be diagnosed from malaria, typhus, typhoid fever, yellow fever, and seven days' fever. The principal positive signs indicating relapsing fever are:—(1) Presence of the spirochætes in the blood; (2) agglutination or Löwenthal's reaction, which consists of taking a drop of blood from the suspected case and adding it to another drop of blood containing spirochætes taken from a patient, mixing the two drops together, and covering with a cover-glass, which is then sealed and placed in an incubator at 37° C. for half an hour. A positive reaction is indicated by the clumping of the spirochætes into non-motile masses.

Differential Diagnosis.—*Malaria* can be diagnosed by the discovery of the malarial parasite in the blood.

Typhoid is indicated by the positive results of hæmo-cultures and by the fever having started gradually. Widal's reaction is not of much help during the first week. *Typhus* can be separated by the absence of spirochætes, by a negative Löwenthal's reaction, and by the presence of its characteristic rash. *Yellow fever* can be diagnosed by its black vomit, though at first the differentiation may be impossible without a microscopical examination of the blood. *Dengue fever* is characterized by its slow pulse and, of course, by the absence of spirochætes. *Weil's disease* may be distinguished by the more marked jaundice and by the different nature of the spirochætes, which are seldom found by the simple microscopical examination of the blood.

Prognosis.—The prognosis is usually favourable. Marked jaundice is a bad sign, while pregnant women generally abort. The mortality appears to vary considerably, being, according to Murchison, only 4 per cent. in the United Kingdom: while, according to Sandwith, it is 14·4 per cent. in Egypt, which is nearly the same percentage as that reached in Russia. The causes of death are toxæmia in the first attack, and collapse in the first intermission, but it may be caused by one of the above-mentioned complications.

Treatment.—This may be discussed under the following headings:—

1. Specific Treatment.
2. Symptomatic Treatment.

Specific Treatment.—Salvarsan or neosalvarsan or their substitutes may be administered either by intramuscular injection or, better, intravenously. This is a specific treatment, most efficacious, but care should be taken not to inject a large dose, as certain patients, especially, it seems, those suffering from Asiatic relapsing fever, stand the drug badly, cases of death having been recorded, even after a medium dose, such as 7½ grains (0·5 gramme). According to Mouzels, an intravenous injection of 4 or 5 grains (0·3 gramme) does not give rise to any unpleasant symptom, and is generally sufficient to make the spirochætes disappear from the blood and cure the attack. If, however, another attack of fever develops, a second injection of the same dose may be given.

Symptomatic Treatment.—Pains in the head and muscles may be relieved by small doses (2 to 3 grains) of salicylates, aspirin, antipyrin, or by quinine. If these pains are very severe, opium or a hypodermic injection of morphia may be necessary. *Epigastric pain* may be relieved by fomentations sprinkled with tincture of opium, while *vomiting* should be treated with ice, champagne, and bismuth mixtures, though occasionally morphia or codeine may be required. Effervescing ammonium carbonate mixtures are often grateful.

A dry, troublesome *cough* may be relieved by codeine or small doses of heroin; in other cases an expectorant mixture will be found useful. *Constipation* must be treated by laxatives or enemata, and high temperatures by cool sponging, which, however, will but seldom be required. The complications must be met by the treatment laid down in textbooks on general medicine.

Prophylaxis.—Prophylaxis consists in the destruction of lice by steaming clothes, as can be done in railway trucks by leading in steam from the engine or by boiling clothes, while the patient is thoroughly bathed. For further particulars see the prophylaxis of typhus (p. 1338).

THE RELAPSING FEVER OF NORTH AFRICA.

Synonyms.—Algerian relapsing fever; Egyptian relapsing fever; Arabic: Homa el Hugga, Homa en Naxy, Naushah.

Definition.—An acute specific fever caused by *Spiroschaudinnia berbera* Sergent and Foley, 1910, and spread by the agency of *Pediculus corporis* de Geer, 1778.

History.—It was noticed by the surgeons of Napoleon's army in Egypt, and later by Griesinger in 1851, when it was called 'bilious typhoid'; while more recently Sandwith, Cummins, Bousfield, Balfour, and Graham-Smith, have published excellent accounts of the disease. In 1910 Sergent and Foley differentiated *S. berbera* Sergent and Foley, in a case in South Oran. The transmission of the disease by lice has been worked out by Nicolle, Blaizot, and Conseil. Toyoda's immunological experiments show that this fever is closely related to the European type.

Climatology.—It is known to exist in Algeria, Tunis, Tripoli, Egypt, and the Anglo-Egyptian Sudan.

Ætiology.—It is caused by S. *berbera* Sergent and Foley, 1910, spread by the agency of lice, as shown by Nicolle, Blaizot, and Conseil (see p. 447).

Symptomatology. The length of the incubation period is not known, but is believed to be more than twelve days. The fever, which may be associated with rigors, reaches its height during the first twenty-four hours, and afterwards shows morning remissions. The spleen enlarges, and the liver becomes tender and painful in some cases; but jaundice is generally absent. Vomiting is present, but diarrhœa is absent. The attack is apparently not very severe. Apyrexia lasts from two to nine days, and is followed by one, two, or, more rarely, three relapses.

Diagnosis.—The spirochætes must be found in the blood, as the cases may occasionally resemble cerebro-spinal meningitis and acute rheumatism.

Prognosis.—This is usually good, the mortality being nil in fifty cases.

Treatment.—This is the same as for the other relapsing fevers.

THE RELAPSING FEVERS OF ASIA.

There are probably a number of relapsing fevers in Asia, but we only know two which have lice as carriers, and these are:—

1. The Indian relapsing fever.
2. The Manchurian relapsing fever.

The Relapsing Fever of India.

Definition.—An acute specific relapsing fever caused by *Spiroschaudinnia carteri* Manson, 1907, and spread by the louse in all probability.

History.—Relapsing fever is one of the endemic diseases of India, being traceable back into the eighteenth century. The credit of first clearly defining the disease, however, rests with Lyall in the epidemic fever in the Punjaub in 1852-53; but Vandyke Carter, in 1876-77, in the Bombay Presidency found spirochætes in the blood of patients suffering from fever, and his work on the subject, published in 1882, is to be regarded as the Indian classic on this fever. Schellack, in 1907, separated this spirochaete from *S. recurrentis* and *S. novyi* by finding that it is not agglutinated by the serum of animals infected with these parasites. Rogers points out that the disease has often been confounded with typhus fever in India. In 1911 Stott suggested that two varieties of fever may be included under this term, and recent research shows that several varieties of relapsing fever probably exist in India. Types of relapsing fever, which may possibly be different from the Indian ones, occur in China and French Indo China, while the Arabian type may be identical with the West African relapsing fever.

Climatology.—The real home of the disease appears to be the Bombay Presidency, but it is also known in the Punjaub and in the Kumaon Hills of the North-Western Provinces.

Ætiology.—The cause of the disease is the spirochæte found by Vandyke Carter in 1877. It is inoculable into man, as was proved by Carter inoculating himself twice, with an interval of two and a quarter years. It can also be inoculated into monkeys, but not into rats and mice. Bugs are capable of retaining it alive in their alimentary canals for from four to seven days when obtained from monkeys, but do not appear to be so effective in obtaining it from man, as only one in fifty-three were found infected after feeding on human beings. Infected bugs are capable of transmitting the disease to monkeys. Rogers, however, thinks that mosquitoes may be found to be more effective than bugs. Mackie has brought forward evidence in favour of *Pediculus corporis* being a carrier. (For description of the spirochæte, see p. 446.)

S. carteri is separated from *S. duttoni* by the latter being far more easily inoculable into animals and producing numerous relapses when injected into monkeys, while, according to Lamb, the former only causes one relapse. Moreover, the two spirochætes may be differentiated by immunization and agglutination tests. *S. macaci*, observed by us in monkeys in Ceylon, appears to be closely related to *S. carteri*, and may be identical with it.

Strong, experimenting with white mice, has come to the conclusion that the Indian *Spiroschaudinnia* is closely allied to the European and North-American types.

Pathology.—The morbid anatomy resembles that of the European type.

Symptomatology.- In accidental inoculations in the post-mortem room the incubation period varies from three and a half to seven days, during which prodromata resembling those of the European type may occur.

The onset is generally sudden, but in most cases without the rigors defined in Europe, though chilliness occurs, and the disease progresses as in the Obermeyer fever. On the fall of temperature to subnormal, however, on the sixth or seventh day, which is associated with profuse perspiration and polyuria, instead of the patient feeling better, he often becomes collapsed, with a small weak pulse and a cold clammy skin, in which condition he may resemble at first sight a cholera patient. In the first intermission, which lasts from three to twelve days -generally about eight days—the patient improves slowly, there being much debility, and in one case in six there is a sudden temporary rise of temperature after the crisis. Spirochætes are not to be seen in the [illegible] but Carter and Pisani have described peculiar structures. [illegible] first relapse occurs about the fourteenth day of the disease and the seventh of the intermission, and resembles the first attack, but the temperature may reach a higher level, and the illness is shorter, ending in a crisis.

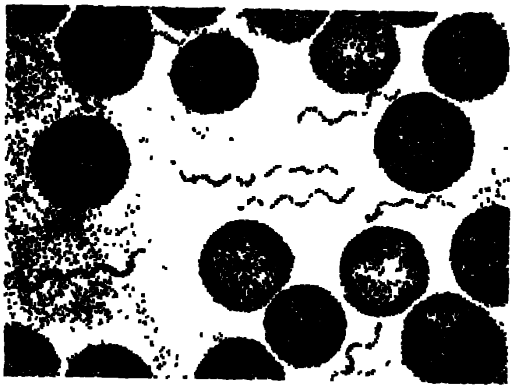

FIG. 649.—SPIROSCHAUDINNIA FROM A CASE OF ASIATIC RELAPSING FEVER.

(From a microphotograph by J. J. Bell)

The second intermission may last about ten days, being longer than the first, and a second relapse takes place, often commencing with chills. The liver does not markedly enlarge, but the spleen increases in size. The fever is remittent or intermittent, and the crisis is not marked. It is now rare for the disease not to end, but after an interval of fourteen to seventeen days a third relapse may take place, with a sudden rise of temperature, which lasts one to four days. Very rarely a fourth intermission of about eleven days ends in a fourth relapse, lasting only two days.

With regard to the frequency of the relapses, Rogers gives the following percentages:—

Without relapse	23·8 per cent.
With one relapse	49·2 „
With two relapses	20·0 „
With three relapses	5·0 „
With four relapses	2·0 „

Varieties.—The typical course may be varied in about 25 per cent. of cases, and present (*a*) *a short, irregular, remittent fever*; (*b*) *a so-called bilious remittent fever*, called by Carter 'icteric fever.'

(*a*) *Short, Irregular, Remittent Fever.*—This is very like malaria, from which it is only to be diagnosed by blood examination.

(*b*) *So-called Bilious Remittent Fever* (*Icteric Fever*).—So-called bilious remittent fever very closely resembles typhus fever, and to some extent yellow fever, showing deep jaundice, with an eruption of red spots. The temperature is irregular, and the pyrexia prolonged; prostration comes on early, and may develop into a 'status typhosus.' The death-rate of these cases is high, being 70 per cent. They are to be diagnosed from typhus by the blood examination, and from yellow fever by the absence of black vomit.

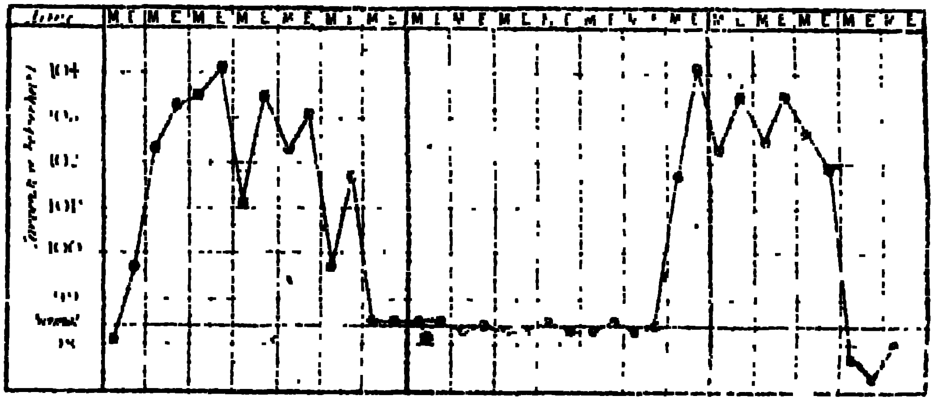

Fig. 650.—Temperature Chart of the Relapsing Fever of India. (Chart made by Major Archibald.)

Complications.—These are the same as in the European type.

Diagnosis.—This is based on the microscopical examination of the blood.

Prognosis.—A prolonged, irregular first attack, ending by lysis, and attacks showing marked jaundice are bad omens.

The mortality is higher than in Obermeyer's type, being 18·02 per cent., of which about one-half take place in the attack, and one-quarter in the first interval, and one-fifteenth in the first relapse, and the remainder from complications.

Treatment.—The treatment and diet differ in no respect from that already laid down, except that these patients often stand large doses of salvarsan badly, and therefore one should not give more than 5 grains of the drug by intravenous injection; moreover, the disease being of a severer type than the European form, and sudden heart failure being common, cardiac stimulants should be given during the attack, and preparation made for preventing the collapse by means of hypodermics of strychnine and ether, or camphor in ether, as well as by hot bottles, blankets, etc.

Prophylaxis.—See remarks with reference to the European type.

Manchurian Relapsing Fever.

This type of relapsing fever is due to a spirochæte which Toyoda in 1916 demonstrated by immunity experiments to be distinct from the African and the European types. The organism is short, 7-20 microns by 0·4 micron, and its spirals number 4-8; it is spread by lice.

Liver enlargement and albuminuria are physical signs of importance. The first paroxysm lasts five to thirteen days, the first interval two to fourteen days; the second attack one to nine days, interval two to thirteen days; the third paroxysm lasts one to six days, the third interval two to ten days; the fourth paroxysm lasts two to six days.

The mortality rate is 5·3 per cent. Two paroxysms are common.

THE TICK GROUP.

THE RELAPSING FEVERS OF AFRICA.

The tick relapsing fevers of Africa may be classified as follows:—

1. West African relapsing fever.
2. East African relapsing fever.

1. The Relapsing Fever of West Africa.

Synonyms.—Tick fever (Livingstone), African tick fever.

Definition.—An acute specific relapsing fever caused by *Spiroschaudinnia duttoni* Novy and Knapp, 1906, and spread by *Ornithodoros moubata* Murray.

History.—The peoples of Africa from time immemorial have had a dread of tick-bites, which they thought caused fever, and this appears to have been noted by Livingstone, Kirk, Hinde, and many other people, with the result that a tick fever of an unknown nature was spoken of as occurring in Africa. Nabarro, in August, 1903, was the first to observe a spirochæte in human beings in Uganda, but as his publication, through no fault of his own, did not appear till much later, his discovery was forestalled by those of Ross and Milne in 1904, and Dutton and Todd, also in 1904, who found the cause of the tick fever to be a spirochæte, the latter observers also proving that it was introduced into the blood by the bite of a tick—*Ornithodoros moubata*. Since that date Koch, Todd, Novy and Knapp, Breinl and Kinghorn, and others, have studied the disease carefully. Fränkel has proved by biological tests that the spirochæte of East African relapsing fever differs from *S. duttoni*, as observed in West Africa, and Nuttall proposed the name *S. rossi* Nuttall, 1908, for this new species; but recent researches seem to have proved the identity of the two conditions.

Climatology.—The disease is found in Angola, the Congo Free State, Uganda, late German East Africa and Portuguese East Africa, and in the Valley of the Zambesi. Franco, Robledo, and others have described a spirochætiasis in Colombia, which is caused by a spirochæte morphologically resembling *S. duttoni*, and said to be spread by *Ornithodoros turicatus*, with reference to which it may be noted that Büldow observed relapsing fever in the Andes in 1865. Robledo asserts that it is spread by the bite of *Ornithodoros megnini*.

The climatic conditions required appear to be heat and moisture, but according to Franco's observations, the disease can occur at an altitude of 7,000 feet. No observations appear to be recorded as to variations due to season. Carter's investigations would tend to show that Arabian relapsing fever is either a separate form of fever, or is allied to this West African form, as it may be spread by an *Ornithodoros*.

Ætiology.—The cause of the fever is *S. duttoni* Novy and Knapp, 1906, which is proved to be distinct from the other spirochætes, because an animal immunized against one of these is capable of being successfully inoculated by it. *S. duttoni* can be inoculated into a number of animals—namely, dogs, goats, sheep, rabbits, guinea-pigs, rats, and mice—but not into cats, chickens, pigeons, or goldfish. The spirochætes can pass through the placenta into the circulation of the fœtus, which they infect. These organisms are easily seen in the blood during an attack, but disappear during an apyrexial interval. The spirochæte is described on p. 444.

The life-history in the vertebrate has been worked out by Breinl, who, as already described, showed that just before the crisis the spirochætes become encysted and undergo schizogony into small bodies, from which the new generation develop. Leishman has demonstrated that when the spirochætes pass into the intestinal sac of the tick they lose their motility and their characteristic appearance, while the central core of chromatin segments into small masses, which are set free into the lumen of the gut. These small bodies, which resemble small rods, or are rounded, like micrococci, appear to multiply in the body of the tick, and to pass into the cells of the Malpighian tubules and into the tissue of the ovary. In the latter position they enter the immature eggs, and can be traced through all stages of development into the adult ticks. In the embryo, and in all the later stages of development up to and including the adults, they are found as small chromatin bodies lying in the cells of the Malpighian tubules. Inoculation of crushed tissue containing these bodies produces a typical infection. From his experiments, Leishman concludes that it is by these chromatin bodies that the disease is carried from the egg to the new generation of ticks, and that infection of man does not take place via the salivary glands, but by the small bodies gaining access to the wound produced by the tick's bite, by being voided in the Malpighian secretion passed by the tick during feeding, or perhaps by regurgitation of the intestinal contents. More recently Leishman and Hindle have shown that the tick produces infection only as the result of its infected fæces contaminating the tick-bite. This is a typical example of the contaminative mode of infection.

The principal predisposing causes are anything which facilitates the life of the tick, such as bad hygienic conditions, which are well exemplified by the native huts of Africa. These huts contain many cracks in the walls and floor, which afford shelter to the tick, and hence predispose to the disease.

Pathology.—Very little can at present be said as to the pathology. The post-mortem reveals only an enlarged firm spleen, while smears taken from the liver and lungs show large numbers of spirochætes.

Symptomatology.—The symptomatology still requires careful investigation on the lines carried out by Carter in India, but much good work has been done on the subject by Dutton, Todd, R and others.

Incubation.—The period of incubation is usually about seven days, but it may extend to eleven or twelve days.

The tick-bite may be accompanied by local inflammatory symptoms, but in some cases the bite is not even noticed. According to Wellman, natives believe that when the tick-bite is accompanied by a severe local reaction, the individual probably escapes fever, and Nuttall calls attention to the possible protective effect of a local reaction.

Usually mental heaviness, lack of activity, profuse sweating, and constipation, are mentioned as prodromal symptoms.

Onset.—The attack may come on gradually, with a feeling of malaise, faintness, and a disinclination for food, or even vomiting, and a slight rise of temperature. In a few hours the temperature will have risen to 103° to 105° F., associated with headache, pains in the back and limbs, and intense pain in the region of the spleen, and chilliness. There is vomiting, first of food, and then of bile, with often diarrhœa, and even at times streaks of blood in the motions. The spleen is generally found to be enlarged, and spirochætes in scanty numbers occur in the peripheral blood, but may be hard to find.

Course.—The next day the symptoms are worse, and the patient is hot and restless, complaining of thirst and splenic pain, and often troubled by a cough. The temperature shows a morning fall, without improvement in the symptoms, and an evening rise, during which the pains increase, and the patient may become delirious. The liver does not enlarge, but the spleen projects below the costal margin. Spirochætes are now found in greater numbers, but diminish remarkably before the crisis. There is a slight decrease in the red cells and hæmoglobin, and a marked leucocytosis before the crisis, while polychromatophile degeneration is noted in the red cells, and a very marked increase in blood platelets. The symptoms last three to four days, and end by a crisis marked by profuse sweats and a fall of temperature below normal. On the day before the crisis there is a pseudo-crisis, with a fall of temperature, but no improvement in the symptoms.

Intermission.—The patient feels weak and tired, but slowly regains his appetite and strength, and no parasites are found in the blood. The disease may now terminate, or the intermission may last from one to twenty-one days, according to Ross; but five to eight days is more usual.

Relapse.—The first relapse begins with a rise of temperature and a return of the original symptoms, and also of the parasites into the peripheral blood. After lasting three to four days, it ends in a crisis marked by sweating, and showing a pseudo-crisis on the preceding day.

Intermissions and relapses follow one another regularly or irregularly, the intervals being from one day to two months, and the relapses usually lasting three days, and showing a pseudo-crisis on the second day and a crisis on the third day. As many as five to eleven relapses may take place, and end by reducing the patient both in weight and strength. Œdema of the eyelids has been noted in the relapses.

Complications and Sequelæ.—Iritis is frequently observed.

Clinical Varieties.—According to Ross, there appears to be a marked difference in the severity of the attack in new-comers, such as Europeans, and natives. Though the attack shows much the same symptoms in natives as in Europeans, it is often far less severe, and the spleen may not enlarge. The attack frequently lasts twenty-four to forty-eight hours, and ends by crisis, after which the patient rapidly recovers, as a rule without a relapse. Should this, however, take place, it is found to be less severe than the attack. Koch believes that these mild attacks and the native immunity are due to infection in early childhood. Dutton and Todd, on the other hand, describe cases very much resembling that in the European, with enlargement of the spleen, and with more than one relapse, leaving the patient anæmic, thin, and weak. Hence it may be concluded that the disease shows two types in natives—a mild type and a severe type—and that the latter may end in death.

Diagnosis.—This can only be made by finding the spirochætes. Löwenthal's method of agglutination can be applied in doubtful cases.

Prognosis.—This is usually good for both the natives and Europeans, but death may occur in both races, and is signalled by a rapid fall of temperature without improvement of the symptoms.

No figures have so far been recorded with regard to the mortality, but it may be taken that it, as a rule, is low, though under adverse circumstances it may be high. Dutton and Todd record that of twenty men who contracted the disease in one caravan, ten died.

Treatment.—This is the same as for the European form (see p. 1313).

Prophylaxis.—The prophylaxis is based on the avoidance of localities where ticks abound and the destruction of these parasites. Koch rightly advised that Europeans should camp at least 20 to 30 yards away from infected native huts and rest-houses.

2. The Relapsing Fever of East Africa.

The relapsing fever found in Uganda and East Africa is clinically indistinguishable from the West African type, and is carried by the same tick, but the *Spiroschaudinnia*, according to Fränkel, is a different species (*S. rossi* Nuttall, 1908). Recent researches seem, however, to identify it with the West African type.

THE TICK FEVER OF MIANA, PERSIA.

Definition.—A specific fever of unknown cause, brought about by the bite of a tick (*Argas persicus* Oken, 1818).

Historical.—Dupré, in 1809, first described this disease, stating that the bite of *A. persicus*, locally known as 'Guerib-guez' 'Garib-guez' 'Miané-bug,' or 'punaise de Miana' (Mallet de Mianeh), was at times dangerous, producing prolonged illness. Kotzebue, in 1819, stated that the natives were immune, and only foreigners suffered. Fischer de Waldheim, in 1823, said that the bite was fatal, and Heller, in 1858, described the effects as being caused by the mechanical injury of the bite of the tick. Taschenburg, in 1873, considered the symptoms to point to a disease, and not merely to the effects of the bite of the tick; and Schlimmer, in 1874, considered the immunity of the natives to be due to the fact that they had been bitten, and so become vaccinated. Megnin, in 1882, showed that the bite *per se* was not dangerous, and later was supported by Fumouze and Loundsbury.

Ætiology.—The causation of the disease is quite unknown, but some virus must be inoculated when the tick bites, for the disease is apparently confined to Persia; and the experiments of Méguin, Loundsbury, and others show that in certain regions the effects of the bite are insignificant.

Manson thinks that this virus will some day be found to be a spirochæte, which, indeed, is not unlikely, as *A. persicus* is well known to be the carrier of *Spiroschaudinnia marchouxi* Nuttall, 1904, which causes a very fatal disease in fowls. Native Persians probably develop a relative immunity due to previous slight infections, but new-comers suffer severely.

Symptomatology.—The knowledge of the symptoms of the disease is very meagre. Severe pain is felt at the site of the bite of the tick, and this is followed by remittent fever lasting from a few days to several weeks, delirium, convulsions, and even at times by death.

Treatment.—The treatment is entirely symptomatic, but salvarsan might be tried.

Prophylaxis.—According to Nuttall, the Persians burn their villages when they suffer severely from the attentions of the tick. In order, however, to devise a rational method of prophylaxis, it must be remembered that *A. persicus* is essentially a parasite of the domestic fowl and other birds, and that its eggs are laid in batches of 20 to 100 in cracks in the walls, and take three weeks to develop into the larva, which, after sucking blood, in eight days becomes the nymph. This may require several weeks before it becomes the adult, which is said to feed only once a month. After considering this life-history, it will be obvious that fowls should be disinfected with a kerosene emulsion, creozozone, or oil of sassafras in the case of old birds, while young birds may be isolated in cages until the ticks drop off. Houses and fowl-houses should be cleansed and treated by lime and corrosive sublimate, and old nests and roosts should be burnt, and after that the new fowl-houses may be sprayed with kerosene emulsion.

THE RELAPSING FEVERS OF AMERICA.

The relapsing fevers of America comprise:—

1. North American relapsing fever.
2. Central American relapsing fever.
3. South American relapsing fever.

1. Relapsing Fever of North America.

Definition.—An acute specific fever caused by *Spiroschaudinnia novyi* Schellach, 1907. Mode of infection not known.

History.—Relapsing fever has been known in America for many years, being recognized as far back as 1844; but it was considered to be identical with the European type until, in 1906, an Englishman who repeatedly travelled between New York and the West Indies was treated by Carlisle in New York for fever which relapsed, and in which spirochætes were found. Novy and Knapp studied these spirochætes, and showed that they were distinct from *S. duttoni*. Later, Mackie also studied them by the agglutination method, and agreed with Novy, who had concluded, from morphological reasons, that they were distinct from *S. carteri*. Finally, in 1907, Manteufel compared them with true *S. recurrentis*, and found that the serum of a person suffering from their type of fever did not agglutinate true *S. recurrentis*. Subsequently Schellach, after studying and comparing the different spirochætes, named this particular species *S. novyi* Schellach, 1907.

Climatology.—The disease is known in North America and in Europe. In America the disease is acquired naturally. In Europe the cases recorded are due to laboratory infection.

Ætiology.—The cause of the disease is *S. novyi* Schellach, 1907.

Symptomatology.—The symptoms appear to be much the same as in the European type of fever. The incubation period seems to be at least five to seven days in duration, though cases have been recorded in which symptoms developed almost immediately after exposure to infection. In experimental cases it varied between six and eight days. The duration of the first attack is about five to six days, and it often begins with rigors; the tongue is moist, except in grave cases, and the jaundice is mild, except in severe cases; but the vomiting of bile is not uncommon, while diarrhœa is only moderate in amount. Tympanites, hiccough, and hæmorrhages from the nose, stomach, and bowels, as well as the kidney, may be present in severe cases. The apyrexial interval is usually seven to ten days, and is followed by the relapse, which is not uncommonly absent. Usually there is only one relapse, and more rarely two to five relapses.

Mortality.—The mortality is not high, varying between 2 and 6 per cent.

Treatment.—The treatment is the same as in the European type.

2. Relapsing Fever of Central America.

Darling has described cases of relapsing fever in Panama, clinically similar to the North American type, but the organism has not been definitely classified.

3. Relapsing Fever of South America.

In South America (Colombia) a relapsing fever occurs in which the spiroschaudinnia resembles more closely *S. duttoni* than *S. novyi*. According to Robledo, this parasite is carried by *Ornithodoros turicatus*.

CHAPTER XLIX

TYPHUS

Synonyms.—Typhus exanthematicus, Synochus putrida, Spotted fever, Gaol fever, Prison fever, Brill's disease; *French*, Typhus exanthematique; *Italian*, Tifo esantematico, Tifo petecchiale; *Spanish*, El Tarbardillo; *German*, Exanthematischer typhus, Fleckfieber; *Dutch*, Vlekkoorts; *Arabic*, Homma typhuisa, Tkout fever; *South Africa*, M'betalala = black fever.

Definition.—Typhus is an acute specific fever of unknown but probably protozoal cause, spread by the agency of *Pediculus corporis* de Geer, 1778, and characterized by a sudden onset, a maculo-petechial eruption, and severe toxemia, lasting some twelve to fifteen days, and ending in a more or less abrupt lysis.

History.—The early history of typhus is wrapped in obscurity by reason of its confusion with plague: for though Hippocrates mentions the word 'typhus,' he applied it to stuporous and delirious conditions, and does not appear to have been acquainted with the fever in question. This confusion with plague continued until Fracastorius, in the sixteenth century, called it 'petechie,' and gave such an account as enabled them to be separated from one another, though the nomenclature at first indicated that they were related, and it was not until 1760 that the term 'typhus' was first applied to the disease by Boissier de Sauvages. In an interesting historical paper Crawford has shown that the only possible explanation of some of the old outbreaks is by means of the louse.

During the eighteenth and nineteenth centuries typhus was well known in Europe, but included typhoid and relapsing fevers, from the former of which it was distinguished by a long series of researches, beginning with those of Strother, Gilchrist, and Huxham, in the early eighteenth century, and ending with Still's classical work in 1837, while the history of the differentiation from the latter has already been described in the chapter on the Relapsing Fevers.

For a long time the disease passed unrecognized in the tropics, and, indeed, in the *Lancet* of 1871 it is even debated as to whether it could exist in those regions; but though it is impossible to deny that Lyell, in his observations in 1852, mistook relapsing fever for it, and that Fairweather in 1869 was confusing it with typhoid, it would appear as though Lyons, in 1869, clearly recognized the disease as occurring in North-West India, where it is now well known to be endemic, and it has since been reported from many parts of the tropics.

Brill's disease appears to be a mild form of typhus fever, attenuated, perhaps, by environment and improved sanitation. He has failed to produce the disease in monkeys.

It is curious the way in which different epidemics have been reported as being characterized by special features; thus the Serbian epidemic of 1914–15 showed a great tendency to gangrene of the feet, while those in Silesia and Ireland have been associated with bronchial and pneumonic complications.

Causal Agent.—The next point in the history is the search for the causal agent. In 1908 Yersin and Vassal succeeded in communicating the disease from man to man by the inoculation of blood, but failed to infect rats, guinea-pigs, or rabbits.

In 1909 Nicolle first produced typhus in a monkey by injecting the blood from a patient, thus showing that the virus was present in the peripheral blood. Later it was discovered that guinea-pigs also could be infected.

In 1910 Ricketts and Wilder, in Mexico, showed that the virus was contained in the blood serum, from which it could be removed by filtration through a Berkefeld candle.

In 1911 Wilder repeated the filtration experiments with confirmatory results, but subsequent experiments showed that the control monkey may have been immune, a point subsequently confirmed by Nicolle, Conor, and Conseil.

In 1911 Nicolle, Conor, and Conseil considered that the virus was mainly associated with the leucocytes, and that the plasma was merely virulent from the débris of these cells. Red blood-corpuscles and cerebro spinal fluid were proved not to contain the virus.

In 1912 Anderson and Goldberger showed that the evidence was in favour of a parasite living freely in blood plasma, and not of an intraleucocytic localization; and, further, they confirmed the work of Ricketts and Wilder.

In 1917 Miss Robertson summarized these investigations by stating that there is *no recorded experiment* which demonstrates that an injection of the filtered serum from a typhus patient can produce an infection. The conclusion is that the virus is too large to pass through the pores of a Berkefeld candle in good condition. Further, this virus is capable of producing a reaction on the part of the patient, because after an attack there is a solid immunity against subsequent attacks, both in men and animals.

The causation of typhus remains undiscovered, though many researches have been made, first by Hallier, who in 1868 described a fungus as the causal agent; and then by Klebs, who found bacilli in 1881; and by Mott and Blore, who in the same year described minute, screw-like, motile organisms as present in the blood during life, and micrococcal-like bodies found in cells between the muscular fibres of the heart after death.

In 1891 Hlava described ovoid bodies which he believed to be part of a streptobacillus; in 1892 Thoinot and Calmette saw flagellate bodies; and in 1892 Lewaschew found a motile organism, sometimes like a thread, sometimes oval and flagellate; in 1893 Dubieff and

Brühl described a diplococcus; in 1899 Balfour and Porter found another diplococcus. In 1903 Gottschlich described a *Piroplasma* existing in non-motile endocorpuscular and flagellate free forms in cases in Egypt, but these parasites may have only been cellular degenerations; and Horiachi described a bacillus which he isolated from the fæces and urine of Japanese troops which in the war in Manchuria suffered from a disease which was probably typhus. Krompecher, Goldzieher, and Augyan have described intracorpuscular bodies somewhat resembling a *Piroplasma*. In 1909 Rabinowitsch grew an aerobic coccobacillus; in 1914 Hort and Ingram described a pleomorphic bacillus, and in 1915 Plotz a pleomorphic bacillus, the so-called *B. typhi-exanthematici*. In 1916 Penfold, and later Miss Robertson, found a blood diphlococcus. In 1919 Borrel, Cantacuzene, Jonesco and Nasha have isolated a capsulated cocco-bacillus somewhat similar to one previously found by Pretjetschsky.

In 1910 Ricketts and Wilder saw some curious double bodies in the blood of a number of cases. In 1913 Hegler and Prowazek saw numerous long, round, and diplococcal bodies in the leucocytes some time after infection began, but not at the commencement thereof. These bodies are believed to be the same as those described in 1905 by Rabinowitsch as 'Turkischen Reizformen.' In addition, they observed the forms described by Ricketts and Wilder, not merely in the blood, but also in polymorphonuclear leucocytes in the exudate of a blister. During convalescence the bodies agglomerate in the cells, and finally tend to disappear. Post-mortem trachoma-like bodies were found in the endothelial cells of the heart, the lung, the liver, and the kidney. They are found in infected monkeys, but not in guinea-pigs. Infected lice were seen to contain small coccoid and diplococcal bodies. These bodies are believed to be Chlamydozoa, and to be allied to Lipschutz's genus *Strongyloplasma*.

Prowazek distinguishes them from Doehle's bodies. To summarize, these bodies appear in the leucocytes on the third day of the illness, and persist until convalescence, in one case as late as the nineteenth day of the illness. These bodies are called *Rickettsia prowazeki* Da Rocha-Lima, 1916, and according to this author are never found in typhus-free lice, but can be found in lice infected by sucking infected blood: then they penetrate into the cells of the alimentary canal of the louse on the fourth to fifth day after an infective feed, and multiply therein, and do not reach full development until the eighth to ninth day. In this situation they are very small, shortly elliptical, or oval, and often lie in pairs. Noller in 1916 considers that the ætiological rôle of this organism is no longer doubtful, and in 1917 Foulerton considered that it was probably a phase in the evolution of the ætiological agent. In 1919 Arkwright, Bacot and Duncan confirm Da Rocha-Lima observations. Bradford, Bashford, and Wilson state that they have succeeded in cultivating the virus, using Noguchi's method, from the blood of two cases. The virus, according to these authors, consists of minute coccus-like bodies, Gram-positive, grouped in pairs, varying in size from 0·3 μ to 0·5 μ, capable of passing through Berkefeld N and V filters.

The Carrier.—With regard to the spread of the disease, there was a great conflict of opinion as to whether it was infectious; most certainly it does not cross air-spaces, though it seems to be associated with bedding, fomites, furniture, and dirt, which causes the suspicion that the agent may be an animal parasite. Moreover, the fact that it only appears in the cool season of the tropics, and its rapid disappearance in the warm season, is also in favour of its transmission by some animal. Its non-infectious nature has been proved by Jürgens keeping twenty healthy men confined with twenty typhus patients freed from lice, with negative results; therefore suspicion is aroused that it may be spread by a blood-sucking parasite, perhaps an insect.

Patton has shown that *Clinocoris lectularius* Linnæus, 1758, is found along the north-west frontier of India; and Husband and MacWalters draw attention to the fact that the distribution of this bug curiously coincides with the distribution of typhus in India.

These latter observers point out that in an epidemic occurring in a gaol, the hospital was found infected with bugs, which occurred nowhere else. On the destruction of these pests the epidemic ceased. Moreover, they draw attention to the fact that predisposing causes of typhus, such as dirt, overcrowding, and the way in which the infection hangs about bedding, buildings, and furniture, are easily explicable on the bug hypothesis. Sambon, in his article on Rocky Mountain fever in Allbutt and Rolleston's 'System,' advances arguments in favour of the identity of Rocky Mountain and typhus fevers; but Husband and MacWalters' researches are not in favour of a tick being the carrier of the disease. It may be that typhus and Rocky Mountain fevers are caused by allied protozoan parasites spread by different blood-suckers. In Glasgow the flea was suspected to be the cause of the dissemination of the disease. Nicolle suspected *Pediculus corporis*, and this was soon confirmed on epidemiological grounds, which Crawford supported by a study of the history of the epidemics.

In 1909 Nicolle, Comte, and Conseil transmitted the virus from infected monkeys to non-infected monkeys by means of the bites of lice, *Pediculus corporis* de Geer, 1778. In 1910 Ricketts and Wilder found that they could immunize monkeys against infection with virulent blood by the bites of infected lice. In 1911 Wilder showed that lice became infective between the second and fifth day after feeding, thus proving that the causal agent had undergone some sort of development in the louse. In 1912 Anderson and Goldberger supported Wilder, and concluded that *P. humanus* Linnæus, 1775, and *P. corporis* de Geer, 1778, could both become infected, and that this infection could be transmitted by the crushed insects or by their bites. In 1914 Sergent, Foley, and Vialatte found cocco-bacilli in lice, and in the same year Prowazek and Rocha-Lima found short elliptical coccal bodies and rods. In handling the infected lice both these observers contracted the disease, and Prowazek died. The further investigations of Rocha-Lima have already been noted, and it only remains to say that he found that lice kept at 23° C. did not become infective, and the organism did not develop, but at 32° C. the organism did develop, and the lice became infective. These results are in direct contradiction, as regards temperature, to those of Nicolle, Comte, and Conseil, of Ricketts and Wilder, and of Anderson and Goldberger, and directly opposed to the distribution of the disease. Da Rocha-Lima believes the virus is passed on to a second generation of lice, of which larvæ produced from eggs laid by a louse six days after an infective feed are themselves infected. The organism will develop in the human and not in the pig louse.

In 1917 Da Rocha-Lima pointed out that Ricketts and Wilder, Gavino and Girard, and McCampbell, have found the parasite in human blood; Von Prowazek in leucocytes; and himself in blood, in smears, and in sections.

Also in 1917 Otto and Dietrich obtained infections best by allowing lice to feed on the fifth to seventh day of the illness, as only 4-5 per cent. became infected on the twelfth day, and all are negative after the fall of the temperature. They infected lice from a patient *sine exanthem*, and they confirm Rickettsia. On the other hand, Brumpt is of opinion that this organism in the louse has nothing to do with typhus. Arkwright, Bacon, and Duncan's recent observations are in favour of *Rickettsia prowazeki* playing an etiological rôle. Futaki's *Spirochæta exanthematotyphi*, found in April, 1917, has been proved to have nothing to do with the disease.

Serological Investigations.—In 1916 Nicolle and Blaizot prepared an immune serum in horses and asses by the inoculation of emulsions of spleen and suprarenal capsules of infected guinea-pigs, and tested its curative power on non-immune guinea-pigs, in which it prevents the disease if inoculated in the stage of incubation, and stops the fever at the onset and during the first and second day, but later its action is doubtful. They then tested it upon nineteen human patients, when all cases treated in the early stage recovered quickly, the temperature fell, the pulse and urine quickly improved, but the nervous symptoms required repeated inoculation. It was used in maximum doses of 10 c.c. per diem. In cases in which the disease had been progressive for some time the serum acted slowly. In 1918 Netley and Blaizot showed that the so-called Brill's disease in Paris is typhus, and that guinea-pigs rendered immune to the Parisian typhus are immune to the Tunisian strain.

Prophylaxis.—Many observers (Maitland, Strong, Hunter, Jackson, Castellani, etc.) have demonstrated in practice the vital importance of louse destruction in the prophylaxis of the disease.

Relapsing Fever.—Since 1739 it has been noticed that typhus and relapsing fever go side by side in an epidemic. We now know that the reason is because they are both spread by lice.

Climatology.—Typhus is essentially a disease of temperate and cold climates, and therefore is well known to occur in Europe and America.

In the tropics it principally appears in places situated at high altitudes, or where there are cool seasons, in which case it disappears in a most remarkable manner as soon as the warm season sets in.

In Africa it is said by Hirsch to be endemic in Nubia, and has been carefully studied in Egypt by Sandwith, where he says that it has been definitely recognized since 1836, and where a few cases are reported every year in the spring months. It is also reported from Tripoli, Tunis, Algeria, and Morocco. In Asia it appears to occur only in epidemic form in Asia Minor and Syria, but is believed to be endemic in Persia, and possibly also in Afghanistan, because it is said to be regularly imported into India by caravans from this country. In India an endemic area exists on the west of the Indus, stretching from Beloochistan in the south to Yusufzai, Hazara, and Kashmir in the north, and then passing eastwards along the ranges of the Himalayas, where it is especially prevalent at Kulu, and also passing southwards into the district of Rawal Pindi. In Ceylon we have met with a few cases in European sailors, who have, however, acquired the disease elsewhere. It occurs in Indo-China; in Northern China, where it is endemic, becoming epidemic every spring; and in Japan, where it occurs yearly in the province of Hiogo. It does not occur in Australasia or Oceania. In tropical America it is endemic in Mexico, rare in Central America, absent in the West Indies, the Guianas, Colombia, and Venezuela, and is rare in Brazil, though it is common in Peru and Northern Chili.

This climatology depends upon the louse and the air temperature which is best for the parasite to develop therein.

The Louse.—As *Pediculus corporis* belongs to man, it can go wherever man goes, but typhus fever does not, being absent in the tropics during the hot seasons.

The Parasite.—The fact that most observers believe that a low temperature is necessary for the development of the virus in the louse is borne out by the climatology, being limited to the cold and temperate climates, and only appearing in tropical or subtropical climates during the cold weather or in the hills.

In Mexico it is found on the lofty plateau, in India in the hills, in Egypt and Northern Africa in the cool season, and it will be remembered that the clothes louse is exposed to the effects of air temperatures.

Epidemiology.—Epidemics are caused by anything which favours the propagation of and dissemination of lice. The principal factors which do so are (1) massing together of people of all classes; (2) retaining these masses under conditions which render personal cleanliness and clean clothing difficult or impossible. Such conditions are typically produced in times of war and famine, and exist endemically among the poor. To these we must add a third condition, (3) an atmospheric temperature not too high—*i.e.*, a Temperate Zone temperature. All this has been well exemplified in the Serbian epidemic of 1914-15, when nearly one-tenth of the population died from the disease.

Ætiology.—The causal agent, which is unknown, is spread by means of the louse, *Pediculus corporis* de Geer, 1778. This insect obtains the virus from the blood of a case in which it is present from the fifth to twelfth day, but in greatest abundance from the fifth to seventh day, and from which it is absent after the fall of the temperature. The louse requires some eight to nine days' interval before it becomes infective. It probably remains infective for the rest of its life, but it is not certain whether it passes the virus on to the next generation or not. When an infected louse bites a non-immune human being, some six to ten to twelve days elapse before symptoms appear. An attack of typhus confers an immunity upon man and susceptible animals. Natural immunity exists in many animals.

With regard to *Rickettsia prowazeki* Da Rocha-Lima, 1916, Brumpt, in 1918, found that it was present in seventy-two *P. corporis* removed from healthy persons who never had had or subsequently did have typhus fever. The bites of these lice did not cause the disease in susceptible animals, nor did they infect the persons who handled them. *Pediculus humanus* has no *Rickettsia prowazeki.* Brumpt's researches tend to show that *R. prowazeki* is not the causal agent of typhus fever, while the observations of Arkwright, Bacot, and Duncan are favourable to Da Rocha-Lima's theory.

Futaki in April, 1917, reported the presence of a spirochæte which he named *S. exanthematotyphi* Futaki, 1917, in sections of typhus kidneys and in the urine of patients, but in 1918 Mijashima, Kusama, Takano, Yabe, and Kanai proved that it was non-pathogenic to guinea-pigs and monkeys which are susceptible to the typhus virus. It therefore has nothing to do with typhus. *Doehle's scarlet fever bodies* have been found by Lopez Vallejo in typhus, but have nothing to do with either disease. Hort has described peculiar coccoid bodies in filtered blood. Bradford, Bashford, and Wilson state that they have grown minute bodies, similar to those they have found in trench fever.

Pathology.—According to Zuelzer, the liver and spleen begin to increase in size during the incubation period, and reach their maximum size at the commencement of the illness, while von Chiari looks upon the congestion of the conjunctiva as due to the action of the virus on the walls of the small vessels, causing perivascular infiltration, which he looks upon as a sign of the roseolar rash in this situation.

The virus can produce immune bodies in infected animals. In man a second attack is rare, but has been recorded, and relapses have been known to occur.

The virus lives in the blood from the fifth to the twelfth day, but is scarce after the seventh day and absent after the fall of the temperature, when it is evidently killed by the immune substances produced by the reaction of the body.

Morbid Anatomy.—Death is most common about the tenth day, being due either to the action of the virus of the disease or to complications such as pneumonia and septic infections. The spleen is enlarged and engorged if the post-mortem takes place up to the middle of the second week, but not later. There is œdema of the lungs and hypostatic pneumonia, cloudy swelling and fatty degeneration of the heart, cloudy swelling of the liver and kidneys, and hyperæmia of all the organs. The cerebro-spinal fluid may show a slight lymphocytosis.

The muscles are dry and the rectus abdominalis may show Zenker's degeneration. The spleen is enlarged, dark red in colour, with juicy dark red pulp, while the kidneys may show punctate hæmorrhages.

Symptomatology—*Incubation.*—This varies from four to five to twenty-one days, according to the older views, but the more correct opinion is some four to ten to twelve days.

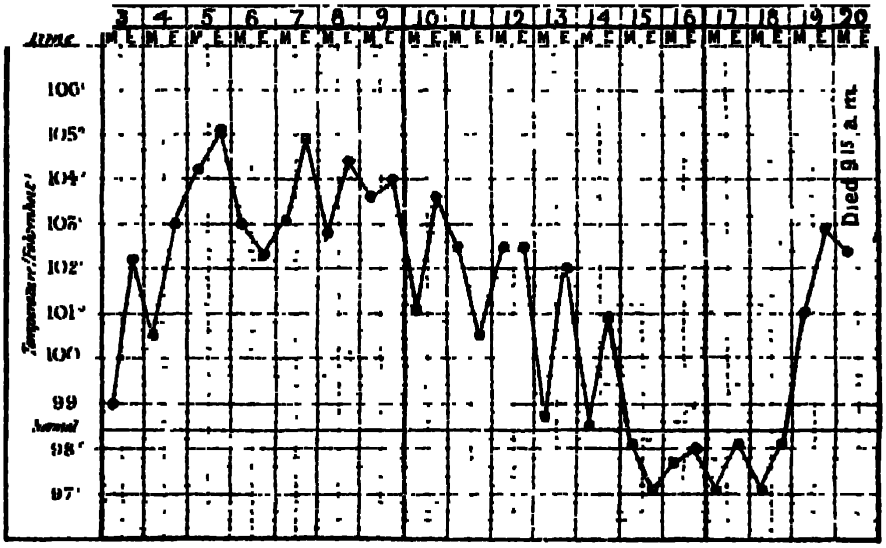

Fig. 651.—Temperature Chart of Typhus Fever.

Prodromal symptoms are often entirely absent, or consist of vague feelings of fatigue, giddiness, and headache.

Attack.—The onset is usually sudden, being characterized by frontal headache; pains in various parts of the body, of which pain in the chest, giving rise to the suspicion of pneumonia, is important; rigors; marked rise of temperature from 101° to 104° F.; quick pulse (100 to 120); flushed face and suffused eyes; quickened respirations; and a sensation of great weakness. Rarely, however, the onset is slow and typhoid-like.

Course.—The duration of the symptoms is from fourteen to eighteen days. During the first two or three days the temperature continues to rise at night, with remissions in the morning, to a maximum of about 104° to 105° F. on the second to fourth days, during which time the tongue becomes dry, swollen, and cracked, with a thick brown deposit on the dorsum, while the tip and sides are red; nausea may be experienced, but vomiting is rare, and the bowels are either constipated or normal.

The nervous system is early affected, the patient being apathetic, drowsy, with a dull expression. The changes in the blood are of the utmost importance, and should be carefully studied. There is sometimes an increase in the red cells, with a corresponding increase in the hæmoglobin, and a leucocytosis, which is usually well marked, being on an average about 24,000 per cubic millimetre, but varying between the extremes of 8,000 and 54,000. The differential leucocyte count is also of importance, for in cases uncomplicated with malaria or other protozoal infections the polymorphonuclear increase is a characteristic feature, and may exceed 90 per cent., while the mononuclears and lymphocytes may be reduced, especially if the case is to end fatally, while eosinophiles are often entirely absent—a most characteristic feature in a case in the tropics, where worm infection is common. The mononuclear decrease is, however, not so evident in cases about to recover, nor is it present in natives in the tropics, who, of course, are liable to previous protozoal infections, and this may lower the relative polynuclear count in these regions to 60 per cent. or less.

Though there is sometimes an increase in the red and almost always in the white corpuscles, the specific gravity is said to be lower than normal, which is rather extraordinary, and must indicate, if true, considerable alterations in the plasma. As the disease progresses the rapidity of the pulse increases, and may reach 140 per minute, and is usually small and of low tension. The blood pressure, according to Rizzuti and Scordo, shows nothing characteristic. The respirations are always quickened, and there are generally signs of pharyngitis, bronchitis, or broncho-pneumonia, while delirium is not uncommon, especially at night.

The Rash.—Definite preliminary rashes are rare, but there is often very marked flushing of the face, neck, and upper part of the chest, with a *cutis marmorata* or subcuticular mottling of the skin of the lower part of the chest and abdomen. The true rash appears on fourth to fifth day, in the form of roseolar macules, like those seen in typhoid fever, but often more abundant. They are first, seen upon the abdomen, and later spread to the chest, arms, and legs on the two latter of which, at all events in recent epidemics, they are rare, although, according to the older authors, they first appear and are most abundant in this position. The roseolar spots at first disappear on pressure, and later some of them may slowly fade away, while others, ceasing to disappear on pressure, become petechiæ, though it is rare for them to develop the dark blue appearance of the petechiæ of such eruptions as those of purpura. This petechial eruption must not be confused with flea-bites, which are characterized at first by a central hæmorrhagic spot, which is surrounded by a circular hyperæmic zone, disappearing on pressure and fading in a day or so and leaving a perfectly circular, dark red, not raised petechial spot which does not disappear on pressure.

A petechial eruption may also appear somewhat later, but is often wanting, and when widespread is an indication of a bad prognosis. A miliary eruption may appear later in the attack, and be followed by a desquamation. After the appearance of the eruption the leucocytosis becomes more marked, as do the nervous symptoms, the patient suffering from severe delirium, which may become quite violent; or he may show a stuporous condition, which becomes a semi-coma, and in fatal cases deepens into a profound comatose condition.

Termination.—As a rule the duration of the fever is from fourteen to eighteen days. On or about the fifteenth day the temperature generally falls by crisis or by rapid lysis, which may extend through three to five days, the rash fades, the spleen becomes normal, the leucocytosis increases, and convalescence begins.

In more serious cases the toxæmia may become severe during the first week, and the patient may die from the seventh to tenth day or even earlier.

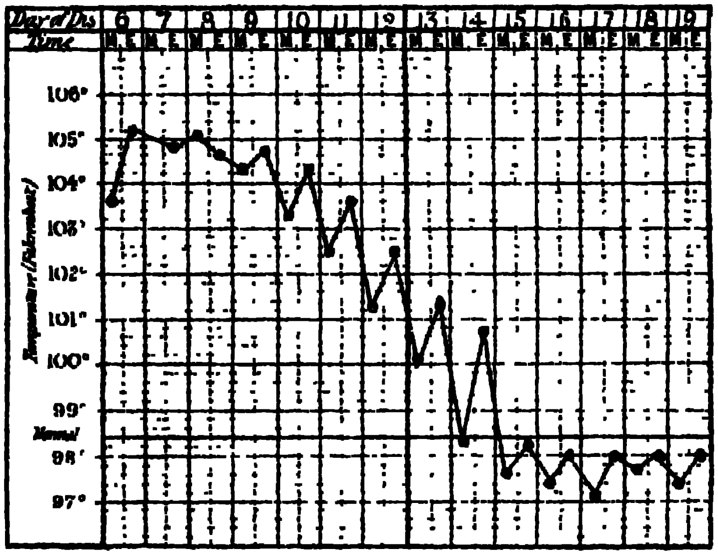

FIG. 652.—TEMPERATURE CHART OF TYPHUS FEVER.
(Chart made by Dr. G. C. Shattock.)

Convalescence.—This may be slow, and not rarely there is danger during this stage, as the general condition may not improve with the cessation of the fever, and death may ensue some two to three weeks after defervescence. In such cases the pulse does not improve, and the patient becomes weaker and weaker until he dies. These are very trying cases for the medical practitioner. Myocarditis may develop during this stage, and shows a weak irregular pulse.

Varieties.—The varieties which may be mentioned are: (1) Mild or ambulatory cases. (2) Abortive attacks. (3) Malignant attacks, causing death on the second or third day. (4) Typhus *sine exanthem*—*i.e.*, typhus without the rash. (5) Typhus in children. This is usually mild, and it is said that death in uncomplicated cases properly looked after is rare. Moreover, these cases are important because they are apt to be missed. Rigors are rare, and often the temperature rises by steps, while the fever lasts only some nine to thirteen days. Bronchitis is frequent. The spleen is constantly enlarged, but the rash is generally scanty. Insomnia is not frequent, but high temperatures often occur. Children remain throughout the illness in a condition of semi-stupor, and waste in a remarkable manner. (6) Typhus with an extensive exanthem all over the body and into the mouth, with or without patches of gangrene.

Complications and Sequelæ.—*Mixed infections* with relapsing fever, malaria, pneumonia, typhoid, and acute miliary tuberculosis occur. *Complications* are:—Parotitis, ending often in suppuration, gangrene of the feet, and polyarthritis, neuritis, hemiplegia, severe mental depression, amounting almost to melancholia (seen during convalescence) may be mentioned. Also bubonic swellings, venous thrombosis, diarrhœa, otitis media, abscesses, and boils occur, while jaundice, endocarditis, and meningitis are rare, but myocarditis is fairly common.

Diagnosis.—This may be most difficult, especially in children. The cardinal points in the diagnosis are:—

(*a*) *Incipient Typhus.*—(1) The sudden onset, with sometimes headache, rigors, and vomiting. (2) The congested eyes and face, and the subcuticular mottling of the skin over the chest. (3) The mental confusion and stupor, associated with the log-like attitude of the whole body. (4) The leucocytosis.

(*b*) *Fully Developed Typhus.*—(1) The typical rash. (2) The leucocytosis. (3) The history of the sudden onset, etc.

Remarks on the Diagnosis.—*Leucocytosis* averages 24,000 per c.mm., and is present in proportion to the gravity of the illness; it is therefore of double value, diagnostic and prognostic. It persists through the fever, and declines after the return of the temperature to normal, and reaches the usual count on or about the twelfth day after defervescence.

The differential count shows polymorphonuclear leucocytes 65-78 per cent., lymphocytes 23-34 per cent., mononuclear leucocytes 7-14 per cent. Eosinophile leucocytes are rarely met with, but in rare cases may reach to 2-6 per cent.

Weil-Felix Reaction.—From the blood of patients suffering from typhus Weil and Felix isolated a bacillus, which they grew on agar and called X_{19}, O. This was completely agglutinated by the serum of typhus patients.

For the reaction the organisms must be grown on neutral agar slants, and must be alive. Cultures of two to three days' growth are best. The reaction is said to be positive on the sixth day of the illness, and to be useful in retrospective diagnosis. Some observers believe that the reaction is due to a mixture of the true virus with *B. proteus*, but others consider it to be of the nature of a par agglutination. The organism X_{19} belongs to the *Bacillus proteus* group of organisms. It is not suggested that the organism has any causal effect in the production of typhus fever. It may give complement deviation when used as an antigen with typhus serum, which is negative to Wassermann's reaction. A modification of the Weil-Felix reaction with killed X_{19} is called 'Neuber's diagnosticum.' It is praised by some and condemned by others.

The *differential diagnosis* has to be made from pappataci fever, dengue fever, relapsing fever, malaria, 'enteroidea' fevers, rat-bite fever, cerebro-spinal meningitis, pneumonia, septicæmias or pyæmias, and uræmia.

From *pappataci fever* it can only be recognized at its commencement by the presence of leucocytosis and the absence of leucopenia, and the same holds good for *dengue fever*.

From *relapsing fever* it may be diagnosed by a blood examination showing the absence of spirochætes and the presence of leucocytosis, as well as by the clinical symptoms, but especially the mental disturbance.

From *malaria* it can only be separated by the absence of the malarial parasites, which may be present in double infections, and by the leucocytosis.

From '*enteroidea*' *fevers* it may be distinguished by the often abrupt onset, by the leucocytosis, and by the absence of the specific 'enteroidea' organisms in the blood and fæces.

From *rat-bite fever* it may be known by the absence of the mark of a rat-bite, absence of the enlarged lymphatic glands, and of the spirochætes in the blood.

From *cerebro-spinal meningitis* it may be told by the clear cerebrospinal fluid containing no meningococci, and by the absence of stiffness of the neck, Kernig's sign, and the presence of the typical rash.

From *pneumonia* it may be parted by the absence of definite apical or basal dulness, of the bronchial respiration, as well as by the character of the sputum, with absence of blood.

From *septicæmias and pyæmias* by blood cultures showing an absence of pyogenic organisms, by the absence of blood destruction, and by the presence of cerebral symptoms. From *septicæmic plague* it can be distinguished by the course and blood cultures.

From *uræmia* it is known by the presence of fever and by the analysis of urine.

From '*flea-bites*' the diagnosis, of course, has only to be made in cases of fever, and can be done by the history, the patient often stating that the rash was in existence a long time before the fever. The distribution is on the limbs equally to the body. The rash is composed of a number of petechial spots of a dark red colour and *perfectly circular* in outline (see p. 1334).

From *smallpox*, by absence of the fall in the temperature on the fourth day, absence of shotty papules appearing on the face on the fourth day; but the diagnosis in times of contemporaneous epidemics may be almost impossible. When in doubt and before the specific rash appears the presence of well-marked vaccination marks are in favour of typhus.

From *influenza*, by the absence of the catarrhal symptoms.

From *plague*, by the absence of the buboes and the plague bacilli therein

To facilitate the diagnosis in cases of typhus with a faint rash Dietsch recommends applying a rubber band round the arm. This procedure makes the rash below the point of application more visible, and may cause formation of petechiæ.

Prognosis.—The case-mortality is variously stated as being from 10 to 50 per cent. The signs indicative of serious trouble and grave prognosis are the absence of eosinophiles in the blood, decrease in the number of the mononuclears, slow pulse, severe petechial eruption or nervous symptoms, alcoholism, pulmonary complaints, meteorism, gangrene, and cyanosis of the face.

The signs indicative of a hopeful prognosis are an increase in the eosinophiles and mononuclears, the absence of the petechial eruption and slight nerve symptoms.

Mortality is low in the young and extremely fatal in the old; it is slightly more fatal in males than in females, while alcoholism, kidney disease, are bad prognostic elements, as is a fat or very muscular subject. Pregnant women generally abort, and this complicates the chance of recovery. Complications are generally serious in regard to prognosis.

Treatment.—The patient should be placed in an airy, well-lighted room, sparsely furnished, and placed upon a diet of milk, broths, jellies, etc., while plenty of water is allowed to be drunk. Careful attention and nursing are required, especially when delirious The temperature should be controlled by cool sponging, and the nervous symptoms by ice to the head, hyoscin, bromides, or morphine, while the heart is supported by hypodermic injections of strychnine, digitalin, etc. Nicolle finds that the serum of convalescent cases for ten to twelve days after the temperature has fallen to normal has prophylactic and curative properties when given in doses of 20 c.c., repeated if necessary, and has manufactured a special horse serum for this purpose. He suggests that in grave cases it should be given intravenously. Salvarsan and neosalvarsan have been tried without any great success.

Prophylaxis.—This is summarized in one word, ' lousing,' in which we include the destruction of lice on the person and on the clothes.

The procedure is sufficiently simple: the person goes into a room, takes off the clothes, which are steamed or boiled, passes into another room, and is sprayed with kerosene oil or petrol, passes into a third room, and receives clean or sterilized clothes.

The sterilization of the clothes may be conducted by boiling, but better still by making them into lightly packed bundles and placing them into a truck or room into which steam is blown. This is easiest done in a truck, the steam being brought from the engine.

A campaign against lice may be conducted on the following lines:—

A. *Methods applied to Man:—*

I. Give illustrated lectures, so that people may understand about the louse, its habits, its association with disease, and its prevention.

II. Advocate the use of soap and water and of the frequent bath, as well as of clean linen frequently changed.

B. ***Methods applied to the louse*** :—

I. ***Pediculicides*** :—

(*a*) ***Dry Heat.***—Lice and nits can be killed by exposing them for fifteen minutes at 60° to 65° C.

(*b*) ***Moist Heat.***—Lice and nits are killed instantaneously by moist heat at or over 80° C.

This is the method most used for clothing, which may be boiled or exposed to steam, but must not be in tightly rolled bundles.

C. ***Chemicals*** :—

For Use on the Person.—Kerosene oil or petrol spray or vaseline, or cresol soap.

For Use on Stored Clothing.—Naphthalene.

II. ***Lice Repellents:***—

Better-class patients:—Dusting powder of menthol 3-5 grains, zinc oxide 1 ounce.

Poorer-class patients:—Naphthalene as a dusting powder.

III. ***Special Points*** :—

Head Lice.—Shave the head or cut the hair very short, or wash the hair thoroughly with 1 in 40 carbolic acid lotion, which is left to act for an hour, the head being wrapped up in a towel in the form of a turban. Then wash the head with soap and water and apply a dressing to any raw areas, carbolic vaseline (2 per cent.) or white precipitate ointment may also be used to destroy head lice.

Body Lice.—The following drugs arranged in order of efficiency (according to Castellani and Jackson) may be used:—

1. Petrol and kerosene oil.
2. Plain vaseline.
3. Guaiacol.
4. Anise preparations.
5. Iodoform.
6. Lysol, cyllin, etc.
7. Carbolic acid, 5 per cent.
8. Naphthalene.
9. Camphor.

IV. ***General Insecticides*** :—

The experiments of Castellani and Jackson in Serbia have demonstrated that ***pyrethrum*** is a very feeble pediculicide, while sulphur, boric acid, perchloride of mercury, when used in powder, have no action whatever.

Substances which may be efficient pediculicides may, however, have little or no action upon other insect parasites of man, such as bugs and fleas. For example, iodoform will kill lice in ten to fifteen minutes, but has no action on bugs and little on fleas. Pyrethrum acts more powerfully upon bugs than upon lice. In order to formulate a general insecticide several chemical substances must be combined. As an example of a general insecticide for use against lice, bed bugs, and fleas, the following is given:—

Equal proportions of naphthalene, previously soaked in guaiacol or creosote, pyrethrum, zinc oxide.

The wearing of undergarments made liceproof by soaking in various disinfectants (crude carbolic acid and soft soap emulsion), as recommended especially by Bacot, is useful. Legroux's 'sachets' or small bags containing naphthalene treated with citronella oil may be used.

CHAPTER L

THE SPOTTED FEVER OF THE ROCKY MOUNTAINS

Synonyms—Definition—History—Climatology—Ætiology—Morbid anatomy —Symptomatology—Diagnosis—Prognosis—Treatment—Prophylaxis—The intermittent tick fever of Wyoming—References.

SPOTTED FEVER OF THE ROCKY MOUNTAINS.

Synonyms.—Black fever, Blue disease, Rocky Mountain spotted fever, Spotted fever of Montana, Rocky Mountain fever, Piroplasmosis hominis, Spotted fever of Idaho, Tick fever of the Rocky Mountains.

Definition.—An acute endemic febrile disorder, associated with a petechial or purpuric eruption of the skin, which occurs after the bites of infected ticks, *Dermacentor andersoni* Stiles, 1905 (which is the same as *D. venustus* Banks, 1908), and probably other ticks—*e.g.*, *D. molestus* and *D. maturatus*—in certain regions of the Rocky Mountains.

History.—The first case of the disease is believed to have occurred in Bitter Root Valley, in 1873, and from that date until 1902 it is said that about 200 cases were observed, with a mortality of 70 to 80 per cent. During this period it was generally known as the 'black fever,' the 'blue disease,' or the 'spotted fever.'

In 1898, according to Anderson, Major M. W. Wood made an unpublished report on the disease to the Surgeon-General of the United States Army. In 1899 Maxy wrote a paper on 'The So-called Spotted Fever of Idaho,' which he described as an acute, endemic, non-contagious, but probably infectious febrile disorder, characterized clinically by a continuous, moderately high fever, severe arthritic and muscular pains, and a profuse petechial or purpuric eruption of the skin, appearing first on the ankles, wrists, and forehead, but rapidly spreading to all parts of the body. In 1902 Gwim and McCullough read separate papers on the disease at a meeting of the Montana State Medical Association, and in the same year Wilson and Chowning were deputed to investigate it in the Bitter Root Valley. As a result of their investigation, they concluded that it was caused by a *Piroplasma*. They believed this *Piroplasma* to be parasitic in a squirrel (*Spermophilis columbianus*), and to be spread to human beings by a tick, *Dermacentor reticulatus*

(= *D. andersoni* = *D. venustus* Banks *nec* Marx). In 1903 Anderson was instructed to investigate the disease, and as a result of his inquiries he supported Wilson and Chowning as regards both the parasite and the tick. In 1905 Stiles published his zoological investigation into the cause, transmission, and source of Rocky Mountain spotted fever, in which he failed to find evidence of the existence of the parasite in man or squirrel, and of the transmission by the tick. His researches were supported in the same year by Ashburn. In 1906 King found distinct experimental evidence of the transmission of the disease by the tick. From 1906 until his recent death Ricketts has been working at the ætiology of the malady, and has proved that the tick *D. andersoni* spreads the disease—a conclusion which he has supported by experiments on guinea-pigs and monkeys: but he says that the credit for proving the transmission of the disease from man to man by the tick must be given to McCalla and Brereton. In 1908 Ashburn and Craig published an excellent paper on this and the tsutsugamushi disease, which they indicate to be distinct from one another, and in this paper Ashburn accepts the transmission by the tick. Ricketts in 1909 found that there were really two different ticks implicated in the spread of the disease, and these were recognized as *D. venustus* Banks, 1908 = *D. andersoni* Stiles = *D. venustus* Marx, 1897, *pro parte*, and *D. modestus* Banks, of which we have been unable to find a description. It is obvious that there is great confusion as to the correct nomenclature of the ticks causing this fever. We follow Stiles, and call the best-known tick *D. andersoni*.

Climatology.—The disease is only known in the United States, in Washington State, Oregon, Montana, Idaho, Nevada, Wyoming, Utah, and Colorado. It has not been reported from New Mexico, as far as we know, but the causal tick is found there and the fever probably exists therein. In Montana it is found in the Bitter Root Valley, on the eastern slopes of the Bitter Root Mountains, and from there to the western bank of the Bitter Root River, by which it is apparently bounded, the worst area being from Lo-lo to Como, a distance of about fifty miles in length, but only about four to five miles in breadth. This country has a considerable snowfall, which, though it begins to melt in March, lies on the mountains until mid-June. The melted snow drains into the river, which does not reach low-water until July. It is only during this period that the ticks (*D. andersoni*) appear in large numbers, and infest men and animals who pass through the forests, thickets, and uncultivated regions. The disease is also known at Rock Creek, 20 miles, and at Bridger, 200 miles, east of the Bitter Root River. In Idaho it occurs throughout the entire valley of the Snake River, including its tributaries, and the foot-hills in the neighbourhood. In Wyoming it is found at Cody and Meetceste. In Nevada it is only known in the north, in the valley of the Quinn River, where it was recognized as far back as 1887. In Oregon it is said to be mild, and to be found only in the eastern portion, towards Idaho.

In 1915 it was noticed at Ismay and Fallow in Montana, which was an extension of its distribution. Possibly it occurs in Alaska.

It will be noted that these districts extend from 40° to 47° N. latitude, and that the elevation is about 3,000 to 4,000 feet above sea-level, and are sharply defined regions in valleys or at the foot of hills.

Wilson and Chowning noted that the cases occur from March to July, as is shown by the following list, taken from their report:—

March	6	cases
April	24	,,
May	46	,,
June	35	,,
July	5	,,
Spring (exact month not known)	10	,,
Total	126	cases.

This seasonal occurrence is associated, as stated above, with the prevalence of *D. andersoni* during the same months. There is a growing suspicion that there is a difference between the Montana and the Idaho strains of infection.

Ætiology.—According to Wilson, Chowning, and Anderson, the cause of the disease is a *Piroplasma*, but Stiles, Ashburn, and Ricketts have failed to find this parasite. Stiles, Ashburn, and Craig seem to have thought that the disease was due to a trypanosome. If so, this has not been confirmed. The bacterial growths so far obtained from cultures of internal organs or of the blood can be considered as merely accidental contaminations.

Ricketts has shown that blood taken from a human being suffering from the disease can be inoculated successfully into guinea-pigs and monkeys (*Macacus rhesus*), and that the transmission from animal to animal can go on apparently indefinitely (100 generations). These inoculations produce a disease characterized by an incubation, a fever, an eruption, and post-mortem appearances similar to those found in human cases. No bacteria can be cultivated from the internal organs or blood of the infected animals, but the virus exists not merely in the serum, but so closely attached to the corpuscles (white and red) that it cannot be separated from them by washing; moreover, it will not pass through the pores of a Berkefeld filter. Immunity follows an attack, and hyperimmunity can be induced in guinea-pigs.

Fricks by centrifuging infected serum for four to six hours at 2,000 revolutions per minute separated a virulent deposit, in which he found in the serum bright red granular and light blue bodies when stained by Giemsa and in the corpuscles elongated chromatinic bodies. He hesitates to draw any conclusion concerning these bodies, but thinks that the virus multiplies in his cultures. Wolbach finds diplo-bacillary-like bodies, resembling those found by Ricketts, in large numbers in endothelial cells in and around vessels and lymphatics, and in the muscle cells of vessels. He thinks that these organisms may possibly be allied to spirochætes. He has been unable to cultivate them.

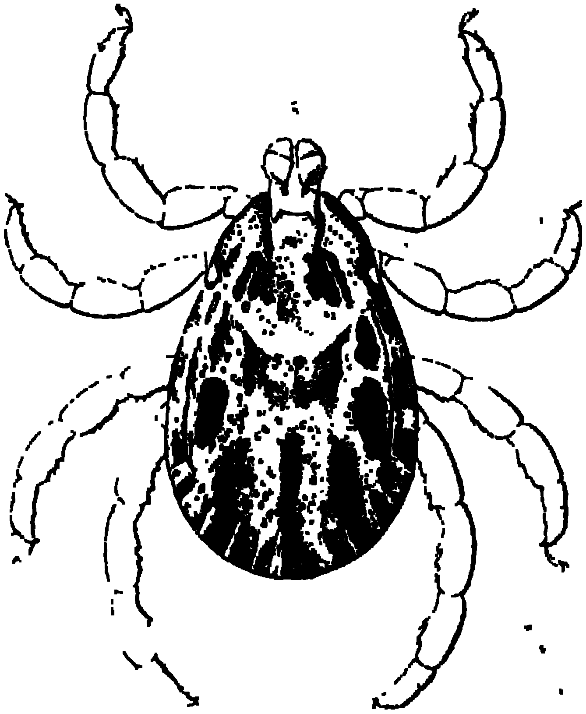

Fig. 653: Male.

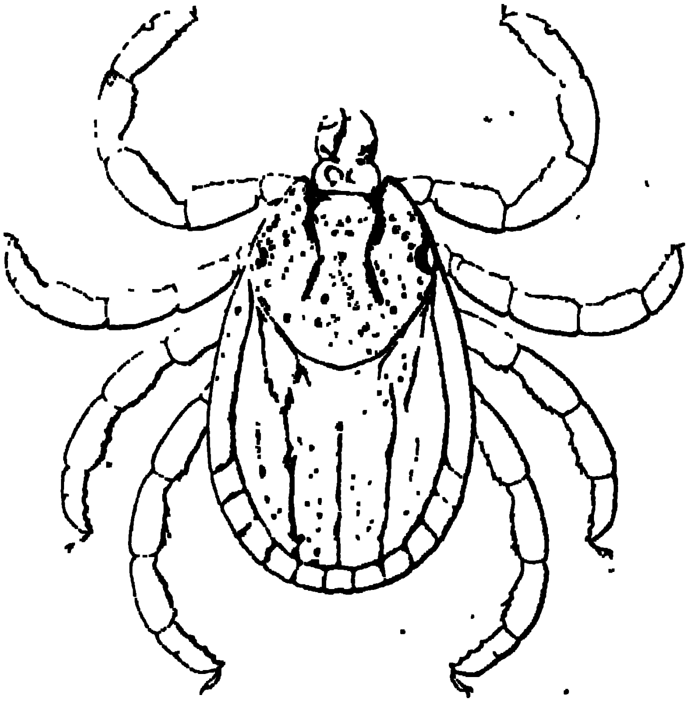

Fig. 654: Female.

Figs 653 and 654.—*Dermacentor andersoni* Stiles, 1905.

The virus can be acquired and transmitted by the larva, the nymph, and the male or female adults of *Dermatocentor andersoni*;

and in a few instances can pass through the eggs into a second generation of ticks. According to Ricketts, the Idaho disease is spread by *Dermatocentor modestus*, and the Montana by *D. venustus* Banks, 1908, *nec* Marx, 1897 (= *D. andersoni* Stiles, 1905). He is inclined to think that there is a difference between the two forms of fever, especially as the former has a death-rate of some 5 per cent. and the latter of about 90 per cent.

Infected ticks are found but sparingly in Nature. Thus, of 513 ticks found on animals, 296 or more were allowed to attack guinea-pigs, with the result that only one of the animals took the disease after an incubation of seven days. The infected guinea-pig was found to have thirty-six male ticks upon it, all of which had come from a horse.

A tick fed on a human being suffering from the disease communicated it first to a man and afterwards to a woman by its bites. Ricketts, examining the blood of patients and the eggs of infected ticks, has observed peculiar bacillary-like structures, which show bi-polar staining. He has not succeeded in cultivating the germ. Wolbach in 1916 and 1918 has confirmed Ricketts' observations. Arkwright, Bacot and Duncan consider the Rickettsia bodies found in Rocky Mountain Fever to be slightly larger and usually longer and more lancet-shaped than those observed in typhus and trench fever. Michie and Parsons have no doubt that the infective agent is in the salivary glands of the tick. Transmission to a tick requires twenty four hours, and infection of a guinea-pig one hour and forty-five minutes at least. The tick is the natural reservoir of the parasite of the disease and lives upon domestic animals, horses, and cattle, as well as upon six varieties of wild rodents, including *Citellus columbianus* and *Marmota flaviventes*, and the jack-rabbit; but according to Fricks sheep are unsuitable as hosts, but this has failed to be confirmed. There is no doubt that the parasite of the fever multiplies in the tick, and there seems to be an opinion that *Dermatocentor andersoni* (= *D. venustus*) in Montana produces a fever with a 90 per cent. mortality, while *D. maturatus* in Idaho one with a 5 per cent. mortality. See also Chapter XXXV.

With regard to *predisposing causes*, there are sex and age influences to be noted. Men are more frequently attacked than women, and the most common age is from fifteen to fifty years, both of which merely signify that persons performing outdoor work run a greater risk of infection than those otherwise employed.

Pathology.—During the fever the virus can be found in the red and white cells as well as in the serum. It also exists in the liver and spleen.

Morbid Anatomy.— Rigor mortis is well marked, and the skin shows lividity in dependent and petechiæ in non-dependent parts, and at times the marks of the tick-bites may still be visible.

The pleura, lungs, and pericardium, and most of the organs, are normal, but petechiæ may be seen on the epicardium; while the liver and spleen are enlarged, congested, and soft, and the kidneys are congested, and may show subcapsular hæmorrhages.

Histo-pathology.—The microscope shows capillary congestion of the organs, with an excess of leucocytes, and an extravasation into and pigmentation of the skin. Acute parenchymatous degenerations of the heart muscle, the spleen, liver, and kidneys, are also to be noted.

Symptomatology.—*Incubation.*—The incubation period varies from two to seven days, during which prodromata, in the form of irritation in the tick-bites, from which pains may radiate, and chilliness with malaise and nausea, may be experienced.

Onset.—The illness often begins with a distinct chill, accompanied by severe headache, pains in the back and other parts of the body, and a rapid rise of temperature to 103° to 104° F., associated with a furred tongue, a dry skin, yellow and congested conjunctivæ, an irritating cough, at times epistaxis, and the passage of febrile urine.

The fever continues to rise, with slight morning remissions, until a maximum of 105° to 107° F. is reached about the fifth to the twelfth day. About the third day (second to seventh) a macular eruption appears on the wrists and ankles which quickly spreads up the arms and legs on to the back, forehead, chest, and abdomen, so that the whole body is included in about one to two days. The macules vary in size from 1 to 5 millimetres in diameter. They are not elevated, and at first disappear on pressure, but later become permanent, and finally turn petechial about the sixth to the tenth day. Associated with the eruption is a dusky-red mottling of the skin, and often a subicteric tinge of both the skin and the conjunctivæ. The eruption is, however, by no means always well marked, and, in fact, mild cases have been reported in which it was absent.

The pulse is from the first very rapid, reaching from 110 to 150 per minute, and not as a rule in proportion to the temperature. At first full and strong, it becomes gradually feebler and smaller, and is often dicrotic, and in severe cases may be intermittent and irregular. The blood shows a diminution of the erythrocytes and hæmoglobin, with a slight increase in the total number of leucocytes and a relative increase of the mononuclear leucocytes; but in considering these blood-counts, allowance must be made for the altitude at which the disease occurs. Œdema of the face and limbs may be present in severe cases

Course.—At first the tongue is covered by a thick white fur, but later it becomes dry, cracked, and brownish, and sordes collect on the teeth. Nausea may be present during the first week, but is more common in the second, and generally lasts till the end of the illness. Constipation is usually present throughout the attack, and the liver is often slightly enlarged, while the spleen extends beyond the costal margin, and is tender. There is usually a slight sore throat, and there may be signs of a mild bronchitis, associated with an increase in the number of respirations, which may reach from twenty-six to sixty per minute.

The urine presents the usual febrile character, and often contains a trace of albumen, which occasionally may reach considerable proportions, and be accompanied by a few granular casts. More rarely the urine may be scanty or even suppressed. The mind is usually clear, but in severe cases a low muttering delirium may occur.

Terminations.—After the fever has reached its height on the fifth to the twelfth day, the temperature either declines by lysis, and recovery takes place, or it remains high, and, a typhoid state developing, death ensues. If the former event is to take place, the temperature, falling by lysis, reaches normal about the fourteenth to the eighteenth day, the eruption commences to fade, and desquamation begins, which extends all over the body, while the other symptoms gradually abate and the patient becomes convalescent. If, however, death is to ensue, the temperature remains about 104° to 106° F., but sometimes shows a sudden final fall just before the fatal event.

Convalescence.—Convalescence may take some time, and it is said that the sites of the eruption are clearly visible even twenty-four days after recovery if a warm bath is taken.

Complications.—Pneumonia is a comparatively frequent complication, but gangrene of the fingers, toes, and skin of the scrotum and penis may occur. Nephritis, cardiac weakness, and meningitis are possible complications.

Diagnosis.—The malady may be difficult to differentiate from typhoid fever, typhus, and the Japanese river fever. From *typhoid fever* it can be distinguished by the more acute onset, the petechial eruption, commencing on the hands and wrists, the absence of marked intestinal symptoms, and the presence of leucocytosis. In doubtful cases all the modern bacteriological methods—serum reaction, search for the *Bacillus typhosus* in the blood, stools, and urine—will have to be used to exclude typhoid.

The distinction between spotted fever and *typhus* on clinical grounds seems to us impossible. Though in typhus the disease may end more often by crisis than by lysis, all the other clinical symptoms, and the appearance of the eruption, are practically identical; in fact, Sambon and others believe that the Rocky Mountain spotted fever and typhus are the same entity. Possibly typhus and Rocky Mountain spotted fever are due to two varieties of the same organism, or two very closely allied species, in the same way as African, European, American, and Asian relapsing fevers are due to very closely allied organisms. It has been noted that guinea-pigs are susceptible to inoculation of Rocky Mountain fever virus. Inoculation of blood, especially if taken at the end of the febrile stage, produces pronounced swelling of the scrotum in guinea-pigs, and this has been suggested as a test to differentiate Rocky Mountain fever from typhus. Recent immunological studies have thoroughly established the difference between Rocky Mountain fever and typhus.

The *tsutsugamushi fever* may present a course very similar to the Rocky Mountain spotted fever, but the presence of one or more eschars near the genitals or the axilla, and the eruption beginning on the face, and not becoming petechial, are characteristic.

Prognosis.—It appears that the prognosis is much more serious in some localities than in others. In Montana the mortality has been as high as 90 per cent., while in Idaho it has always been very low (5 per cent.). The reason for this difference may be that there are two distinct varieties, one spread by *D. andersoni* (*D. venustus*) and the other by *D. maturatus*. When the eruption is not much marked and not generalized, the prognosis is favourable.

Treatment.—Quinine has been advised and given in large doses, but it does not show any specific effect. Atoxyl and salvarsan have no effect. Adrenalin has also been advised. The treatment can be only symptomatic. To relieve the severe headache cold applications may be used, or, with prudence, small doses of antipyrin, or pyramidon, or Dover's powders. Large quantities of water should be drunk, so as to flush out the kidneys. The water may be slightly acidulated. Tepid sponging is useful and refreshing. When the temperature rises above 103° F., cold sponging should be used, and, if necessary, the cold bath or cold pack. Should the pulse become small and irregular, cardiac stimulants must be administered. The room should be darkened, and the patient kept undisturbed.

The diet should be liquid, chiefly milk and broths. Alcoholic stimulants may be indicated in some cases.

Prophylaxis. This may be considered under two headings:—

(*a*) Man.

(*a*) *Man.* This consists in avoiding as much as possible localities where the ticks are abundant, and destroying these arachnids. A tick should be removed by applying ammonia, turpentine, kerosene, or carbolized vaseline, and then the bite may be cauterized with pure carbolic acid. Some authorities advise the internal administration of quinine, but this does not prevent the development of the fever.

(*b*) *The Tick.* The prophylaxis campaign against the tick is divided into:—

1. Destruction of ticks.
2. Removal of natural tick hosts.
3. Protection of domestic animals against the tick.

These ends are accomplished by periodic dipping of cattle and horses in the usual arsenic solution to destroy the ticks, by poisoning and shooting rodents, by restricting the movements of domestic animals from infected areas, and prohibiting the entrance of animals into these areas during the period from February to July.

The arsenical solution used as a dip is composed of the following ingredients:—

Sodium carbonate	24 pounds.
Trioxide of arsenic	8 ,,
Pine tar	2 gallons.
Water	to 500 ,,

A galvanized tank is used containing 30 to 40 gallons of water, which is brought to the boil. The sodium carbonate is now added and dissolved by stirring, and then the arsenic is dissolved in the same way. The fire is now stopped and the pine tar added in a thin stream and thoroughly mixed by stirring. The solution so formed is the stock and can be diluted to 500 gallons as required.

THE INTERMITTENT TICK FEVER OF WYOMING.

Definition.—An intermittent fever due to the bite of *Dermacentor andersoni*.

History and Geography.—This fever was described by Kieffer in 1907 as being found at Fort D. A. Russell, in Wyoming, United States of America, but his account so far has not been confirmed.

Ætiology.—The fever comes on after the bite of *D. andersoni*—*i.e.*, the same tick which causes the spotted fever of the Rocky Mountains—but no specific organism has so far been described.

Symptomatology. The incubation period varies from three to seven days, after which the disease begins suddenly with a rigor, nausea, vomiting, and pains in the joints and muscles. The temperature rises between 103° and 104° F., and continues high for twenty-four to forty-eight hours, after which a remission of forty-eight hours occurs, and then another attack, and so on for three to seven attacks. Less frequently the attack resembles typhoid, with a ladder-like rising temperature and abdominal symptoms, but Widal's reaction is absent. There is marked decrease of the erythrocytes and hæmoglobin, and a slight lymphocytosis, due to increase in the number of the large mononuclear leucocytes.

Treatment.—Hypodermic injections of arsenic in some form are recommended as the best treatment for the disease. Salvarsan should be tried.

CHAPTER LI

TSUTSUGAMUSHI FEVER AND ALLIED FEVERS

Synonyms—Definition—History—Climatology—Etiology—Pathology—Symptomatology—Diagnosis—Prognosis—Treatment—Prophylaxis—Allied fevers—References.

TSUTSUGAMUSHI FEVER.

Synonyms.—Japanese River fever, Flood fever, Island disease (Shima disease) Kedani disease ('kedani' is the hair louse), Akamushi disease ('mushi' is the Japanese for a bug or insect; 'akamushi' means 'red insect'), Shima mushi disease (Island bug disease), Tochu bio, Shashitsu, Pseudotyphus

Definition. Tsutsugamushi disease is an acute endemic febrile disorder caused by the bite of a mite, *Microtrombidium akamushi* Brumpt, 1910, producing a small local necrotic area, painful enlargement of the proximal lymphatic glands, and an exanthematous eruption.

History.—Tsutsugamushi disease is said by Ashburn and Craig to have been mentioned under the term 'shashitsu' in Chinese writings more than one thousand years ago, when it was described as a fever due to the bite of a mite, which produced a pustule in summer-time in people who entered those parts of the country which had been flooded by the spring rains. The Japanese literature on the subject is considerable, but the descriptions written in European languages are not extensive, the earliest contributions being by Palm in 1878 and Baelz in 1879, while Ashburn and Craig, in 1908, give an excellent account of the disease and its causation, together with a comparison with the spotted fever of the Rocky Mountains.

Climatology.—The geographical distribution is limited to the island Nippon, of Japan, where it is confined to the districts Akita-ken and Nugata-ken ('ken' means a 'district'), in which certain lands are flooded in June, in the former district by the Rivers Omonogawa and Minasegawa, and in the latter by the Rivers Shinanogawa, Akagawa, Uwonumagawa, and Hajadegawa. Further, it is limited to certain parts of the regions flooded by these rivers. The floods only last a few days, and the regions do not become dangerous till after a few weeks, when a red mite appears, which may attack any person entering these places. In fact, so great is this danger that the lands have been abandoned, except by the very poor, who enter them in order to cultivate hemp or corn, or to gather mulberry-leaves to feed silkworms. The disease is to a limited extent transportable with corn, hemp, and other articles. It occurs most frequently from the middle of July to October.

According to Weir, a similar disease exists in Korea; to Dowden, in the Malay States; to Schöffner, in Deli; and to Noc and others, at Saigon.

Ætiology (*vide* also pp. 726 and 920).—The causation of the disease is not known, but there are three theories which have been supported by various investigators.

These theories are:—

1. *The Bacterial Theory*. Many bacteria have been described as the cause of the disease, the first being a *Proteus*, found by Balz and Takana, associated with staphylococci and streptococci in the lungs, sputum, and urinary sediment.

2. *The Protozoan Theory*.—Ogata considers that the cause of the disease is a *Plasmodium*, which he states he has found in the blood of numerous patients. Ogata's observations have not been confirmed. In 1917 Hayashi claimed that the parasite was a *Piroplasma* which existed in monkeys, guinea-pigs, and calves, inoculated with blood from a patient, in the form of granules and rod shaped, globular, and annular masses in giant cells found in the lymphoid tissue, especially of the guinea-pigs.

Myashima has found rodlets in the akamushi and in inoculated animals.

Nagayo, Miyagawa, Mitamura and Imamura state that they have cultivated an oval non-capsulated non-motile organism from patients suffering from the disease.

3. *The Chemical Theory*. Tanaka believes that the true cause is a toxin contained in the body of the mite, and introduced by its bite.

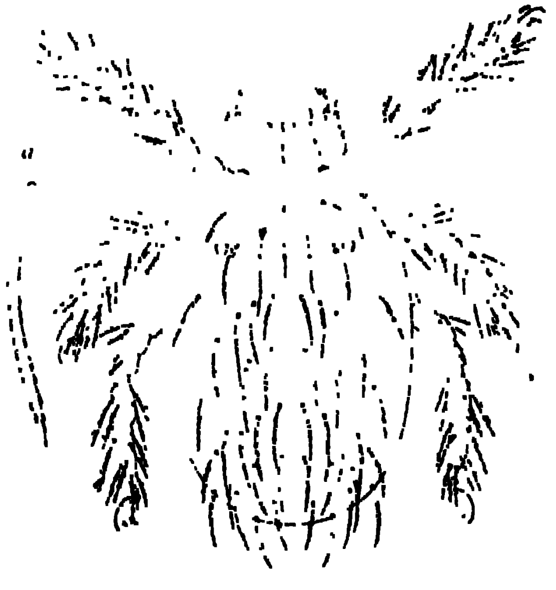

FIG. 655.—*Microtrombidium akamushi* BRUMPT.
(After Hirst, from the *Journal of Economic Biology*.)

The only certain facts which we know concerning the ætiology of this disease is that the symptoms follow the bite of the larva of *Microtrombidium akamushi* Brumpt, and that immunity is not conferred by an attack. This larva (akamushi), which, though bright red or orange in colour, is so small that it is almost invisible to the naked eye, is found in large numbers on the inner surfaces of the ears of field-mice (*Arvicola natanedzumi* Sasaki) caught in July and August in the infected regions. The akamushi of other regions do not cause the disease, which, of course, is against the chemical theory as to the ætiology. Miyajima claims to have infected monkeys by inoculating blood derived from a person suffering from the disease, and also by the bites of the mites. Mice and guinea-pigs are said to be immune—a statement which, however, is opposed by Ogata. The larva has been reared and adult mites obtained by Nagayo, Miyagawa, Mitamuar, and Imamura, as well as by Miyajima and Okumura. The last-named suggest that the correct name for the mite is *Leptus akamushi* (Brumpt).

Only poor people enter the infected lands during the months of July to October, and as any person who does so is liable to infection, the disease is mostly found among the poor.

Pathology.– The post-mortem reveals a small ulcer, sometimes still covered by an eschar at the site of the bite, and enlargement of the proximal lymphatic glands. The spleen is enlarged and softened, the lungs are œdematous and congested, and the bronchial mucosa is often slightly swollen and reddened, and the kidneys are inflamed. We are not acquainted with any description of the histology of the organs.

Symptomatology.—The incubation period varies from four to ten days (4-7 Scheube), during which there may be a feeling of prostration, giddiness, and general malaise, but definite prodromata are wanting.

The disease begins with a chill and rigors, accompanied by severe pain in the forehead and temples, and a sensation of weakness, while the temperature quickly rises to 101° to 103° F. The patient usually complains of pain in certain enlarged lymphatic glands, which, on inspection, are found to be tender, quite distinct from one another, and freely movable under the skin. A search in the region drained by these glands may reveal a circular vesicle measuring 2 to 4 millimetres in diameter, but more usually one or more black or brownish necrotic areas of skin, surrounded by a dullish red areola, are found. These areas indicate the sites of the bites of the mite.

The temperature continues to rise during the next few days, reaching a maximum in the second week, when it may be as high at 105° F. During this time the eschar has been thrown off the necrotic area, and reveals a circular punched-out ulcer, the periphery of which is red and infiltrated, but not painful nor tender. About the fifth to the seventh day an eruption appears on the face in the form of large red papules, which may become confluent on the cheeks, giving the face a swollen appearance. From this situation the eruption spreads all over the body, but more in the form of macules than papules. These maculæ, which are 2 to 5 millimetres in diameter, fade on pressure, but quickly return.

when the pressure is removed, and do not itch. Between the spots on the trunk and forearms follicular papules may be noted, but the eruption is not so well marked on the arms and thighs.

At first the pulse is full, and not very rapid, varying from 80 to 100 per minute; later it may become small and quick, and at times dicrotic. The first cardiac sound is often impure, and the transverse diameter of the cardiac dulness may be increased.

In the blood the red cells are found to be diminished, and the hæmoglobin proportionately reduced. In mild cases there is often an increase in the large mononuclear leucocytes and lymphocytes, but in severe cases the total number of leucocytes is often diminished, though there may be a relative polymorphonuclear increase.

The tongue is at first moist and slightly coated, but later it becomes dry, brown in the centre, and glazed at the tip and edges. The gums in some cases are spongy, and bleed, while sordes may collect on the teeth, and a few punctiform spots be noted on the palate. The epigastrium and left hypochondrium are tender; the liver, however, is not as a rule palpable, though the spleen is usually slightly enlarged.

The nose and throat are normal, but the rate of the respirations is increased, and the breath-sounds are harsh and accompanied by rhonchi, which can be heard all over the chest. Usually there is a certain amount of coughing, but the expectoration is scanty.

The urine is diminished in quantity, high-coloured, and may contain albumen, and often gives the diazo-reaction. Strangury may occur.

The conjunctivæ are early injected, a feature which becomes more marked as the disease progresses, and is associated with lachrymation.

From the very first there is a great hyperæsthesia all over the body, and there may be delirium at night, and difficulty in hearing.

About the fourteenth day of the illness the eruption begins to fade and the fever to remit, and in the next five or six days the temperature falls by lysis to normal, and, the general condition rapidly improving, convalescence begins. Recovery is usually quick, and by the twenty-first day from the commencement of the attack the patient is well.

In bad cases, however, coma and hyperpyrexia may develop in the second week, and cause the death of the patient. In other cases death may be caused by complications, which may arise either in the second week or during convalescence.

Varieties.—Severe types of the disease end in death about the ninth to the fifteenth day from hyperpyrexia, cardiac failure, pulmonary œdema, or from complications. Mild types, showing only the bite and the enlargement of the lymphatic glands, and associated with but little fever or eruption, quickly end in recovery.

Complications.—The commonest complications are parotitis, melæna, mania, and cardiac failure with pulmonary œdema.

Diagnosis.—The differential diagnosis from Rocky Mountain spotted fever and typhus has already been discussed (p. 1347). At the onset—when the inguinal or other lymphatic glands are enlarged and painful—plague might be suspected. The presence of the necrotic area, and, in any doubtful case, the microscopical examination of the gland juice, which in plague contains numerous bi-polar staining bacilli, will enable a diagnosis to be made.

Prognosis.—The prognosis is good in the young, and in second and third attacks, which are always milder than the first. It, however, gets worse as age progresses, and especially in first attacks. The mortality is about 30 per cent., but increases markedly with age, being only 12·5 per cent. in the first, and 57 per cent. in the seventh decade of life.

Treatment.—Quinine is generally administered, but it does not influence the fever to any marked extent. Salvarsan might be tried. Narcotics may be required to combat the sleeplessness, and constipation must be relieved by purgatives and enemata. Phenacetin, antipyrin, and salicylates are generally badly borne by the patient.

Prophylaxis.—The prophylaxis consists in the avoidance of the infective regions during the months of July to October inclusive, while the cultivation of the infected regions, and especially the planting of *Eucalyptus globulus* and *Paulownia imperialis*, are advised, as well as the smearing of the exposed parts of the body with eucalyptus oil and balsam of Peru, which are said to keep away the mites.

The natives believe that the manuring of the infected lands with human fæces for three consecutive years will make them free from the mites, provided there is no flooding during that period.

ALLIED FEVERS.

PSEUDO-TYPHUS OF DELI, SUMATRA.

In 1902 Schüffner observed a peculiar fever in Deli, Sumatra, which he described in 1913, and which he thinks may possibly be due to a tick.

In occurs from June to August and from November to January.

The site of the inoculation is marked by a small red spot, followed by necrosis of skin and inflammation of the local lymphatic glands. The necrotic ulcer may measure 2-7 mm. in diameter, and shows little tendency to heal, while other lymph glands enlarge.

On or about the second to third day a roseolar eruption appears all over the body, being most marked upon the trunk and flanks, and less so on the face and limbs. This eruption slowly fades during eight to ten days. Sometimes it is but slightly marked; sometimes it is hæmorrhagic and followed by desquamation.

The fever is like that in enteric fever, and is associated with severe nervous symptoms.

Diarrhœa is rare, but pulmonary complications are not unusual, and albuminuria is generally present. The blood shows an increase in the white cells, particularly the lymphocytes, while the eosinophiles are diminished.

No organisms could be found in the blood, and there were no reactions to serum tests for the enteric fevers, nor could monkeys be infected by inoculation.

KOREAN CONTINUED FEVER.

A somewhat similar fever to the Sumatra fever is described by Weir. It occurs in spring and early summer. No bite is mentioned, but there is the rash; no diarrhœa, but frequent pulmonary complications and the nervous symptoms. The course of the fever is often short and terminates by lysis.

MALAY STATES FEVER.

Dowden in 1915 described a somewhat similar fever in the Federated Malay States, but gave no ætiological information.

CHAPTER LII

RAT-BITE AND CAT-BITE FEVERS

Rat-bite fever—Cat-bite fever—Squirrel-bite disease—Addendum References.

RAT-BITE FEVER.

Synonyms.—Sodoku (So = rat, doku = bite); Fièvre par Morsure de rat Morso-di-Topo; Rattenbisskrankheit.; Rattenbeetziekte.

Definition.—A relapsing fever of long duration characterized by redness and swelling at the site of a rat-bite, often by a generalized papular eruption, and caused by *Spiroschaudinnia morsusmuris* Futaki, Takaki, Taniguchi, and Osumi, 1916, living in the mouth of *Epimys norvegicus* Erxleben, 1777, in many parts of the world, and inoculated by means of their bite.

History.—Rat-bite fever is mentioned in Japanese medical books from the most ancient times, and Scotch, French, and Spanish literature have references to the disease, but it was not until Katsura in 1899 and Miyake in 1899 reported cases that any interest was taken in the malady. In 1908 some twenty-one Japanese investigators, according to Hora, had reported some thirty cases, which have recently been increased very considerably. It has also been recorded by Horder in England; by Proescher in the United States, in which the literature of the nineteenth century shows occasional cases among settlers; by Frugoni in Italy, who has given a very good general account of the malady, and by Lou and Cockin from East Africa. As we stated under this heading in the first edition of this book, there is a curious belief in Ceylon that a rat's bite is a serious injury, and is apt to be followed by a chronic disorder which is popularly called leprosy, but which we have never been able to see. In Ceylon the belief is that the rat's bite is only pernicious in the breeding season. And in Japan Hora's case is stated to have been due to a bite of a female rat which was suckling its young. It is said that the same disease may follow the bite of a weasel, and it is known that weasels kill rats, and therefore it is possible that infection may come in this manner to the weasel.

In 1898 Millot and Carpentier, and in 1907 Roger, drew attention to the existence of the disease in France.

In 1908 Ogata considered that the causal organism was a sporozoön (Rattengift sporozoön). In 1914 Schottmüller obtained a nocardia, which he called *Streptothrix murisratti*, from the blood of cases of the disease. This organism has been supported by the observations and experiments of Blake and others, but is now merely of historical interest. Douglas, Colebrook, and Fleming, in 1918, found a streptococcus, while Coles has suggested that more than one germ may be the causal agent.

In 1916 Futaki, Takaki, Taniguchi, and Osumi discovered a spirochæte in the lymph glands and pathological products of patients suffering from the disease. In the same year Costa and Troisier reported cases in France.

Climatology.—As the rat is widespread, so the disease is found in many parts of the world, being recorded in Japan, China, Ceylon, India, Dutch Indies, East Africa, England, France, Italy, Balkans, Holland, Germany, and North and South America.

Ætiology.—Futaki and his collaborators, in 1916, reported the presence of a spirochæte 9-10 microns in length in the lymph glands and in the tissue fluid from the bitten area. Later they found in man and inoculated animals shorter and thicker spirochætes 2-6 microns long, with regular close steep waves and a filament at each end. Ishiwara, Ohtawara, and Tamura, in 1916 and 1917, in investigations with regard to experimental rat bite, found spirochætes morphologically identical with the short forms described above, and Kitagawa and Mukoyama, in 1917, found forms measuring 6-10 microns in length, with a smaller one measuring some 4 microns and a larger measuring 12 microns, in their inoculated guinea pigs.

In 1917 Kaneko and Okuda, in performing a post-mortem on a case, found:—

1. *Long spirochætes*, 6-10 microns in length, with numerous small, steep, irregular waves, identical with Futaki's long spirochæte.

2. *Short spirochætes*, 1·7 5 microns in length, with two to six steep, close, regular waves, identical with the short spirochæte of Ishiwara and Futaki, and also to the spirochætes found by Ido and his collaborators in guinea-pigs bitten by rats and so infected.

These short parasites have been found by Ido and others in human blood films taken at the height of the disease. Kaneko and Okuda found the spirochætes in the kidney in casts in the straight tubules, the canals of Henle, and the intercalary portion of the boundary layer. They have also been found in the cortical cells of the suprarenal capsules and in an interstitial space in the testicles, but not in other organs.

The long and the short spirochætes belong to the same species, as is proved by pure cultures. The long spirochætes are considered to be old forms, and are exclusively found in human tissues. The short spirochætes are the typical young forms, and can be found in the blood of patients suffering from rat-bite fever, as well as in experimental animals. In no instances have they been found in healthy guinea-pigs, white rats, or mice. They are absent from the blood and tissues of infected animals receiving salvarsan treatment.

Ido, Ito, Wani, and Okuda have demonstrated that the serum of persons who have recovered from the disease contains an immune body which destroys *S. morsusmuris*, as demonstrated by Pfeiffer's test and by the fact that the guinea-pigs employed for this test remain well.

Human serum shows definite spirochætolytic and spirochæticidal properties eleven months after the onset of the disease.

These researches make it probable that *S. morsusmuris* is the ætiological agent of the disease.

Naturally infected guinea-pigs have been seen by Niowaka, Yoshizawa, and Mumento, who have shown that the disease can be spread from guinea-pig to guinea-pig by subcutaneous injections of the saliva or by bites of infected guinea-pigs. The organisms may possibly live in the salivary glands of rats. The men mostly infected are agriculturists and sailors, but it has been seen in soldiers in the trenches and persons living in ordinary houses.

Row regards the strain found by him in Bombay as being different from the Japanese strain

Pathology.—At first the reaction against the organism is weak, but later immune bodies specific against the spirochætes are found.

Morbid Anatomy.—Only four post-mortem examinations are on record—viz., those by Miura and Toriyama in 1897, by Blake in 1916, and two by Kaneko and Okuda in 1917.

In the first the conditions were increase of the cerebro-spinal fluid, hyperæmia of the meninges, inflammatory œdema of the lungs, and cloudy swelling of the liver.

In the second there were acute ulcerative endocarditis, subacute myocarditis, interstitial hepatitis, glomerular and interstitial nephritis, infarcts in the spleen and kidney, hæmorrhages and œdema of the lungs. Microscopically, degeneration and necrosis of the cardiac muscles; polymorphonuclear infiltration into the liver and into the shrunken kidney, but many of the changes may have been due to the nocardia found by Blake.

In the third case there were no marked pathological changes, except parenchymatous changes in the organs, such as hyperæmia, swelling, and degeneration of the tubular epithelium of the kidney. There is degeneration, necrosis, and destruction of the liver cells, particularly in the centre of the lobule, with hyperæmia and fatty degeneration of the periphery of the lobule, with also hæmorrhages. No abnormalities in the spleen, lymphatic glands, or bone-marrow, except that the local lymph glands show a hyperplasia of the parenchymatous cells. Catarrhal changes are seen in the mucosa of the stomach, as well as catarrhal cystitis, congestion of the lungs and meninges, and degeneration of the muscles of the leg and nerve cells of the brain cortex and spinal cord.

The skin near the bite shows hyperæmia, œdema, and polymorphonuclear infiltration into the corium and subcutaneous tissue, but no changes in the epidermis.

The changes found in experimental animals agree with those seen in man.

Symptomatology—*Incubation.*—The incubation period varies from seven to twenty-two days, but the average is twelve days. During this period the wound caused by the bite heals.

The Attack.—The onset is sudden. The site of the bite, which, in the large proportion of cases, is on the head or upper extremity, becomes red and swollen, and an ulcer forms, while the regional lymph glands become enlarged. The temperature now rises (103° to 105° F.), the pulse becomes small and rapid, and there may be sensations of chilliness, while an eruption of purple spots, which often resembles erythema polymorphum, appears on the body, and the patient feels very ill, with pains in the muscles and joints, and perhaps delirium. In a few days the temperature declines and the patient feels well.

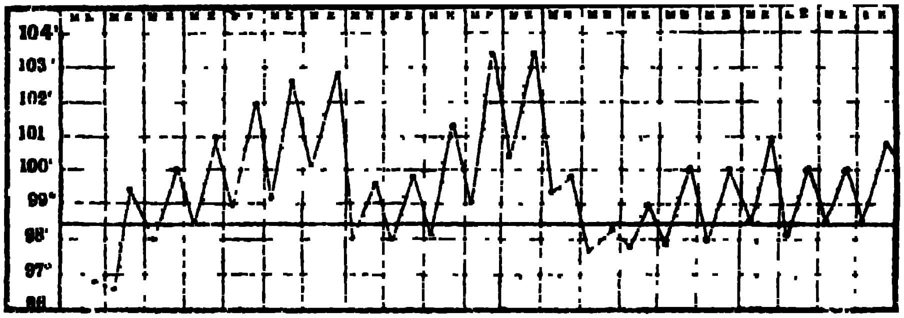

FIG. 656.—RAT-BITE FEVER.

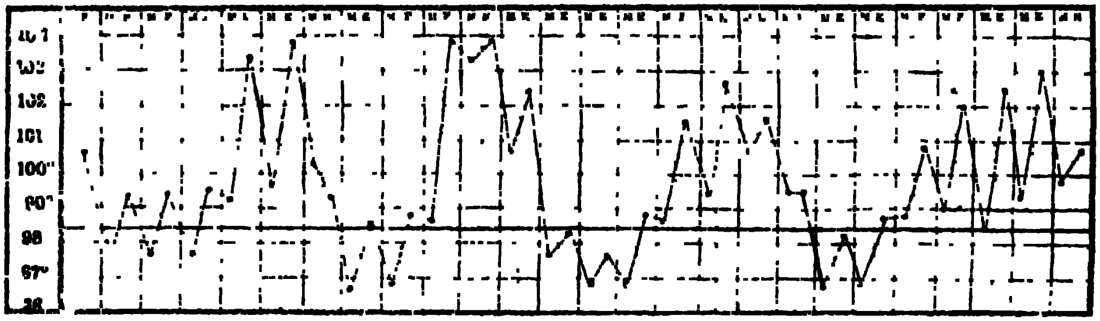

FIG. 657.—RAT-BITE FEVER.

Relapse.—After a few days or a couple of weeks of apyrexia, however, the attack is repeated, and these intervals of apyrexia and attacks of fever may be repeated for months or years. The relapses may be fairly regular, at five days' intervals, for months, and may be preceded by premonitory symptoms. Thus Hora's case had about ten relapses a year for a period of seventeen years. The blood may show eosinophilia. During the fever red cells are about four millions and the leucocytes about six to twelve thousand. In the interval there may be only four thousand leucocytes. Death may occur in old people from exhaustion, or in others from complications.

Varieties.—Three different types of the disease are described: a febrile type with a marked eruption, a febrile type with nervous symptoms, and an abortive type; but the first is most common.

Complications.—Sloughing and gangrene at the site of the bite and nephritis may occur.

Diagnosis.—The presence of a relapsing fever associated with a purple-coloured eruption and a non-suppurative adenitis following a rat-bite should make the diagnosis easy. The discovery of the spirochæte in the blood confirms the diagnosis.

Prognosis.—This is good, as the mortality is only about 10·5 per cent., and death is most usually due to collapse or septicæmic symptoms during the first attack, or to nephritis or to complications.

Treatment.—Treatment by salvarsan is quite successful. For details of the treatment see pp. 1313 and 1560. Mercury has been recommended by Borelli.

Prophylaxis.—The rat-bite should be thoroughly disinfected.

CAT-BITE DISEASE.

Definition. A relapsing fever caused by a spirochæte, probably identical with *Spiroschaudinnia morsusmuris*, introduced by a cat's bite or scratch.

History. Cat-bite disease was first described in Japan by Fujida and Sato in 1902, while Izumi and Kato, in 1917, brought forward evidence to show that the causal organism was a *spirochæte*, probably identical with *S. morsusmuris*. In 1917 Sano described a case due to scratches caused by a cat.

Ætiology.--Futaki and Ishihara, Ido, Ite, Wani and Okuda, Izumi and Kato, have all found spirochætes in the blood of patients. They were discovered by the first named and confirmed by the others. The last named believe this spirochæte to be the same as that causing rat-bite, because--

I. The serum of a patient suffering from cat-bite, when mixed with an equal quantity of guinea-pig blood containing rat-bite spirochætes, immobilizes them. When repeated with normal and syphilitic serum the spirochætes are not affected.

II. When 1 cubic centimetre of guinea-pig blood containing rat-bite spirochætes is mixed with 2 cubic centimetres of the blood of a patient suffering from cat-bite, and then the mixture injected into the peritoneal cavity of a guinea-pig and removed in an hour, no spirochætes are found. In a control guinea-pig the spirochætes were abundant and active.

III. In II. the first guinea-pig remained healthy and the control died.

Symptomatology--*Incubation.*--This varies from ten to twenty-one days.

Attack.--The onset begins with some premonitory symptoms, followed by fever, pains in the muscles and joints, enlargement of the spleen and the lymphatic glands. Infiltration of the skin takes place near the site of the bite, and macular or urticarial eruptions which spread all over the body.

The bite may heal readily or may ulcerate deeply.

Course.--The fever is of the relapsing type, the intervals being some three to nine days, and without treatment the disease will last for months.

Diagnosis.--This is the same as for rat-bite fever.

Prognosis.—This is good *quoad vitam*, except in old age or debilitated persons.

Treatment.—One injection of salvarsan will cure some cases, while others require several injections.

SQUIRREL-BITE DISEASE.

Synonym.—Eichhörnchen-Bisskrankheit.

Schottmüller described a case of this infection in 1914 in a woman bitten by an African squirrel, *Taraxerus cepapi*. The disease was characterized by fever and also by nodules, which destroyed the sight of one eye. Another case was a man bitten by the same squirrel, and from the pus of this case Schottmüller obtained a nocardia which he called *Streptothrix taraxeri cepapi*. The nocardia infection is probably a complication, possibly also introduced at the time of the bite, as its presence has been confirmed by numerous observers, and species of nocardia are well known to live in the human tonsil, and may well exist in the mouth of rats, squirrels, and other animals.

ADDENDUM.

Weasels are also said to cause similar symptoms by their bites, and it is likely that many other animals do the same, and it is possible that they inoculate the bitten person or animal with various types of organisms, of which spirochætes appear to be more important as regards the causation of fever.

CHAPTER LIII

THE ENTEROIDEA GROUP OF TROPICAL FEVERS

General remarks—Enteroidea or intestinal fevers—Enteric—Parenteric—References.

GENERAL REMARKS.

We use the word *enteroidea*, or intestinal fevers, for all those fevers which are caused by any of the intestinal bacteria, while the term *enteric fever* denotes those which are called *typhoid* and *paratyphoid A and B fevers*. By *parenteric fever* we mean those febrile conditions which, though clinically resembling 'enteric fever,' are caused by intestinal bacilli specifically different from *B. typhosus* and *B paratyphosus A and B*. These parenteric germs may be closely related to the enteric germs or may be widely separated therefrom (*vide* Chapter XXXVI., p. 934).

ENTEROIDEA OR INTESTINAL FEVERS.

The term *enteroidea* covers both the enteric and the parenteric groups, and applies to any fever caused by intestinal germs in the widest sense of the word (p. 934). These fevers may be classified as follows.

- ENTEROIDE FEVERS:—Synonyms: Enteroidea, Intestinal fevers, Enterica *sensu lato*
  - *Enteric Fevers:* Synonym: Enterica *sensu stricto*
    - Typhoid.
    - Paratyphoid A.
    - Paratyphoid B.
  - *Parenteric Fevers:*—Synonym: Parenterica
    - A, due to germs of genus Eberthus and Alcaligenes.
    - B, due to germs of genus Salmonella.
    - C, due to germs of genus Enteroides.
    - D, due to germs of genus Lankoides.
    - E, due to germs of genus Balkanella and Wesenbergus.
    - F, due to germs of genus Escherichia.

ENTERIC.

Synonyms.—Typhoid Fever, Abdominal Typhus, Gastric Fever, Pythogenic Fever, Endemic Fever, Autumnal or Fall Fever, Remittent Fever of many writers, Common Continued Fever, Slow or Lent Fever, Nervous Fever, Little Fever, Irregular Low Fever, Low Fever, Bilious Fever, Bilio-gastric Fever, Bilious Continued Fever, Night-soil Fever, Cesspool Fever.

French Synonyms.- Fièvre Typhoide, Dothienenterite, Fièvre Continue, Fièvre gastrique, Fièvre nerveuse, Enterite septicemique, Adéno-meningee, Fièvre meningogastrique.

Italian Synonyms.--Febbre tifoide, Tifo addominale.

German Synonyms. — Abdominaltyphus, Nervenfieber, Darmtyphus, Gastriches Fieber.

The Latin synonyms are very numerous, and have been classified by Murchison into:--

(*a*) From supposed resemblance to typhus: Typhus nervosus, T. mitior; T. gangliaris vel entericus, Ileo-typhus; Typhos, Typhus (of many old writers).

(*b*) From mode of prevalence: Febris non pestilens

(*c*) From its remittent character: Febris semitertianæ seu composita; Tritæophya typhodes.

(*d*) From its length: Febris lenta.

(*e*) From septic symptoms: Febris putrida, Febris putrida quæ vulgo lenta appelatur; Febris putrida aut biliosa; Febris a putredine orta

(*f*) Resemblance to hectic fever: Febris hetica.

(*g*) Occurrence of gastric symptoms: Febris gastrica, Febris acuta stomachica aut intestinalis; Synochus biliosis.

(*h*) From intestinal symptoms: Febris mucosa, Febris pituitosa, Febris mesenterica maligna, Febris intestinalis

(*i*) From supposed origin from worms: Febris verminosa, Typhus verminosus.

With regard to the nomenclature, we have adopted the term Enteric Fever, used by Ritchie in 1840, because we describe under the term three distinct diseases caused by distinct micro-organisms, all of which produce symptoms either identical with or so closely resembling one another as to be nearly impossible of clinical separation at the present time.

Definition. – The term 'enteric fever' is used at the present time to indicate three clinically similar fevers, typhoid fever due to *Bacillus typhosus* Eberth, 1880, the paratyphoid fevers due to *B. paratyphosus A* Schottmuller, 1901, and *B. paratyphosus B* Schottmüller, 1901, and varieties of these bacilli.

History. - The history of enteric fever may be considered under two headings viz., the general history of the disease, and the special history of its occurrence in the tropics.

It is quite impossible to recognize it with any degree of certainty in the meagre descriptions written by Hippocrates and the ancient physicians, which may or may not have referred to this disease. In the Middle Ages enteric fever, typhus fever, and relapsing fever were always confused with plague until Fracastorius, in the sixteenth century, distinguished typhus (which included enteric fever and relapsing fever), or febris pestilens, from plague, or febris vere pestilens. Spigelius, in 1624, is probably the first writer to clearly recognize the symptoms of enteric fever, because he described in Padua a disease characterized by fever, abdominal pain and tenderness, diarrhœa and delirium, having remissions and relapses, and associated with the post-mortem appearances of inflammation in the ileo-cæcal region. Similar descriptions can be found in the writings of Willis in 1659, who drew a distinction between febris pestilens and a febris lenta, the latter being associated with the enlargement of the mesenteric glands. Sydenham, in 1685, described a fever lasting fourteen to thirty days, and associated with diarrhœa, vomiting, epistaxis, etc., as distinct from febris pestilens. In 1715 Baglivi of Rome described the hemitritæus of older writers under the term 'febris mesenterica.' This fever was characterized by being irregularly remittent, lasting from fourteen to twenty-one days, and associated with inflammation of the intestines and mesenteric glands. Lancisi thought that the enteric ulcers were caused by round worms. Hoffman's febris petechizans vel spuria, Strother's lent fever, Gilchrist's nervous fever, Huxham's slow nervous fever, Riedel's febris intestinalis, and Manningham's febricula, are all synonyms of enteric fever. In 1810 Hildenbrand distinguished between contagious typhus and a non-contagious nervous fever, which were respectively named typhus exanthematicus and typhus abdominalis by German authors.

In 1813 Bretonneau of Tours associated this fever with hyperplasia of the solitary and agminated glands of the ileum, and gave it the name 'dothienenteric' (from *δοθιήν*, a tumour, and *ἔντερον*, the intestine).

In 1829 Louis gave the fever the name 'fièvre typhoïde,' and the work of Gerhard of Philadelphia in 1837, Shattuck of Boston in 1839, Barlow in 1840, Bartlett in 1842, Ritchie in 1846 (who introduced the term 'enteric fever'), Jenner in 1849-51, completed the clinical differentiation of enteric fever from typhus, from which relapsing fever was also being separated. Thus arose the clinical conception of enteric fever, but in the meanwhile many theories had been promulgated as to its causation; thus Bretonneau held the view that it was spread by means of contagion, but this opinion was slow in gaining definite support. In 1847 Canstatt pointed out '*that truly the exhalations of the sick man, his excrements, and possibly the typhus eruption in the skin, are the carriers of the contagion.*'

In 1850 Riecke recorded outbreaks due to drinking-water becoming contaminated with sewage; Murchison implicated milk.

In 1880 Eberth discovered the *B. typhosus* in the mesenteric glands and spleens of persons dying from enteric fever, and in 1884 Gaffkey cultivated the bacillus so discovered.

In 1885 Fraenkel and Simmonds obtained definite animal reactions in guinea-pigs, mice, and rabbits; and more recently Grünbaum, Metchnikoff, and Besredka reproduced the typical characters of the disease in chimpanzees: and Bland-Sutton described deaths of lemurs and monkeys in London which were associated with post mortem appearances resembling enteric fever.

The diagnosis of the disease was greatly facilitated by Grüber and Durham's, Widal and Grunbaum's, works on agglutinins and specific agglutination reactions. Later, the cultivation of the bacilli from blood obtained by splenic puncture, and by the dilution method as devised by Castellani from the circulating blood, assisted the diagnosis; while the bile enrichment method and the Conradi-Drigalski's, MacConkey's, and other media generally aided the investigation of the disease. Chantemesse has devised an ophthalmo-diagnostic method. The diagnosis of a mixed infection has been rendered easier by the absorption test as introduced by Castellani in 1902, which is of use also in the determination of closely allied bacteria. The *B. typhosus* has been found to be capable of living for weeks in the spleen, and for years in the gall-bladder, of people who are designated 'typhoid-carriers,' as the bacilli escape in the fæces in the latter case. The bacilli have been shown to occur naturally in water-supplies, earth, dust, fomites, flies, shellfish, and milk, etc. The subject of relapses has been studied by Chantemesse and Widal in 1892, Wright and Lamb in 1899, and Durham in 1901.

Attempts to obtain an antityphoid serum by Macfadyen, Hewlett, and Chantemesse, have not been successful, but Wright and Semple devised a vaccine in 1897 which was perfected by Leishman, and has been much used and has rendered great service: later Castellani brought forward vaccination with a mixed typhoid + paratyphoid A + paratyphoid B vaccine dead or living (attenuated) as a method of prophylaxis, while more recently Besredka and Metchnikoff have advised a living, not attenuated, sensitized vaccine.

The subject of variation of the *B typhosus* has been studied by Twort, Horrocks, and Penfold.

In 1895 Gilbert gave the name '*para-colon*' to bacilli occupying an intermediate position between *B. coli* and *B. typhosus*. In 1896 Archard and Bensaude used the term '*paratyphoid*' as a name for such organisms when capable of producing the symptoms of enteric fever, but this name dropped into oblivion, only to be revived by Schottmüller in 1901, when he clearly demonstrated his *B. paratyphosus A* and *B. paratyphosus B* as the cause of two forms of enteric fever, the diagnosis of such cases being obtained by the specific agglutinative reactions, or, better, by cultivation from the circulating blood. This is the reason why the symptoms characteristic of enteric fever are ascribed to three allied organisms—viz., *B. typhosus* Eberth, *B. paratyphosus A* Schottmüller, and *B. paratyphosus B* Schottmüller.

The presence of typhoid fever in the tropics has, even in recent times, been much debated, and apparently the view has been held that it was overlooked by the older tropical physicians. This, however, is quite erroneous, for typhoid fever was early recognized in the tropics after its separation as a clinical entity by the workers in the Temperate Zone. Thus Scott and Milley, in 1830, showed that it existed in Tasmania; Levacher, in 1840, in St. Lucia; while it was recognized in 1841 on the Niger River, in West Africa, and in Martinique, and somewhat later in Sierra Leone and Gaboon. In 1842 an epidemic is mentioned as occurring in Rio di Janeiro in Brazil, and others in Tahiti in 1847, 1849, 1853-54, and also in Damascus in 1852, and in Cayenne in 1852-53. Other epidemics were recorded in Cuba in 1853-54, while in the latter year Scriven definitely proved its existence in India by demonstrating the typhoid ulcers found by post-mortem examination. In the same year Thomson described enteric fever in New Zealand, and Ripley about the same time in Fiji. In 1865 Massey recognized it in Newera Eliya, in Ceylon, while its occurrence in Trinidad and the Bermudas was known in 1866, and Davidson, in 1868, described it in Madagascar. In 1877 Defant said it was common in Senegambia.

Notwithstanding all this early work, the fact of its prevalence in the tropics was not generally recognized, the disease being concealed under the terms 'remittent fever' and 'malarial fever' with ulcers, which latter became the so-called 'typho-malarial fever,' which we now know to be a mixed infection -enteric fever complicated by malaria. The cause of this long delay in the general diagnosis appears to have been the slow recognition of the disease by the profession as a whole in England, which reflected itself upon India and the British Colonies; while the authority of Morehead, who in the first edition of his book, 'Researches on Disease in India,' stated that typhoid fever was unknown in that country, is also believed to have had a deterrent effect upon the diagnosis of enteric fever therein. He, however, soon doubted the correctness of his original statement, for in 1860 he writes that in 1856 he recognized the disease in Bombay, and he quotes a lecture given by Goodeve on seven cases of undoubted typhoid fever: still, he is of the opinion that typhoid fever will be found in extra-tropical India or in inter-tropical provinces in the near proximity of the tropics.

Another point which prevented the general recognition of enteric fever was the supposed antagonism of malaria to it, and the immunity of malarial districts from its attacks. These views were simply based upon the opinion that all remittent fevers were malarial, and that swelling and ulcerations of Peyer's patches could take place in these fevers: and the practitioner in the tropics was carefully warned that he was not justified in asserting the existence of typhoid fever from the mere character of the post-mortem appearances, and that the so-called 'typhoid symptoms' were not peculiar to one form of fever, but might occur in all.

Such teaching probably had a marked effect upon the diagnosis of enteric fever in the tropics until the recent establishment of bacteriological institutions, wherein a bacteriological diagnosis could be made.

Still more recent is the general recognition of the fact that the disease may be prevalent among the natives: in Ceylon, however, the fact that the malady is common among natives has been recognized for several years, and typhoid wards for natives have been established, as well as a special typhoid hospital.

It may now be said that it is well known that enteric fever is prevalent in many, if not most, tropical countries, and that it occurs, not merely in Europeans, but in natives also.

Ætiology.—Enteric fever is caused by the *B. typhosus* Eberth, *B. paratyphosus A* Schottmuller, *B. paratyphosus B* Schottmüller. The description of these germs may be found in any manual of bacteriology. It is probable that there are several varieties of each of these germs, and certain characters have been given in Chapter XXXVI., p. 934. Of the *B. typhosus*, for instance, two varieties can be easily differentiated—one rendering milk alkaline after an initial acidity; the other making milk *permanently acid*.

Of *B. paratyphosus B* several varieties have been described by Castellani, Alcock, and others. As regards the so-called *B. paratyphosus C*, this term, used by several observers, among whom recently Hirschfeld, covers different germs, one of which is serologically identical with *B. aertryke*.

With regard to the *B. typhosus* of Eberth, it is found in the intestine, not merely during the attack of fever, but during the incubation, and for a period extending perhaps as long as thirty years after an attack—that is to say, the bacillus has been grown from the fæces of a person thirty years after an attack of enteric fever; but whether it had existed in the bowels for the whole period is naturally not known, but it is possible. In other words, the bacillus can live in the bodies of people for years after an attack. These people are reservoirs or carriers of the bacillus, and may be called *intestinal carriers*. People who pass the bacilli in their fæces during the period of incubation are called *precocious intestinal carriers*; the patients passing the bacilli during the attack and convalescence are called *acute intestinal carriers*; while people who continue to pass the bacilli in their fæces for a year or less than a year after an attack of enteric fever are called *temporary or transitory intestinal carriers*; and those in whose fæces the bacilli are found after an interval of longer than a year are called *chronic intestinal carriers*.

In addition, there are carriers who are not known to have had an attack of typhoid; that is to say, there may be people in whom the *B. typhosus* Eberth may live for an unknown period without showing any pathological signs at any time. These are known as *paradoxical intestinal carriers*. This is possible, but it is also probable that some of the carriers in question may have been cases of ambulatory typhoid, and therefore really belonged to the class of *chronic intestinal carriers*. As to the habitat of the bacilli while in the carrier, it seems that the gall-bladder is of the greatest importance, while during the actual attack of fever the bacilli are to be found not merely in the intestinal contents, but also in the mesenteric glands, the spleen, and the circulating blood. Now, the proportion of female carriers to male carriers is as five is to one. This is a curious fact, and, moreover, the bacillus is often found in the gall-bladder. Now, the frequency of gall-stones in women as compared with men is as three is to one; further, it is a well-known fact that gall-stones are often discovered for the first time at an autopsy; in fact, it is believed that only 10 per cent. of the persons suffering from gall-stones show any sign of the disease during life, and it is a curious fact that the percentage of persons showing signs of gall-stones after an attack of enteric fever is 14 per cent.

All these factors considered together, along with the known fact that *B. typhosus* has been isolated on several occasions from the centre of gall-stones removed by surgical operations, tend to support the view that the gall-bladder is, at all events in some cases, the home of the *B. typhosus* in a chronic carrier. Fornet, in 1909, has, however, stated that he believes the bacilli found in the fæces of a carrier are not descended from those which caused the attack of fever, but are derived from a reinfection which does not produce any clinical symptoms, because the human host has attained a tolerance to the parasite, which therefore leads a saprophytic existence, presumably in the lumen of the intestines.

The discharge of bacilli by means of the fæces appears to be intermittent, and not continuous, which is a most important fact, as the duration of the possible intermission is not positively known, and therefore it is difficult to say definitely when the carrier is really clear of the parasite.

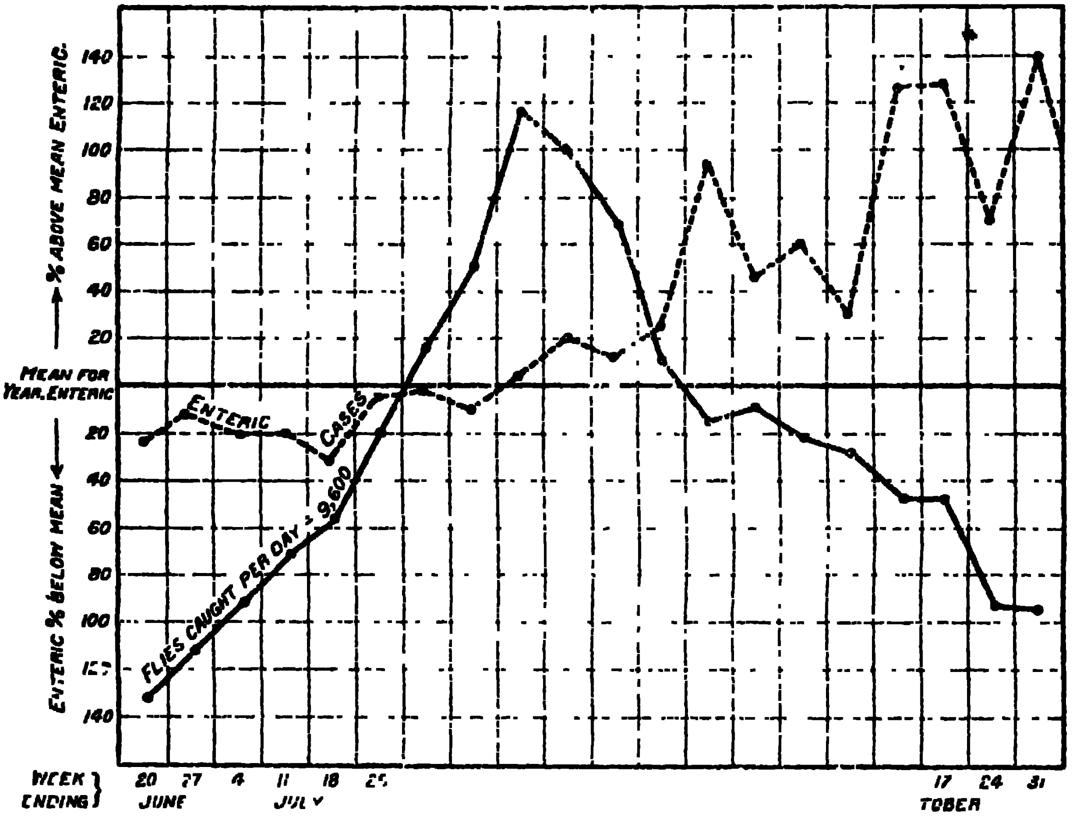

FIG. 658.—CURVES ILLUSTRATING NUMBER OF FLIES AND CASES OF ENTERIC FEVER. (After C. J. Martin.)

The reason why women are more commonly carriers than men is said to be due to the loss of resisting power brought about by the decrease in the alexins of the blood during the menstrual and puerperal periods, and this is supported by the fact that, while the incidence of enteric fever is greater in females from fifteen to twenty years of age, the possibility of becoming a chronic intestinal carrier increases steadily from the fifteenth to the forty-fifth year. A more probable reason seems to us to be that women are more liable than men to affections of the gall-bladder.

With regard to age, it appears that the transitory carriers are generally young—five to twenty years of age—while the chronic carriers are usually old—thirty to forty-five years of age.

The greatest infectivity of a carrier is during the incubation period, and the first weeks of the attack of fever; but chronic carriers are important in producing the endemicity of enteric fever in houses, groups of houses, and streets, as well as in institutions, etc.

As to the method of infection of the healthy by the carrier, evidence is being produced in favour of food contamination. So far, the evidence produced in favour of milk contamination by carriers is very strong, and it is quite possible that water, dust, fomites, etc., will all in course of time be shown to often obtain their infectivity from carriers.

The question of the infection of the house-fly (*Musca domestica*) by means of the bacilli in the fæces of carriers is most important, because the fly may take the bacilli into its crop or alimentary canal, where they not merely increase in amount, but also increase in virulence. Moreover, according to Nicoll's work, it is probable that larvæ may become infected, and thus infection pass to the adult insect. The mouth-part of the fly consists of a proboscis (*vide* Fig. 469) with oral lobes provided with tubules, so that solid particles and liquids pass up readily. It is a matter of everyday observation that the house-fly apparently tastes everything on which it settles that is to say, it extends its proboscis and presses on the substance on which it is standing by means of its oral lobes. When this proceeding is carefully examined, it is seen that the fly is regurgitating a little fluid from its crop via the pseudo-tracheæ of the oral lobes on to the solid substance, with the view of attempting to dissolve some of the solid substance so that it may be able to pass readily along the minute pseudo-tracheæ. This simple act is of the greatest importance pathologically, because the house-fly is an exceedingly foul feeder, and may absorb the liquid from the fæces of a case of enteric fever or from those of a carrier.

In this way the bacilli enter its crop, only to be extruded on to sugar, bread, milk, meat, the rim of a cup, etc., and in this way to gain entrance to the human victim. Naturally, the presence of carriers increases greatly the opportunity for the infection of flies. But it is not merely by the mouth that the fly can infect food materials and utensils, but also by means of its fæces; for the fly defæcates very frequently, and the typhoid bacilli can pass from its alimentary canal in an enhanced condition of virulence—according to some authors—on to food, drink, or utensils, and so reach the human host.

Intestinal carriers are not the sole carriers of the enteric germs, for, though more rarely, the bacilli can escape in the urine of people who have recovered from enteric: these people are called ***urinary carriers***. It is not uncommon to find bacilli in both the fæces and the urine in the case of transitory carriers, but it is much more uncommon to find them in the fæces and the urine in the case of chronic carriers if precautions are taken to prevent the contamination of the urine during or after micturition.

In urinary carriers the *B. typhosus* has its habitat generally in the renal pelvis, which is usually chronically inflamed or cystic, and it has also a secondary habitat in the chronically inflamed bladder; but it appears possible that it may also live in recesses in the pelvis of the kidney, the bladder, the urethra, the prostate, and the vesiculæ seminales, from which bacilli pass into the urine. The methods of urine infectivity are the same as fæcal infectivity.

To summarize, the reservoir or carrier of the *B. typhosus* Eberth is a human host who has suffered from enteric fever, and who affords food and protection for the bacilli in the gall-bladder in the case of intestinal carriers, or in some recess or recesses in the urinary tract from the pelvis of the kidney downwards, and in the male in the prostate and vesiculæ seminales in the case of urinary carriers. This carrier passes the bacilli into the exterior in the fæces and urine, and these may, in cases of defective hygienic surroundings, directly infect air, food, or drinking-water, or may be conveyed by fomites or by flies to the victim's hands, or food, or food utensils.

The problem of the carriers of the paratyphoid bacilli is a similar one. *B. paratyphosus B* is commonly met with in Europe, where it is disseminated by means of intestinal carriers when it lives in the gall-bladder; but its urinary carriers have so far not been recognized. It has, however, been found in the common house-fly in 1911 by Nicoll. Its infectivity and its auto-infectivity are well known. *B. paratyphosus A* is prevalent in India and Ceylon, where precocious and acute carriers are frequently met with. The germ, however, during the war has now become common also in Europe. It is known that it can live in the gall-bladder for a considerable time and pass out in the fæces, and several outbreaks of enteric fever have been traced to this source.

With regard to the general question of carriers, the persons most liable to be carriers are first of all those who have had attacks of enteric fever, and, secondly, nurses and other attendants upon these patients; while the carrier who is likely to prove most dangerous in spreading the infection is a person who is in any way engaged in the preparation or the handling of food intended for other people to consume, because the infection of the hands is a prolific source of infection for healthy people.

So far we have merely referred to *Musca domestica* Linnæus as an important intermediary host for these bacilli, but the fruit-fly, *Drosophila ampelophila* Loew, has been definitely implicated by Dutton in 1909. With regard to the accusations against the bug, *Clinocoris lectularius* Linnæus, and the flea, it can only be said that there is as yet no definite proof that they play an active part in the spread of enteric fever.

To summarize, it may be stated that *B. typhosus*, *B. paratyphosus A*, and *B. paratyphosus B* can escape from the bodies of precocious, acute, temporary, chronic, or paradoxical carriers by means of the fæces or the urine, and can infect food and drink directly or indirectly through the agency of flies, and by means of this infected food or infected hands the bacilli can gain entrance into another human host, and set up the infection anew. Of the foods and drinks which are of importance, the first and most important is milk, while water, shellfish, fish, and dried fish, may also be mentioned as of great importance. Attacks have also been traced to ice, and, indeed, no food or cooking utensil can be considered free from possible infection. Of great importance in the tropics are uncooked green vegetables, which are grown in gardens often manured by means of human excrement. Fæcally polluted dust and fæcally polluted clothes must also be assigned a prominent place in connection with the spread of the disease.

With regard to the *epidemicity* of enteric fever, it will be clearly understood that the basis of the epidemic as the basis of the endemic is the carrier, but the characters of the epidemic will largely depend upon the means by which the bacilli are introduced into the new non-immune hosts. Often this is by flies; hence the name 'autumnal fever' sometimes applied to the disease, because the local epidemic takes place after the time of their greatest prevalence. Epidemics due to milk will be found to agree with the distribution of this food by, generally, one dairy. The present writers once, during an outbreak of enteric fever and dysentery in a tropical town, bought by chance a sample of milk which, on investigation, was found to contain the *B. coli*—a sure proof of human fæcal contamination, which might have arisen from watering the milk, because water is often added by the seller to the milk of *Bos indicus*, and this escapes the notice of the buyer, because the milk is much richer than that of *Bos taurus*, and therefore does not appear to be diluted. As the water may have come from some polluted source—*e.g.*, a well or a roadside drain—this is very dangerous. Epidemics due to oysters and other shellfish will agree with the seasonal use of these shellfish, and may even be traced to certain breeding-grounds which may be situate near the mouth of a sewer, or in which the oyster-bed itself has become infected with bacilli. Another good instance of the cause of small epidemics is the tracing of the infection by Hamer to the fried-fish shops so common in London. But the infection of food materials will not give rise to the sudden widespread epidemic which will arise if the water-supply is contaminated. Maidstone, in 1896, had 35,000 inhabitants, of whom 1,900 persons suffered from enteric fever during the months of September, October, and November, due to contamination of the town's water-supply. In the tropics polluted wells are a prevalent cause of endemic and epidemic enteric fever. The present writers were acquainted with a town in which so-called 'remittent,' really typhoid, fever was very prevalent, and where in a certain area the wells and the cesspits, which always contained water, were only separated by a wall one brick thick.

The bacilli do not live when dried; still, it is probable that they can live, attached to particles of dust, long enough to contaminate food, which in certain tropical regions may become covered with dust.

Predisposing Causes.—With regard to predisposing causes, it was long considered that the native of the tropics enjoyed a partial or, as some said, an absolute immunity against enteric fever. This cannot be maintained, as we know definitely that enteric fever is quite common in all races. The position at the present time is that, while certain authorities consider that a considerable number of cases of enteric fever still lie hidden under the terms 'remittent fever' and 'simple continued fever,' and perhaps 'febricula,' as applied to natives, and especially to native children, who are not often treated by physicians trained in modern methods, still, there are others who maintain that there is a partial immunity in some races—*e.g.*, such an immunity is said to exist among the native Egyptians, Sudanese, and Japanese, which is believed to be due to racial inheritance. This question has been investigated by the Board for the Study of Tropical Diseases in the Philippine Islands, and ably reported by Chamberlain, who finds that epidemics of great severity among Filippinos are rare or unnoticed; that Widal reactions performed on the blood of 591 healthy Filippinos suggest a comparatively recent attack of enteric fever in about 6 per cent. of adults, but do not indicate that the disease is prevalent in childhood; that the native Filippino scouts show a lower typhoid rate than the white troops, possibly due to failure to diagnose the atypical cases; that more than one-third of the cases of enteric fever, whether among Americans or Filippinos, are entirely atypical, and cannot be diagnosed without laboratory methods. One-half of the total number of cases can, however, be diagnosed clinically, and do not differ from enteric fever as seen in the Temperate Zone. He concludes that much work still needs to be done among the natives to estimate the actual amount of mild and atypical enteric fever which is occurring, and to determine why extensive and destructive epidemics are not more often seen.

Our own experience in Ceylon causes us to believe that the disease is very prevalent among the natives of that island, and as dangerous among them as in Europeans. When the causes of death in the races of Ceylon were considered by us some years ago, it was noted that the total deaths contained the following percentages:

Race.	*Enteric Fever.*	*Simple Fever.*	*Remittent Fever.*
	Per Cent.	Per Cent.	Per Cent.
European	10·1	1·7	1·5
Sinhalese	7·6	12·0	0·3
Tamils	0·7	17·3	3·8

Added together, these give—Europeans, 13·3 per cent.; Sinhalese, 19·9 per cent.; Tamils, 21·8 per cent. The incidence of enteric fever among these peoples is probably more nearly approximating the conjoint figures than those given solely under Enteric Fever. Tamils are labourers on estates, and cases of fever among them are generally lumped together under the heading of Malaria.

Age is another predisposing cause, for there appears to be a general consensus of opinion that twenty to twenty-five years of age is a period more susceptible to the disease than the other periods of life, but no age period is free from attacks.

During the first journey from the Temperate Zone to the tropics the metabolism of the young resident in the Temperate Zone is possibly somewhat disturbed, leading to a weakening in the antibacterial and phagocytic reactions, as some authorities maintain; and hence, perhaps, his great liability to attacks of enteric fever and other complaints. It must not be forgotten that the young new arrival is apt to eat too much, to drink too much, and, being stimulated by the heat—the bad effects of which at first he does not notice—is apt to work too hard and play too hard, or, in other words, to attempt to exhaust his system in every possible way, and to thoroughly disregard the evil effects of the sun; and we consider these indiscretions play a certain rôle in the relative frequency with which these young new arrivals become infected.

Young people often live together in what are called '*chummeries*' —*i.e.*, several of them live together in a house, while one of them runs the messing. These houses, having no proper supervision, are allowed to become most insanitary, especially with regard to the servants' quarters, which are naturally the nearest to the kitchen and the places in which food is stored. The pollution of food in these places is often self-evident to the naked eye, while the whole place teems with flies. Moreover, the weakening of the system by venereal disease may play a part in producing the heavy incidence of enteric fever in new arrivals. In Bengal 50 per cent. of the cases in Europeans occurred within one year of arrival from Europe.

In India the disease is believed to be common among native children and among Europeans born in India; thus it was noticed by Rogers that 41·67 per cent. of the cases were under fifteen years of age, whereas in Europe and America only 9·45 of cases are under fifteen years of age.

As regards sex, we have already drawn attention to the apparently special incidence upon women between fifteen to forty-five years of age.

With regard to the conditions of life, the poor whites living in insanitary conditions are very liable to be attacked, and this may account for the prevalence of the disease among Europeans born and living in India, as may the natural habits of children playing among earth and rubbish, which are often more or less fæcally polluted. But of all predisposing causes, that of bad sanitation stands out pre-eminently first; thus Europeans are apt to get the disease most commonly in the dry season, when it is spread by dust and flies, and the natives in the wet season, when it may be due to water contamination.

With regard to meteorological conditions, we have observed that anything which prevents the heavy rainfall at the proper season tends to an increase in the enteric, dysentery, etc., rates; and, absurd though it may read, certain observations which we made some years ago led us to believe that the eruption of Mount Pelée may have had a disturbing effect upon the meteorological conditions, producing less rainfall, and preventing the filthy drains and other places being properly flushed, and thus indirectly causing an increased incidence of epidemic intestinal diseases.

Pathology.—Enteric fever is a septicæmia which is produced by the bacilli already mentioned entering the body by the mouth, and passing into the small intestine and colon, the lymphoid tissue of which they invade. In this tissue they increase in number, and pass via the lymphatics to the abdominal lymphatic glands and spleen, in all of which they multiply. No doubt they very soon reach the blood, but are probably quickly destroyed and their toxins neutralized, and so long as this continues the patient is without definite signs of the disease. This constitutes 'the period of incubation' or latency, and may possibly be the explanation of those persons who, though chronic carriers of virulent typhoidal germs, maintain that they themselves have never had any illness.

If the quantity of antitoxin substances produced are only sufficient barely to neutralize the toxins, then an ambulatory or an abortive attack may ensue.

When, however, the bacilli multiply in such numbers that, though still largely destroyed by the bacteriolysins of the blood, there is insufficient antitoxin to neutralize their liberated toxins, then the fever begins. The possible explanation of the intermittent type of the fastigium of the tropics is that the supply of antitoxic substances in the blood waxes and wanes. The evidence in favour of the above theory is the presence of the bacilli in the fæces in the incubation period, the presence of enlarged Peyer's patches, mesenteric glands and spleen found accidentally in post-mortem examinations of people who have died from other causes, and in whom enteric fever was not suspected: the possibility of cultivating the bacilli from specimens of the circulating blood obtained during the first week of the fever; and the constant necessity for immediate dilution of this blood if a successful culture is to be obtained.

Relapses can be explained as being due to any cause which so disturbs the metabolism of the body that the antitoxin production decreases, and the germs again gain entrance to the blood in such quantity as to produce fever.

The endotoxin contained in the bacilli has a markedly stimulant effect upon endothelial cells, causing them to swell and to block small lymph capillaries, thus causing patches of focal necrosis in the liver.

The bacilli can occur in any part of the body, but they have a predilection for the lymphatic system. When arrested in the lymphatics of the skin, they give rise to the rose-coloured maculo-papules so characteristic of the disease. The appearance and distribution of these red maculo-papules in the skin of the anterior abdominal wall, chest, and back is believed by Greenhalgh to agree with the cutaneous distribution of the nerves which supply the small intestine, the mesenteric lymph nodules, and the spleen. But this seems hardly possible, as papules can appear on the arms, legs, and other regions. It would appear as though local heat was a more important factor in their production than nerve-supply. The bacilli may attack the respiratory system, giving rise to bronchitis, pneumonia, etc., and they are commonly found in the gall-bladder, in which they cause cholecystitis, and may give rise to gall-stones. They also pass through the kidney into the urinary passages, and at times appear in large quantities in the urine (bacilluria).

They are also capable of living locally in the tissues, giving rise to inflammation, abscess formation, and local death of the tissue.

It has already been noted that they can live for years in the gall-bladder and the pelvis of the kidney, producing the chronic intestinal and urinary carriers, who are liable to infect, not merely themselves, but others also.

Auto-infection may possibly be the explanation of such cases as have second or even third attacks, within a short period after the first attack.

The typical gradual onset of the disease may be explained by the struggle between the antitoxins of the body and the bacterial toxins.

The occasional sudden onset seen especially in the tropics may be due to lowered resistance, owing to many causes—*e.g.*, climatic influences, other infections, etc.

Immunity is generally acquired after an attack, but second attacks are by no means rare; moreover, the immunity is homologous—viz., an attack of typhoid fever will protect against *B. typhosus*, but not against the paratyphoid bacilli.

The fever is due to a lessened loss of heat rather than to an increased production of heat, and this is the reason why, in ordinary cases, there may not be marked emaciation.

Morbid Anatomy.—On opening the abdomen in a typical post-mortem, the bowels will usually be seen to be distended with gas, and the small intestine will be noticed to present marked areas of congestion, especially near the ileo-cæcal junction.

The mesenteric glands will be observed to be enlarged and congested, as will the spleen and at times the liver. If there has been a perforation, a fæcal odour will be perceived on opening the abdomen, and there may be gas, fæcal matter, round worms, or pus in the peritoneal cavity, while careful search will reveal the perforation; but care must be taken not to artificially perforate the gangrenous, or almost gangrenous, intestinal wall by manipulation.

On opening the intestines, it will be noted that the most important site of disease is, as already stated, in the ileum near the ileo-cæcal valve; while the contents of the bowel will be noted to be of a yellowish colour, unless there has been a hæmorrhage, when blood will be seen, or unless medicines have been administered which alter the colour of the motions. The Peyer's patches in the lower few feet of the ileum will be enlarged, prominent, and whitish in colour, and covered, perhaps, with yellowish sloughs, or perhaps containing ulcers, which may be in the form of one large central or several small ulcers.

On inspection, a typical ulcer will be noted to have its long axis in the same direction as the long axis of the bowel, to be of oval form, with thin and undermined edges, and a base formed from the muscularis mucosæ, the infiltrated submucosa, or from the muscular or even the peritoneal coats of the bowel; while in cases of perforation a rent may be noticed through this last coat, permitting communication between the lumen of the bowel and the cavity of the peritoneum. In cases of extensive hæmorrhage injection of water into the carefully dissected out mesenteric artery may demonstrate more or less correctly the source of the bleeding. The solitary glands will also be seen to be enlarged and congested with sloughs or roundish ulcers, while the mucosa around these and the Peyer's patches will be seen to be intensely congested and red in colour. This congestion may be traced for a considerable distance along the ileum and into the jejunum, but it is rare to find the duodenum or the gastric mucosa in a state of acute congestion.

Tracing the bowel downwards into the ascending colon, it will be noticed that the mucosa of the cæcum and ascending colon is often congested, and at times the solitary glands will be seen to be swollen; but as a rule they are not ulcerated.

These typical appearances may be varied by finding only one or two Peyer's patches enlarged, and perhaps only one or two small ulcers, and very rarely there may be no signs beyond a catarrhal inflammation of the mucosa of the bowel. On the other hand, the ulceration in the region of the ileo-cæcal junction may be so extensive that there are only ridges and islands of intensely congested mucosa left, while at other times pieces of the bowel may be black and almost or quite gangrenous.

The mesenteric glands will be seen to be swollen and congested, and on section they will show marked congestion and perhaps pus.

The spleen is enlarged and swollen, dark red in colour, friable, with a tense capsule, while the liver may also be enlarged and congested, and may even on rare occasions show multiple abscesses brought about by a septic pylephlebitis. The gall-bladder and bile-ducts may be congested, or more rarely may contain pus, while the bile is usually light-coloured and watery, but may be inspissated. The pancreas is usually normal, but we have seen it congested and even hæmorrhagic. The suprarenal capsules are generally normal in uncomplicated cases. The kidneys are usually enlarged and congested, with a capsule which strips off readily. On section, both cortex and medulla are seen to be congested, with often fatty degeneration, and more rarely small abscesses or infarcts. The pelvis is congested, but the ureter and bladder are usually normal, though signs of cystitis may be found at times.

With regard to the thorax, if there is much meteorism, the diaphragm may be noted to be pushed up considerably higher than usual. The trachea and bronchi may show signs of inflammation, and in the lung pneumonia, hæmorrhagic infarcts, pyæmic abscesses, and purulent infarcts may be seen. The heart is usually flabby and without any sign of rigor mortis, and is often pale, soft, and friable, from fatty degeneration. Rarely will vegetative or ulcerative endocarditis or aortitis be found.

In the neck the thyroid gland may in cases of great rarity be seen to be enlarged, and even to have abscesses. There may be congestion and ulceration of the larynx and tonsils, but they are not common in our experience. The tongue will be seen to be covered with sordes, and may, perhaps, show fissures.

The brain is often congested, as are the meninges, but meningitis and other naked-eye signs are rarely met with. Venous and, much more rarely, arterial thrombosis may be seen, while Zenker's vitreous degeneration may be found, especially in the adductors of the thigh, the rectus muscles of the abdomen, the pectoralis, and the diaphragm, and very rarely one of these degenerated muscles may be found ruptured and surrounded by hæmorrhages. The bone-marrow may also be congested and show signs of focal necrosis.

Finally, there may be the signs of the complications or sequelæ—as, for example, the arthritis of the joints, the abscesses in various parts of the body, etc.

The pathological history of these post-mortem appearances may now be briefly related, beginning with the history of the lesions of the Peyer's patches.

At first a Peyer's patch or lymphoid follicle is hyperæmic, but this is followed by a proliferation of the lymphoid and epithelioid cells of the follicles, together with a swelling of the endothelial cells of the capillary vessels, and these together produce a more or less definite blocking of the capillary vessels, which causes an anæmia, and produces the whitish colour of the hyperplastic Peyer's patches, to which attention has already been drawn. The typical bacilli can be found lying in the centre of the follicle, and also in the lymphatic vessels, not merely of the follicle, but also of the submucosa. Such is the condition of the follicle about the eighth to the tenth day, and now one of two things may happen: either the excess of lymphoid cells undergo fatty degeneration and absorption, with the result that the blood-flow returns, and the follicle becomes normal; or the blockage of the bloodvessels is increased by fibrinous thrombosis, with the result that the superficial portion of the swollen follicle dies and forms a slough, which, separating from the edges towards the centre, becomes an ulcer some time during the second week. These ulcers may increase in depth by an extension of the necrosis, and may lead to perforation; on the other hand, there may be a formation of granulation tissue over the base, which subsequently leads to fibrous tissue formation, and thus eventually to the healing of the ulcer, which process is completed by the growth of the mucosa over the young fibrous tissue. The site of a previous typhoid ulcer is often clearly visible as a depressed pigmented area, which, on microscopical examination, is seen to consist of atrophic mucosa covering a fibrous submucosa, which is also often atrophic.

The mesenteric glands show at first hyperæmia and cell proliferation, among which the typical bacilli can be found. Pus formation may also be found at times.

The spleen early becomes hyperæmic, and swells considerably, remaining enlarged until the third or fourth week. The capsule becomes tense, and the pulp assumes a dark red colour. The swelling is due to the hyperæmia and cellular infiltration with leucocytes, endothelial cells, and macrophages, among which the typhoid bacilli may be found. During the third week the pulp becomes softer, and the Malpighian bodies become prominent, and absorption begins to take place, which produces a paler colour in the pulp, and eventually leads to an increase in the amount of fibrous tissue.

The liver shows cloudy swelling and fatty degeneration of the cells and spots of focal necrosis, which may be produced by accumulations of epithelioid cells in the lymphatic spaces of the portal system, or to small areas of necrosis of liver cells owing to occlusion of adjacent capillaries. These foci are associated with clumps of the specific bacilli.

The kidneys show cloudy swelling of the cells of the convoluted tubules, but in the cases when the kidney is specially involved there may be considerable hyperæmia, together with perivascular cellular exudation and granular degeneration of the cells of the convoluted tubules.

The heart muscle may show fatty or, rarely, waxy degeneration, while endarteritis obliterans in the small arteries is said to be seen in cases of sudden death without obvious cause.

In the nervous system there are no very marked changes, but pigmentation of the ganglion cells and leucocytic infiltration of the perivascular spaces may be seen, as well as fatty degeneration of the nerve fibres.

The bone-marrow is generally congested, and may show signs of focal necrosis, with hyperplasia of lymphoid cells and clumps of typhoid bacilli.

Symptomatology.—Enteric fever is a very protean disease, the description of which is usually divided into incubation period, onset, course, subdivided into weeks, relapses, and terminations in death or convalescence. In general terms, it may be stated that the fever presents physical signs and symptoms not unlike those seen in the Temperate Zone, but a number of cases are atypical.

These atypical cases may have a slight and short attack of fever presenting but few symptoms, and very liable to be overlooked, or the attack may be ushered in by some other fever—as, for example, malaria or dengue. We will first describe a typical attack with mild or severe symptoms.

Incubation.—The incubation period of enteric fever ranges in its known extremes from three days to twenty-three days, or much longer. The shortest known period—that is to say, the one with three days' incubation—was exceptional, the infection being due to swallowing a culture of virulent bacilli, and therefore it may be excluded for ordinary purposes. It is by no means easy as a rule to define the incubation period, and it is usual to agree with Murchison, and to state that it is most commonly about two weeks (ten to fourteen days), but that it is often less than this, and may possibly be as short as four or five days; while, on the other hand, it is often longer, and no definite maximal limit can be mentioned, because the study of typhoid carriers has demonstrated that persons, apparently in good health, may be infected with the bacillus, and it has further been shown that these people may suffer from auto-infection, all of which naturally complicate the question of the duration of the period of incubation.

We therefore conclude that the usual incubation period for enteric fever is about two weeks.

During this period the patient may apparently show no signs or symptoms of the disease, though at times headache and general malaise may be felt.

Onset.—Typically the onset is gradual, the patient attending to his ordinary duties, though suffering more markedly from the feeling of malaise and lassitude and from headache than during the period of incubation, and associated with these symptoms there may be constipation, or there may be diarrhœa with pains in various parts of the body, but especially in the back, the iliac regions, or the legs. At times there is a troublesome cough. The disinclination for exertion, mental or bodily, increases, as does the headache and the pains, until the patient feels so ill that he consults his medical attendant, when it is found that the temperature is raised above normal (100° to 101° F. in the morning); that it is higher in the evening (103° to 104° F.) than in the morning; that the pulse, though accelerated (80 to 90 per minute), is relatively slow as compared with the temperature, and may be dicrotic; while the tongue is coated on the dorsum, though red at the tip and along the margins; the headache is generally frontal, and there may be thirst, vomiting, or epistaxis, as well as abdominal tenderness and slight distension, especially in the right iliac region. If the case is observed early, a step-like rise of the temperature may be noted—that is to say, the evening temperature is always slightly higher than that of the preceding evening—while the morning remission is less, until about the third or fourth day, when the temperature reaches 103° to 105° F. at night.

The onset, however, is often atypical in the tropics, the symptoms being but little marked, and the patient, though feeling wretched and ill, perseveres with his work, and may never consult a doctor until well into the second week of the fever, and in some cases may even advance farther in the illness than this before the complaint is diagnosed.

With regard to the other atypical onsets, it is well to remember that the disease is a septicæmia, and that, following the account of the pathology given above, any organ or system of the body may be specially attacked. Thus, for example, the nervous system may be specially attacked, with the result that the most urgent symptom is a neuralgia, an earache, a backache, or pains resembling those of pleurisy; or, again, there may be signs as though cerebro-spinal meningitis were coming on, or there may be early delirium. If the respiratory system is specially attacked, the signs will be those of bronchitis, pneumonia, or suggestive of acute tuberculosis. If the alimentary canal is selected, there will be symptoms indicating irritant poisoning or appendicitis; if the renal system is marked out for attack, they will resemble the signs of acute nephritis. The above remarks do not by any means cover all the possibilities of the onset, but enough has been said to indicate the remarkably protean nature of the signs and symptoms of enteric fever, and of the way in which it imitates other diseases.

The First Week.—The early days of this week are as a rule occupied by the onset of the fever, as described above, and often the medical attendant does not see the patient until about the end of the third or fourth day of the illness. In the tropics, however, the attack is at times ushered in by some other fever—as, for example, malaria, by which its symptoms are more or less masked. It is, however, possible, even at this early stage, to observe, associated with the symptoms of the predominant disease, signs and symptoms which arouse suspicion of enteric fever. This suspicion is presently converted into certainty as these signs increase in evidence, while the symptoms of the original ailment decrease and finally disappear. The signs and symptoms to which we specially refer are the alteration of the temperature chart from one of remittent or intermittent fever in malaria to one of more continued fever, with more marked headache, slowing the pulse, the appearance of dicrotism, the signs of abdominal distension, the local pains, the tenderness, and perhaps the gurgling in the right iliac region, and the altered condition of the tongue.

During this first week the facies of the patient becomes at times typical—*i.e.*, the cheeks are flushed and the eyes bright, and there may be some photophobia. The decubitus is almost always dorsal. As the week proceeds, the patient becomes more or less apathetic, listless, and drowsy. Headache, noises in the ears, and pains in various parts of the body are the marked symptoms of this week, while sleeplessness is often another marked symptom. Delirium is, however, rare. The temperature continues high, being usually from 103° to 104° F. in the evening, with a remission of a degree or so in the morning; but in our experience a much greater remission than a degree or so is by no means unusual, and the temperature, as already mentioned, may assume an intermittent character. The pulse is about 80 to 100 beats per minute, often with more or less dicrotism, while the blood-pressure varies, the systolic being about 120 millimetres, and the diastolic about 90 millimetres of mercury. At this stage of the disease there is usually little or no change in the blood, though slight leucopenia may be present. The specific agglutinin reaction is not available, but the bacilli can be cultivated from the blood. In uncomplicated cases the spleen is more or less normal at the commencement, but enlarges distinctly towards the end of the week. The respiratory symptoms may cause the patient much annoyance, especially the dry, hacking cough, and there may be signs of mild tonsillitis, pharyngitis, laryngitis, or bronchitis. Pneumonia must be looked upon rather as a complication than as a symptom of the disease. The gastro-intestinal symptoms present much variability. The mouth is often dry, and the patient may be worried by thirst. The lips and teeth are normal, but the tongue, which is moist, is generally coated by a white fur on the dorsum, while the tip and edges are red. There is little or no desire for food; the stomach is irritable, and vomiting may occur, especially if indiscretions in feeding are allowed. The abdomen is more or less distended, especially in the region of the right iliac fossa, where it is often painful and tender, as, indeed, it may be in other places. There may be constipation or there may be diarrhœa; the motions may be of an ordinary colour, but more typically they are ochre-yellow. It is not often that hæmorrhage is seen during this week, and is then generally small in amount: but its presence is, in our opinion, a relatively serious symptom. The urine is generally diminished in quantity, high in specific gravity, dark in colour, with a markedly acid reaction, but there is usually no albumen, no casts, and the diazo-reaction cannot be obtained.

The skin is hot and dry, with, however, paroxysms of greater or lesser amount of perspiration, followed by the presence of more or less sudamina. The typical rose spots do not as a rule appear before the seventh day, and therefore will not be described under this week. At times a bluish subcuticular mottling is to be observed, especially on the abdominal wall, towards the end of this week of quite a different nature to the bluish spots (*taches bleuâtres*), which are generally assigned to the action of lice. There is often a yellowish coloration of the palms of the hands, the lateral aspects of the fingers, and the soles of the feet, sometimes called 'Philipowicz's sign,' which, however, is by no means characteristic of enteric fever.

The most marked feature of the week is the gradual increase in severity of the disease as marked by the growing apathy and dulness of the patient; the aggravation of the symptoms, with the exception of the pains, which tend rather to abate towards the end of the week; the enlargement of the spleen; the possible occurrence of the typical spots; and the continued fever.

The Second Week.—The signs and symptoms described in the first week continue to increase, with the exception of the headache and local pains, which usually diminish and disappear by about the middle of the week. The tendency to hæmorrhage is, however, more marked, and the danger of perforation of the bowels has now to be considered, while the typical rose-coloured rash should appear to a greater or lesser extent; the specific agglutinin reaction should be obtainable, as well as the diazo-reaction in the urine, while the specific bacilli are much more difficult to obtain from the circulating blood, but can still be recovered from the spleen, the fæces, the rose spots, and often from the urine. Liver or gall-bladder symptoms and other complications may appear. With this introduction the signs and symptoms of the second week may be considered in slightly more detail.

During this week the patient, who may have been up and about, is generally confined to bed, and may be seen for the first time by the physician. The facies is dull, apathetic, and listless; the reaction time is prolonged for answering questions; the hearing may be diminished; and the patient is drowsy. At night there may be sleeplessness and mild delirium. There may be slight subsultus tendinum. The decubitus is dorsal. The temperature continues high, varying from about 102° to 105° F., while the pulse is generally relatively slow (90 to 100 beats per minute), although it may reach to 120. The dicrotism may have disappeared, but the blood-pressure has generally diminished somewhat, and the first sound of the heart is not as appreciable as normal. The circulation is as a rule not good; the extremities are apt to be cool, or even cold; and the hands and feet, or more usually the tips of the fingers and toes, may be of a bluish colour. The nails often show signs of lack of vitality, and transverse ridges may be observed. Philipowicz's sign may disappear, or may persist through the week, and even later. The typical rose-red or pink maculo-papules appear in successive crops on the front of the abdomen or chest, beginning about the seventh to twelfth days, though in exceptional cases they may occur as early as the fifth day, or they may be delayed as late as the twentieth day, while they may be entirely absent. Their number and presence depends upon some unknown secondary cause and not upon the severity of the attack, to which they bear no reference. They are pinkish or rose-red, circular, slightly elevated, isolated maculo-papules about 4 millimetres in diameter, usually few in number, which disappear temporarily on pressure, but reappear as soon as the pressure is removed. They usually last three to five days, more rarely as long as ten days, and as a rule undergo no change until they fade and disappear, leaving occasionally a brownish stain. They are not associated with any subcuticular mottling, and are but rarely met with on the face, though they may at times be found on the arms and legs. They continue to appear until the end

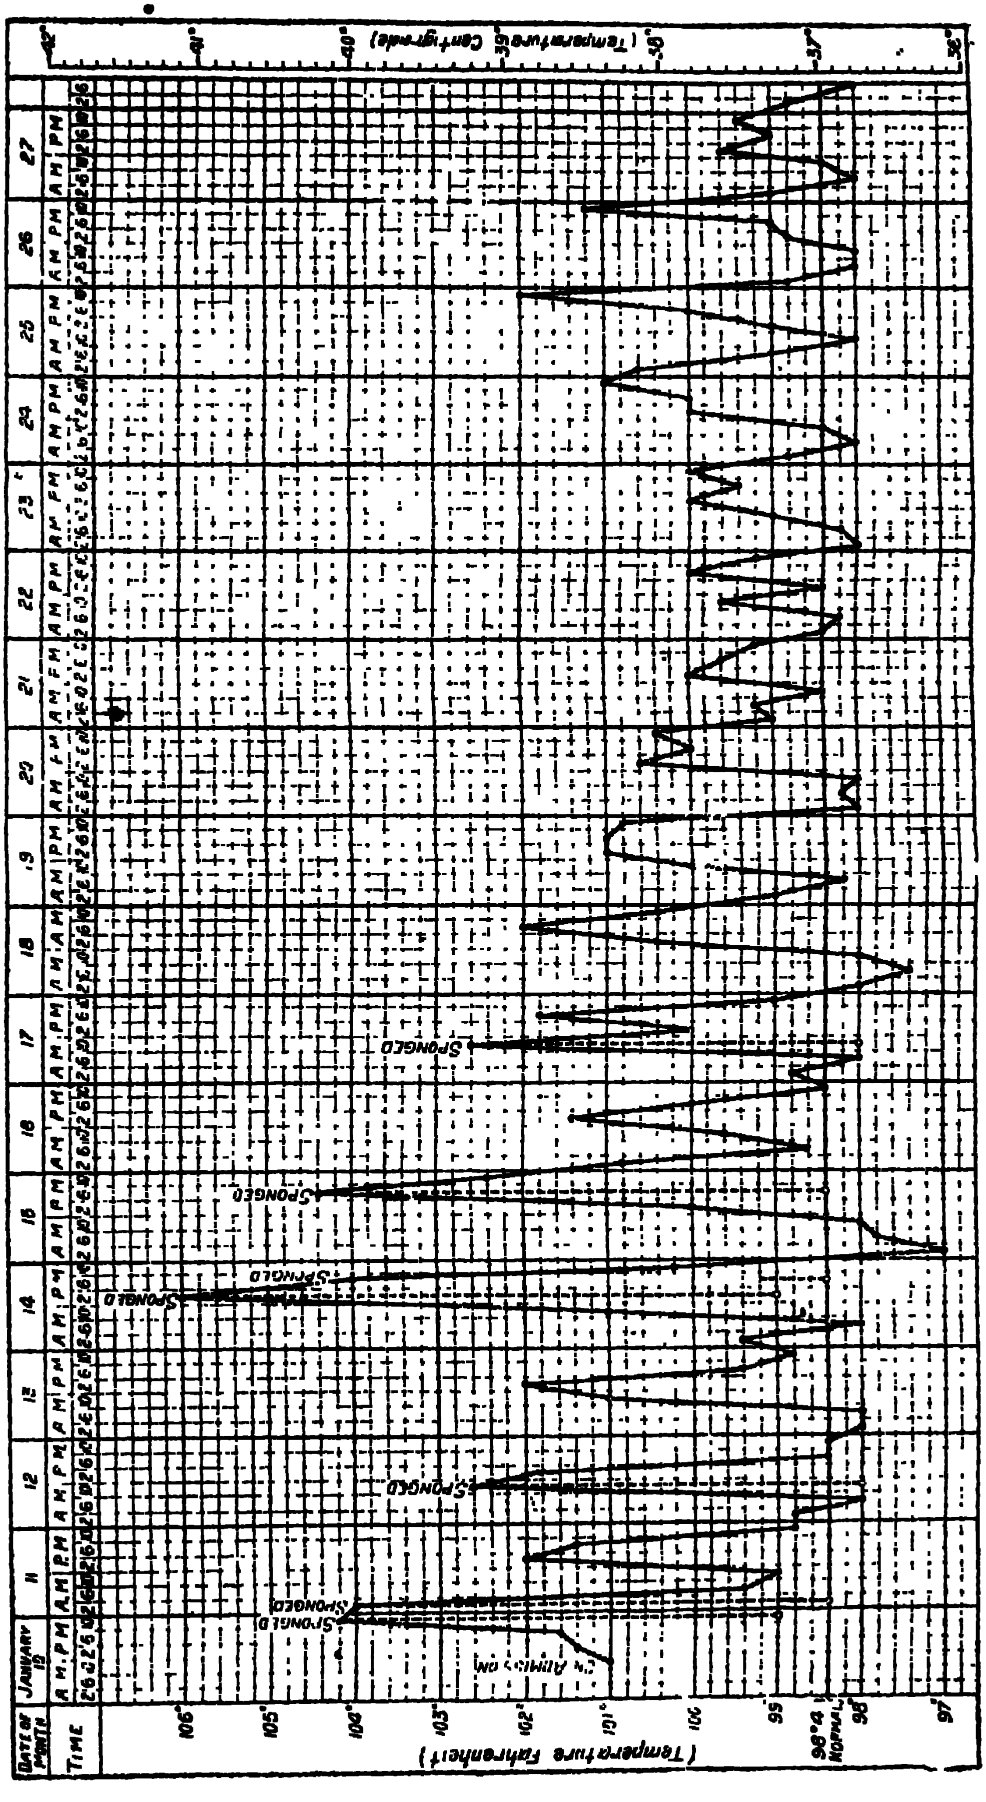

Fig. 659a.—Temperature Chart of the Intermittent Type of Enteric Fever.

of the second week, during the third week, or even during convalescence.

The lips and tongue at the commencement of the second week are in much the same condition as at the end of the first week, and if the attack is of mild or medium virulence, they may remain in this condition during the whole week: but if the attack is severe, and if the patient passes into the typhoid state, they alter in appearance; for in this condition the patient lies on his back, breathing through the partially open mouth, with the lips and teeth covered with the dark brown scabs, formed from epithelial débris, micro-organisms, and food, which are called 'sordes.' The tongue becomes dry, and is covered with a brown or brownish-black fur or crust, and may have painful cracks: but this condition is largely due to oral sepsis, and is not part of the disease, and may be more or less avoided by careful nursing and oral antisepsis. The pharynx is generally more or less inflamed, and may be ulcerated, as may the tonsils. Gastric disturbance, if present in the first week, is not continued into the second week as a rule, and it is rare to observe vomiting in this week unless there is some complication. There may be constipation or there may be diarrhœa, and the motions are often of a yellowish colour, with alkaline reaction and somewhat offensive odour, and may contain sloughs, which will be recognized as greyish-yellow fragments of tissue about an inch in length.

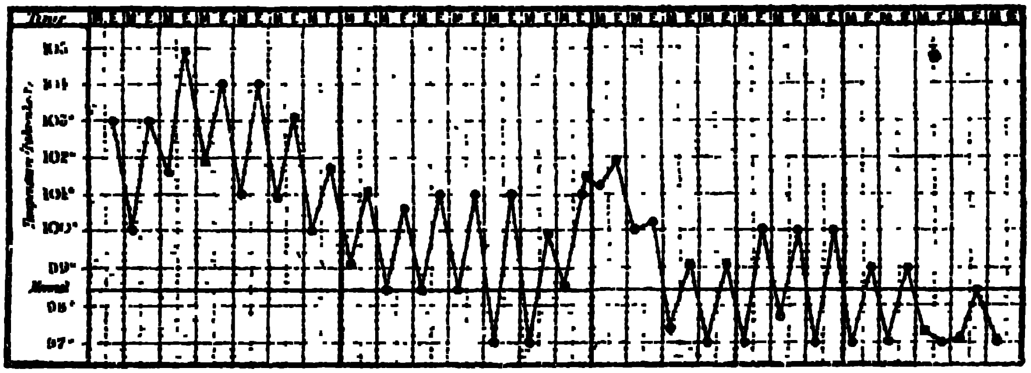

FIG. 659B.—TEMPERATURE CHART OF A CASE OF PARATYPHOID A FEVER.
(Chart made by Major Archibald.)

Hæmorrhage is said to occur in about 10 per cent. of cases, but our experience would indicate that it is more frequent than this. It varies from a mere trace to a serious haemorrhage, and most usually occurs from the end of the second to the end of the third week—that is to say, during the period of separation of the sloughs.

Often there are little or no signs or symptoms to mark a slight hæmorrhage, but a profuse hæmorrhage produces serious symptoms. Often a hæmorrhage takes place without warning, but as it is known to be possible, the attendants will be on the outlook for signs; and our experience is that there often is warning given by the presence of a trace of blood in the motions, by the slight increase of the pulse-rate, or by a slight drop in the temperature. In sudden severe cases of hæmorrhage the facies alters, becoming pinched and pallid; the pulse increases in frequency, and the temperature drops perhaps quite suddenly. In very severe cases a sudden fatal collapse may take place before any sign of blood has been visible in the motions.

More or less meteorism is always present during this week, and at times this becomes a great trouble to the patient, and very rarely may reach to such a degree that it embarrasses the heart's action. It is dangerous in that it favours perforation, which may occur in this week, but is more commonly met with in the third week, under which heading it will be described.

Usually the spleen is distinctly enlarged during this week, and the blood shows an anæmia due to the reduction of red blood cells, while the hæmoglobin and the leucocytes are also reduced. The leucopenia is due to a reduction of the polymorphonuclear leucocytes and eosinophiles, while the mononuclear leucocytes are usually increased in numbers. The presence of a marked leucocytosis would indicate the occurrence of some complication. The coagulability of the blood is reduced.

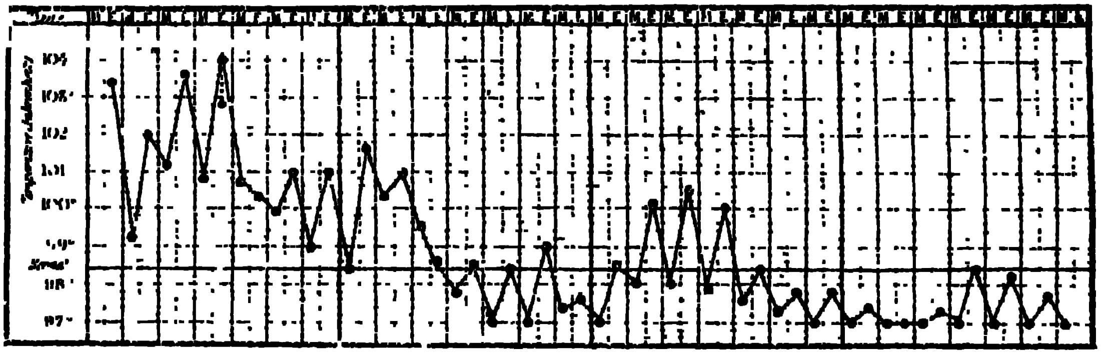

Fig. 650c.—Temperature Chart of a Case of Paratyphoid B Fever.
(Chart made by Major Archibald.)

Pain and tenderness may occur in the right hypochondrium over the area of the gall-bladder, and is often due to a slight attack of cholecystitis, which may also be indicated by slight enlargement of the liver, slight jaundice, and rigidity of the abdominal muscles.

The lungs should be carefully watched during this period, as lobar pneumonia may occur, and as the symptoms are not marked, and rusty sputum is rare, it may be overlooked.

Rarer symptoms during this week are local neuritis, tetany, eye troubles, and ear complications; but muscular cramp is by no means rare, and may cause great inconvenience to the patient.

The urine is febrile, and may contain albumen. The diazo-reaction may appear before the rash, or may be deferred as late as the end of the third week. Bacilluria is found in about one-third of the cases, while urobilin and indicanuria are also fairly frequently met with. Acetone and diacetic acid occur, but may be due to the starvation. In mild cases the patient may show marked improvement during this week, and the temperature may decline gradually, and reach normal about the fourteenth day. This, however, is rare, and usually the temperature keeps high during the whole week, and the patient enters the third week with all the signs and symptoms of the fully developed attack.

The Third Week. During the third week the temperature may gradually fall to normal about the twenty-first day in typical cases, and with this the various symptoms may subside and convalescence begin. In moderately severe cases all the symptoms described in the second week may continue, but the fever may be less, and may gradually remit towards the end of the week. In the severer cases the fever continues, and the patient passes into a condition commonly called the 'status typhosus.' This is the week in which there is a great danger of hæmorrhage and perforation of the intestine.

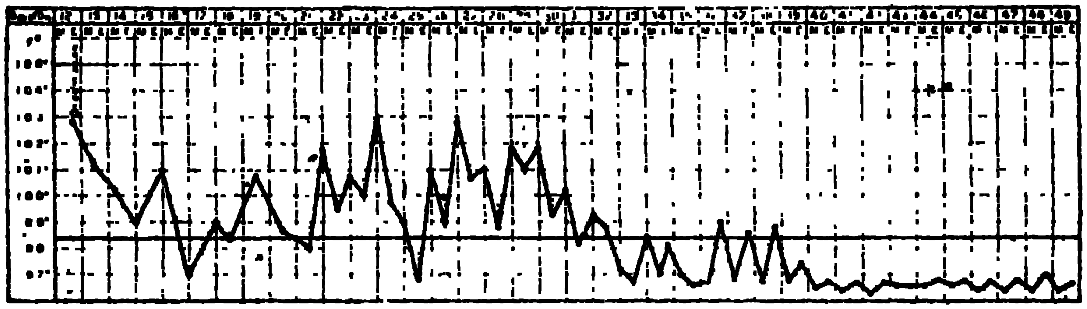

FIG. 660.—TEMPERATURE CHART OF A DOUBLE INFECTION OF TYPHOID AND PARATYPHOID B FEVERS

In the severe cases the temperature remains high; the pulse becomes quick; the tongue, teeth, and lips become covered with sordes; the diarrhœa and abdominal distension become worse; and the toxæmia produces delirium, at first mainly at night, but later more or less continuously; or the patient may develop a quiet state of delirium, lying quietly in the bed with the eyes open and staring, and quite unconscious of the surroundings. The muscles are markedly irritable, and show fibrillar contractions, tremblings, and twitchings, with or without subsultus tendinum. Emaciation now progresses, and the anæmia is more marked. This is the time for the pharyngo-typhoid ulcer to appear, and tympanites develops.

The great danger of the third week is perforation, which is said to occur in about 3 per cent. of cases. It may take place in the mildest of cases, and we have seen it in one in which only two small ulcers could be found at the post-mortem examination, so that no case can be said to be free from this danger.

The symptoms are often sudden, severe, stabbing pain in some part of the abdomen, and often referred to the region of the right iliac fossa, but may also be referred to the left iliac fossa. This sharp pain disappears, but is replaced by a more general pain all over the abdomen, which may be persistent or intermittent. At times this general pain may be absent. Sometimes, but by no means always, there is vomiting. Usually there is more or less collapse, as indicated by the pinched features and the quick, small, thready pulse. The temperature generally falls, but quickly rises again; the abdomen becomes distended: the liver dulness is encroached upon by the tympanites, and the breathing becomes thoracic; while the urine may be suppressed. The prostration increases, and the patient may gradually sink and die. In other cases peritonitis may intervene before death. A small perforation may not present the above typical symptoms, and may be only suspected at first by the fall of temperature and the rise of the pulse-rate.

The Fourth Week.—In typical cases the temperature has fallen to normal by the commencement of this week, and the tongue has begun to clean and all the symptoms abate and gradually disappear, and convalescence begins. Now comes the danger of a relapse, as towards the end of this week the patient begins to get hungry.

In severe cases the symptoms may continue unabated, and complications may occur.

In protracted cases the patient lies in the status typhosus with a high temperature, passing urine and fæces involuntarily, and may die from cardiac failure, from perforation, or some other complication.

The Fifth and Sixth Weeks.—These should be weeks of convalescence, but at any time a relapse may take place, while complications and sequelæ may occur.

Varieties.—The various types of typhoid fever may be classified in the following sequence: Ambulatory, abortive, mild, typical, severe, and the masked.

The ambulatory is typically presented by a person who feels ill for some days or weeks, but goes about his usual work, feeling exceedingly wretched, until, perhaps, someone, noticing how ill he looks, may take his temperature, and perhaps find it over 104° F.; thereupon the patient seeks advice for the first time, and may be well into the second or even third week of the disease. More rarely a patient may go through the whole attack without medical assistance. Often, however, the illness may begin with the ambulatory variety and end with an exceedingly severe attack.

The mild, the typical, and the severe, have been included in our general or typical account given above, and these are estimated to be about two-thirds of all cases of enteric fever.

The masked type of fever is that in which one special group of symptoms is pronounced, as, for example, the nervous, with the severe headaches, neuralgias, early delirium, and other marked mental symptoms—*e.g.*, mania or the signs of meningitis. Another example is that in which the pulmonary symptoms are specially marked—*e.g.*, the early bronchitis or the pneumonia. Other examples are the severe gastro-intestinal symptoms, imitating poisoning, or the signs of an acute nephritis. Lastly, the type in which hæmorrhages begin early and are persistent is often spoken of as the hæmorrhagic type.

One curious form may be just mentioned, as, for example, the spleno-typhoid, in which the spleen is very markedly enlarged, without signs of malaria or relapsing fever.

Complications and Sequelæ.—The most important complication is malaria, but dengue and certain unclassified fevers of intestinal origin are occasionally met with during the first week, and complicate the diagnosis. Bedsores and boils are not infrequent complications, and loss of hair is a frequent sequel. Venous thrombosis in the femoral vein is a frequent complication, and infarction may occur in various organs. Arterial thrombosis is much rarer. Acute ascending myelitis is noted, while joints may be attacked, giving rise to a typhoidal arthritis, and the spine to a typhoidal spondylitis. Periostitis of various bones is not rare. Inflammation of the thyroid gland may also occur. Hæmorrhage and perforation have been noted. Iritis, orbital cellulitis, and purulent choroiditis have been recorded as due to typhoid fever, but purulent otitis media and mastoiditis, described as associated with typhoid fever, are generally due to other causes than the typhoid bacilli. Appendicitis and meningitis may also occur.

Relapse.—One of the most important sequels to an attack of enteric fever is the relapse which may occur at any time during the three or four weeks following the fall of temperature to normal. It usually resembles an ordinary attack of typhoid fever.

Diagnosis.—The diagnosis of enteric in typical cases is not difficult, being based principally on the slow onset of the fever, the enlargement of the spleen, the presence of roseola at the beginning of the second week, the apathetic appearance of the patient, the leucopenia. Every medical man, however, practising in the tropics has noticed that enteric fever there, much more frequently than in temperate climates, presents an atypical course. The temperature chart may be very irregular, sometimes of a well-marked remittent or intermittent type (Fig. 659); the enlargement of the spleen may be absent during the whole course of the disease, or in other cases it may be much more enlarged and harder than is usually the case; roseola, invisible, of course, in natives, may be absent in Europeans, while at times these may present a profuse rash. In a few cases some of the peculiarities met with, especially the very irregular type of temperature, are explained by the presence of two infections—typhoid and malaria. Individuals who have had an attack of malaria may harbour in their spleen Laveran's parasites for a long time without any symptoms, but as soon as the resistance of the organism is diminished by any cause like a chill, a disorder in dietetics, or the onset of some disease, an attack of malarial fever ensues. When these malarial carriers develop enteric, the malarial infection breaks out again, and probably modifies the course of the temperature. It must be admitted, however, that in the largest number of cases no such explanation can be found. As regards a clinical differentiation of the three varieties of enteric—typhoid, para B, para A—this is impossible, at least in

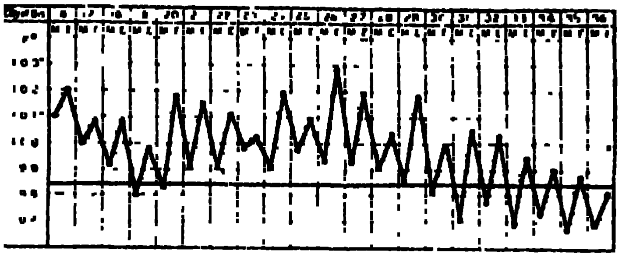

Fig. 1.—Temperature Chart of a Triple Infection of Typhoid, Paratyphoid A and B Fevers.

the tropics. With these clinical difficulties the bacteriological diagnosis of enteric fever acquires in the tropics even more importance than in temperate climates.

The bacteriological diagnosis of enteric is based on the following methods:—

1. Agglutination test.
2. Hæmocultures.
3. Search for the enteric bacilli (*B. typhosus*, *B. paratyphosus A*, *B. paratyphosus B*) in stools and urine.
4. Splenic puncture.
5. Ophthalmo-reaction and cuti-reaction.
6. Subcutaneous inoculations of dead cultures and Vincent's splenic diagnosis.
7. Complement fixation, etc.

The first two processes are really the only ones of practical importance, but a few words may be said also on some of the others.

Agglutination Test (Widal Reaction). This test is based on the work of Grüber, Durham, Widal, and Grünbaum. Either the microscopical or the macroscopic method may be used. The simplest way to perform the microscopical test is to place on a slide 19 loopfuls of broth and 1 of blood, and mix the whole gently together. A loopful of this dilution is then mixed with a loopful of a young typhoid broth culture, a hanging-drop made, and the preparation examined microscopically for agglutination after one hour. The technical details may be found in any textbook on bacteriology. It suffices here to say that the blood should be sufficiently diluted—at least 1 in 40—and the agglutination should be first tried, using the typhoid bacillus, and if this is negative, the paratyphoid A and the paratyphoid B bacilli. If the medical man in attendance cannot perform the test himself, he should send the blood to a bacteriological institute. The sample of blood is obtained by pricking the finger and collecting a few drops of blood in a capillary tube. After closing both ends in the flame, the tube is packed in cotton-wool, and despatched to the bacteriological institute.

Macroscopic tests (sedimentation test) are also in use, and various forms of apparatus (agglutinometers) can be obtained, which enable the general practitioner to carry out the test himself without using a microscope. A convenient rapid method is Alcock's, the blood being diluted very little and examined after only a few minutes. Dreyer's method, using specially standardized emulsions, is useful, as this method renders much easier the making of agglutination curves, which are of great practical importance in the diagnosis of enteric in inoculated individuals. Technical details may be found in any modern textbook on bacteriology.

In the tropics, even at the present time, one is apt to be asked what value is to be placed on the result of the agglutination reaction. Some medical practitioners are inclined to be sceptical, while others tend to base their diagnosis solely on the result of the test. We would emphasize the fact that in enteric fever, as in any other bacterial disease, in order to come to a definite diagnosis the results of the clinical examination and those of the laboratory must not be dissociated.

The practitioner should give his attention to the following points:—

Reaction Negative.—(1) The reaction is generally absent during the first week of the disease

(2) In some very rare cases—in our experience generally of very malignant type—the test may remain negative during the whole course of the malady.

(3) The reaction with the *B. typhosus*—which in certain tropical laboratories is still the only bacillus of the typhoid group used for the test—is negative in two varieties of enteric fever—paratyphoid A and paratyphoid B.

Reaction Positive.—(1) When the reaction is positive, it should be remembered that the blood may contain specific agglutinins many years after an attack of typhoid is over. In the event of fever in such a case the medical man who would solely rely on the Widal test would easily fall into error.

(2) The reaction is not rarely positive in cases of jaundice, but recent researches have demonstrated the fact that these cases are in reality often due to the colecystitis caused by *B. typhosus*.

(3) The reaction is positive in vaccinated persons for a variable period of time after inoculation.

(4) One must be sure that the test has been carried out with sufficiently diluted blood. A dilution of 1 in 40 is sufficient for ordinary purposes.

HÆMOCULTURES.—Two methods may be used—the so-called 'dilution method,' introduced by Castellani in 1898, and the 'bile-enrichment method,' introduced by Drigalski and Conradi, and modified by many authors. The latter is at the present time to be preferred, being simpler. The former is still of use when a mixed infection is suspected, as, for instance, a typhoid-pneumococcus infection. The pneumococcus and many other germs would grow very badly, or not at all, in bile media.

Castellani's Dilution Method.—The region of the bend of the elbow is cleaned with spirit or ether, then disinfected with perchloride lotion (1 in 1,000), then a little spirit or ether is poured again on the skin, or the region may be simply painted with tincture of iodine. When this has become dry, a few c.c. (2 to 5) of blood, by means of a sterile all-glass syringe, are taken aseptically from a vein of the region, generally the median basilic. The blood is immediately added to several large sterile flasks (at least three), each containing

200 or 300 c.c. of faintly alkaline broth. A dilution of about 1 in 100 to 1 in 200 is generally sufficient. The flasks are incubated at 37° C. Generally, after twelve to twenty-four hours in positive cases, the broth becomes cloudy, and shows a growth of the germ.

The germ, of course, must be further identified in the usual way by cultivation in milk, various sugar broths, and by the agglutination test. The method gives satisfactory results, the *B. typhosus* having been found by Schottmuller, Auerbach, Widal, Pinot, Vegrès, and others, in a percentage varying from 70 to 100 per cent. The novelty of the method is the dilution of the blood in a very large amount of broth instead of employing the usual small quantities of the medium. This simple innovation makes all the difference in the result. With the old methods the majority of observers failed to detect the germ. These satisfactory results are probably due to the fact that the blood being greatly diluted, the agglutinins are also diluted, and any bactericidal properties of the blood serum greatly weakened.

Gildemeister recommends dilution in sterile water, while Cummins and Cumming consider a solution of 0·5 per cent. taurocholate of soda to be a very efficient medium.

Drigalski and Conradi's Bile-Enrichment Method.- We use the following modification: 2 to 5 c.c. of blood are withdrawn from a vein by means of a sterile syringe (see above), or if a vein puncture is objected to, a deep prick is made in a finger, and the blood collected and dropped in Coleman and Buxton's glycerine-ox-bile medium, which consists of ox-bile 90 c.c., glycerine 10 c.c., peptone 2 grammes, distributed in small flasks, each containing 20 c.c. of the medium. If the blood is taken in the evening the percentage of positive results seems to be larger.

OPHTHALMO-DIAGNOSIS. -Chantemesse has introduced a method of diagnosis similar to the ophthalmo-diagnosis of tuberculosis. An extract of typhoid bacilli, specially prepared, is used. A drop is instilled into the conjunctival sac; after two to three hours, if the case is typhoid, the conjunctiva becomes very red, and the inflammation persists for two or three days.

CUTI-REACTION. Attempts have been made by several authors to evolve a method of cuti-reaction for enteric in analogy to that which has been done in tuberculosis. The results have not been very satisfactory.

SILVESTRINI'S TEST. -A small amount of broth typhoid culture killed by heat is injected subcutaneously. If the case is typhoid, this procedure induces a sharp rise of the temperature for a day or two.

COMPLEMENT FIXATION.- -A complement fixation test has been worked out for typhoid, para A and para B, by several authors, but its use has not become general.

VINCENT'S SPLENO-REACTION.- Vincent has noticed that in many cases after the subcutaneous injection of dead vaccine the spleen becomes temporarily distinctly larger. The reaction is specific viz., a patient suffering from typhoid shows an enlargement of the spleen if he is injected with typhoid vaccine, but not if injected with paratyphoid A or paratyphoid B vaccines.

SPLEEN PUNCTURE.- The point of maximum spleen dulness is found, the skin is disinfected by painting with tincture of iodine, and the puncture made by using a sterile syringe supplied with a long, strong needle. A few drops of splenic blood and juice are obtained with facility, and should be immediately sown in bile-glycerine medium. The method gives good results, but is not advised as a routine procedure.

Bacteriological Examination of Stools for B. typhosus and Paratyphosus A and B.—A small portion of the stool recently passed and collected into a sterile vessel is smeared on several large MacConkey's agar plates. These are incubated for twenty-four to forty-eight hours at 35° to 37° C., and then any suspicious white colonies further investigated. As is well known, on MacConkey's medium the colonies of coli like bacteria are red, while those of the typhoid and dysentery group appear whitish. Instead of MacConkey's agar, the Drigalski medium may be used, or Holt-Harris and Teague's methylene blue-eosin medium, the inoculation of which may be done from a growth of the fæces in Douglas' peptone-free broth.

Castellani's Contemporaneous Gas-Agglutination Test.—Twenty tubes of salicin (or raffinose) peptone water, each containing a small fermentation tube, are used, and to each tube 1-2 drops of trivalent typhoid and para A and para B agglutinating serum are added, or 1 drop of each monoserum may be added instead of the trivalent one. Each tube is inoculated from one of the lactose non-fermenting white colonies present on the MacConkey plates made from the suspected fæcal matter. The tubes are placed in the incubator at 35°-37° C. for twelve to twenty-four hours and then examined. All tubes showing diffuse turbidity or gas, or both, are discarded. If one (or several) of the tubes shows agglutinated growth as well as absence of gas a diagnosis of enteric may be made, at once, for practical purposes.

If the search is limited only to typhoid and not para A or para B, it is better to use glucose-peptone-water tubes slightly tinged with litmus, to which 1-2 drops of typhoid agglutinating monoserum have been added. If one of the tubes (or several) shows agglutination and absence of gas while the medium has taken a reddish colour (acidity), the diagnosis of typhoid may be made.

Castellani's Poliserum Method. This is an application of Castellani's general method to isolate a bacterium from a mixture of other bacteria by using a multivalent serum which will agglutinate and delay the growth of all or most of the bacteria present, while it does not influence the growth of the germ or group of germs one desires to isolate. Great difficulty, however, is found in practice in preparing such a serum, the best method of preparation being that of mixing several plurivalent sera. The poliserum method may be carried out in various ways. Two may be mentioned:—

1. (*a*) Inoculate with the fæcal matter to be investigated several tubes of taurocholate of soda peptone water, or Browning, Gilmore, and Mackie's telluric acid peptone water may be used.

(*b*) Immediately after, or better immediately before, the inoculation, add 3 drops polyvalent lactose-fermenting intestinal-bacteria serum, 3 drops polyvalent non-lactose fermenting fæcal bacteria serum (*B. proteus* group, etc.), taking care to use serums containing only a very small amount of typhoid coagglutinin; or serums can be used from which the typhoid coagglutinin has been removed by absorption

(*c*) Incubate for twelve or twenty-four hours, then make plates on MacConkey, Conradi Drigalski, or similar media, from the most superficial portion of the liquid medium, and investigate further any suspicious colonies which may develop, testing them with typhoid, paratyphoid A, and paratyphoid B serums, etc. When there are many flocculi of agglutinated bacilli also in the upper portion of the tube, these may be got rid of by a short centrifugation. A short centrifugation with an ordinary electric centrifuge will cause the agglutinated bacilli to fall to the bottom, while it has practically no effect on the non-agglutinated germs in young cultures.

2. Instead of inoculating the suspected fæcal matter direct in taurocholate peptone water and poliserum, the stool is plated on MacConkey's medium. After fifteen to twenty-four hours' incubation at 35°-37° C. all the white colonies (lactose non-fermenters) are inoculated in a tube of peptone water, to which has been added 2-3 drops of the poliserum for lactose non-fermenters apart from enteric group. After fifteen to twenty-four hours' incubation the growth from the top of the tube is further investigated.

Bacteriological Examination of Urine.—The urine should be collected aseptically. In women a catheter should be used. In males this is not necessary. It is sufficient, after purifying the glans and meatus first with a disinfecting lotion, and then with boiled water, to make the patient pass his urine. Any germs of the anterior portion of the urethra will probably pass with the first portion of urine, which is thrown away, while the last portion is collected into a sterile vessel, and immediately sown in tubes containing Coleman and Buxton's bile-glycerine medium. These are incubated at 35° to 37° C. for twenty-four to thirty-six hours, and then the further bacteriological investigation is carried out in the usual manner by making plates, etc.

Diazo-Reaction.—A chemical laboratory test often used is Ehrlich's diazo-reaction, which, however, is positive in several other febrile conditions.

Marris's Atropine Test.—Marris found out that the injection of $\frac{1}{33}$ grain of atropine sulphate in fevers of the enteric group hardly accelerated the pulse-rate, while in patients suffering from other diseases such an injection will increase the rate of the heart by some twenty to forty beats per minute in the same manner as in normal individuals.

Marris's technique is as follows:—The patient should lie horizontally, perfectly quiet, and the test should be carried out at least one hour after meals. The pulse-rate is taken and recorded minute by minute until found to be steady. This usually takes ten minutes. An injection of $\frac{1}{33}$ grain of atropine sulphate is then given in the deltoid region. The patient remains absolutely quiet, and after twenty-five minutes the pulse-rate is taken and recorded minute by minute. An increase of the pulse-rate by about twenty or more per minute indicates that the patient is not suffering from enteric. If the increase in the pulse-rate is only ten beats or less, the reaction is suggestive of enteric.

Diagnosis of Enteric in Inoculated Persons.—The diagnosis of enteric in inoculated persons may be very difficult, the symptoms being often most atypical. Moreover, the commonest laboratory test—agglutination—is of little use unless carried out according to certain methods.

It is well known that in individuals inoculated with the triple vaccine typhoid and para A and para B, specific agglutinins develop for the three germs, as was shown by one of us long ago. The maximum agglutination titre is reached two to three weeks after the first inoculation, then the titre falls at first—for a few weeks—rapidly, but later on in an extremely slow, gradual manner, so slow as to remain practically constant for months and years. After two months from inoculation only very exceptionally one finds an agglutination limit greater than 1 in 320 for *B. typhosus* and *B. paratyphosus B*, and for *B. paratyphosus A* greater than 1 in 180. Therefore, in a person inoculated longer than two months, if the agglutination limit is higher than 1 in 300 for *B. typhosus* or *para B*, or more than 1 in 180 for *B. para A*, and there is fever, a provisional diagnosis of enteric may be made. It is always advisable, however, as emphasized especially by Dreyer, Walker, and Gibbon, to take the agglutination titre at intervals of three to five days several times during the course of the suspected fever and make an agglutination curve for *B. typhosus*, *B. paratyphosus B*, and *B. paratyphosus A*.

If the agglutination for *B. typhosus* exhibits a regular rise, with a maximum of even 100 per cent. in the third or fourth week from onset of fever, and then a subsequent regular fall, as seen in non-inoculated subjects, but starting from and returning towards the higher base line of inoculated persons, while there is little or no rise in the agglutination titre for *B. paratyphosus B* or *A*, a diagnosis of typhoid fever may be suggested with great probability.

If there is a regular rise and subsequent fall in the agglutination for *B. paratyphosus B*, while the agglutination titres for *B. typhosus* and *B. paratyphosus A* show only a slight or no increase, the diagnosis of paratyphoid B may be suggested.

If there is a regular rise and later fall in the agglutination titre for *B. paratyphosus A*, while the titre for *B. typhosus* and *B. paratyphosus B* is only slightly raised or not at all, a diagnosis of paratyphoid A fever may be made with a certain degree of probability.

If there is a very distinct rise in the agglutination for all three germs or any one of them, there is the possibility of the patient suffering from one of the three fevers with non-specific agglutinins for one or both the germs producing the other two, or there is the possibility of the patient suffering from a mixed infection. In the first case the agglutination curves are generally synchronous, and the germ for which the agglutination is highest is often the infective germ.

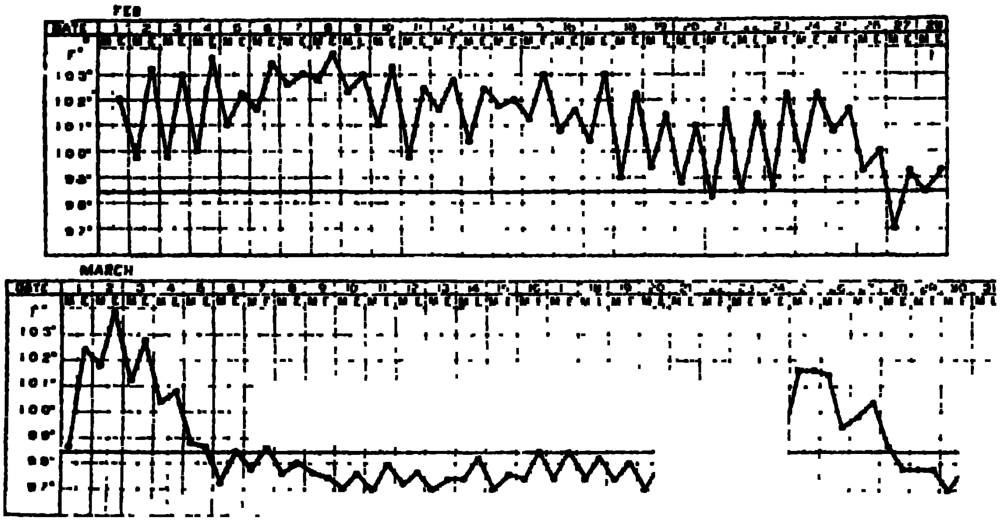

Fig. 662.—Temperature Chart of a Triple Infection: Typhoid and Paratyphoid A and B Fever.

In *mixed infections*, whether in inoculated or non-inoculated subjects, the agglutination curves for the various infecting germs are as a rule not synchronous, and follow their ordinary course independently of each other.

To carry out the above tests it is necessary to have recourse to an accurate quantitative method, and we recommend for the purpose Dreyer's standard agglutination method, using standard agglutinable emulsions. Details will be found in any modern manual of bacteriology, such as Hewlett's seventh edition.

Of course, in inoculated persons the search for the infecting organisms in the blood, stools, and urine, as already described, is even of greater importance than in non-inoculated individuals. Marris's atropine test may also at times help the diagnosis of enteric in inoculated people, the test apparently not being affected by previous vaccination.

Differential Diagnosis.—The term 'enteric fever,' as already stated, is used to cover three infections—typhoid fever, paratyphoid fever A, and paratyphoid fever B, which clinically, at least in the tropics, cannot be distinguished from one another, except by bacteriological methods. Enteric fever imitates many diseases, and many diseases resemble enteric fever, and this renders the differential diagnosis complicated and difficult. Of the many fevers which may possibly be mistaken for some usual or unusual attack of enteric fever, we have chosen the following for differential diagnosis—viz., malaria, the relapsing fevers, dengue, undulant fever, plague, yellow fever, typhus, influenza, trichiniasis, acute miliary tuberculosis, appendicitis, pneumonia, rat-bite disease, psittacosis, parenteric fevers, ulcerative endocarditis, and pyæmia.

Malaria.—Intermittent fevers are hardly likely to be confused with enteric fever, but remittent fevers are liable to cause difficulty, and may be recognized by the presence of the parasites in the peripheral blood, by the presence of pigment in the leucocytes, by the enlargement of the spleen, and the reaction to quinine. Moreover, the attack of fever is usually sudden, the temperature quickly rising to 105° F., while the pulse is, as a rule, not dicrotic, and if the fever has lasted a few days, there is generally some sign of anæmia. It must, however, be remembered that malaria is a not infrequent complication of the first week of an attack of enteric fever in the tropics, as malarial carriers are very apt to develop this fever when commencing an attack of enteric fever.

Relapsing Fevers.—In these fevers the onset is sudden, and characterized by chills and severe pains in some region of the body, while a careful examination of the blood in a first attack should reveal the spirochætes.

Dengue.—Dengue begins suddenly with often severe pain in some part of the body, and often congestion of the conjunctiva, and perhaps a sensation of chilliness. It must not be forgotten that typical cases of dengue fever sometimes develop enteric fever.

Undulant Fever.—This disease may very closely resemble enteric fever, and during the first week can only be definitely recognized in a locality in which both diseases occur by cultivation of the specific germ from the blood, while later sweating and the undulating type of fever, together with the articular symptoms, are characteristic.

Plague.—The ordinary severe type of plague may be recognized by the sudden onset, the severity of the symptoms, the mental dulness, and the full development of the typical symptoms and bubo in a few hours.

The milder forms of plague are more difficult to recognize, because there is little fever; but the enlargement of a group of lymphatic glands will arouse suspicion as to the true nature of the disease.

Plague pneumonia may be distinguished from the pneumonic form of enteric fever by an examination of the sputum.

Yellow Fever.—Mistakes are most apt to occur at the commencement of a yellow-fever outbreak before the disease is recognized. The diagnosis may be effected by the rapid onset of the fever, the tenderness in the region of the pylorus, and by the albuminuria which is often present on the first day, and later by the vomit. But in such an important point as the diagnosis between yellow fever and typhoid fever, bacteriological examination of the blood and motions should not be neglected.

Typhus.—This fever may be distinguished by its sudden onset, and by the early appearance of mental symptoms, and especially by the early appearance of delirium and coma, while the macular petechial eruption appearing on the fourth day materially assists the diagnosis. Brill's disease is merely a mild form of typhus, and may be differentiated by the appearance on the fifth or sixth day of a maculo-papular eruption, which does not disappear on pressure, and does not appear in crops.

Influenza.—The diagnosis between influenza and enteric fever can be made by the presence of catarrhal symptoms in the former.

Trichiniasis.—The presence of œdema of the eyelids, together with swelling and painful tension of the muscles, associated with dyspnœa, are in favour of trichiniasis. The blood should be examined for any signs of eosinophilia, while the worms may be discovered in the motions.

Acute Miliary Tuberculosis.—The differential diagnosis here is very difficult, and is complicated by the fact that the two diseases may occur together. The fever in acute miliary tuberculosis is irregular, and the pulse and respiration are rapid, and there is embarrassment of the breathing, often leading to cyanosis; but the diagnosis is very difficult, and may have to depend entirely upon bacteriological research.

Appendicitis.—In appendicitis the onset is usually abrupt, and the pain in the right iliac fossa is distinctive, but there are cases which closely resemble enteric; and it must be remembered that the typhoid bacillus can cause appendicitis.

Pneumonia.—Enteric fever may, though very rarely, begin with a typical attack of pneumonia, when the specific organisms may be found in the sputum; otherwise, a diagnosis must be made by the examination of the blood, or later clinically, when the more typical symptoms of enteric arise in the second week.

Rat-Bite Disease.—This may be recognized by the history, by the blotchy, measly eruption, and by the fact that the fever ends for the first time after a few days, only to reappear again later.

Psittacosis.—This enteric-like fever may be suspected by the history of there having been sick parrots in the house in which the patient has been residing, and this can be confirmed by the isolation of the specific bacilli from the blood.

Parenteric Fevers.—These can only be diagnosed by the bacteriological examination of the blood and fæces.

Ulcerative Endocarditis.—Usually in this complaint there are recurring chills, irregular fever, substernal pains, and endocardial murmurs, while bacteriological examination of the blood may not merely differentiate it from enteric fever, but may indicate the germ which is causing the endocarditis.

Pyæmia.—In the first week this may be difficult, and depend upon the bacteriological examination, but the usually intermittent fever, the prostration, and the sweats, may give rise to suspicion. The marked leucocytosis may also arouse suspicion.

Weil's Disease.—This may be recognized by the early onset of jaundice.

Diagnosis of Mixed Infections.—As already stated, mixed infections, especially typhoid and malaria, typhoid and paratyphoid, typhoid or paratyphoid and coli-like germs, are not rare. In the typho-malarial-infection cases the microscopical examination of the blood will reveal Laveran's parasites. As regards the diagnosis of the second group of mixed infections—viz., typhoid + paratyphoid, or typhoid + coli infections—the diagnosis is based on:—

1. Hæmocultures.
2. Castellani's absorption test.

The technique for hæmocultures has already been given. We may here remind our readers that the finding in the blood of some other organism besides the *B. typhosus* does not mean always that the case is a real mixed infection. The organism found may play only a saprophytic rôle, especially if the blood does not contain *specific* agglutinins for the germ.

Castellani's Absorption Test.—The usual agglutination tests are not, as a rule, sufficient to make a diagnosis of mixed infection, because coagglutination does not always mean multiple infection. If the blood of a typhoid patient agglutinates the *B. paratyphosus,* besides the *B. typhosus,* one is not justified in coming to the diagnosis of a mixed infection brought about by the *B. typhosus* and the *B. paratyphosus B,* because it is well known that the blood of a typhoid patient may contain, besides the specific, primary or homologous agglutinins for the typhoid bacillus, secondary or non-specific or heterologous agglutinins for *B. paratyphosus B* and many other bacilli, such as many strains of coli. This has been demonstrated by many authors. Grüber and Durham, as long ago as 1896, demonstrated that the typhoid sera may agglutinate Gaertner bacilli. Zupnik and Poser later found out that 89 per cent. of typhoid sera reacted with paratyphoid B, and 40 per cent. with paratyphoid A.

Boycott, who has made a very complete investigation of the subject, has noted that 59 per cent. of typhoid sera present coagglutinations; 55 per cent. reacted with Gaertner, or Brion and Kayser; 41 per cent. with Schottmüller B; 33 per cent. with Aertrycke; and 12 per cent. with Schottmüller A.

The greater the quantity of typhoid agglutinin, the greater, as a rule, the subsidiary agglutination.

To distinguish between primary and secondary agglutinins, and to facilitate the diagnosis of closely allied organisms and mixed infections, the absorption test, discovered by Castellani in 1902, is useful. This test has been further studied, and the technique improved, by Boycott, Bainbridge, O'Brien, Cummins and Cumming, Alcock, and others. An excellent monograph on the absorption test is the very recent one by Frank E. Taylor.

Castellani found out that in rabbits immunized for typhoid only, whose serum agglutinated besides the typhoid bacillus, also certain 'coli' germs, the saturation with an excess of typhoid bacilli would remove not only the primary (specific, homologous) typhoid agglutinin, but also the secondary (heterologous, non-specific) coli agglutinin; while in a serum derived from rabbits immunized both for typhoid and coli bacilli, neither saturation with typhoid alone nor coli alone, but only both together, simultaneously or successively, would remove the whole of the agglutinins present in the serum.

He experimented with various other germs, and applied the method to the differentiation of closely allied bacilli and mixed infections in man. For practical clinical purposes it may be said that if the blood of a typhoid patient presents, besides agglutination for the *B. typhosus*, also agglutination for, say, *B. paratyphosus B* or *A*, or a coli-like germ, and if this agglutination for the *B. paratyphosus B* or *A*, or coli-like, persists to a great extent after saturation with *B. typhosus*, the case is very probably one of true mixed infection: typhoid + paratyphoid B, or paratyphoid A, or coli-like, as the case may be.

Of course, as with every other biological test, the results obtained cannot be accepted as absolute, but are only of relative value.

To remove the typhoid agglutinin from the typhoid serum, this is diluted, and an excess of typhoid bacilli from young agar cultures added and kept in contact for two hours. The serum is then tested for agglutination for the various germs. A similar technique is used for removing the specific paratyphoid B, paratyphoid A agglutinins, etc.; by adding to the serum an excess of paratyphoid B or paratyphoid A, etc., bacilli. For technical details one should consult books on advanced bacteriology, or Taylor's excellent monograph on the absorption test.

Prognosis.—The typhoid mortality is, in the tropics, about 20 to 25 per cent. for ordinary hospital practice, and rather lower for private practice. The mortality from paratyphoid A and paratyphoid B is lower. Unfavourable symptoms are the early appearance of hæmorrhage, severe nervous symptoms, considerable meteorism, and severe diarrhœa. A bad sign, pointing to a probable relapse, is the temperature falling while the pulse remains rapid.

Severe hæmorrhages are of grave import, as is perforation. Sudden death may occur at any stage of illness and during the convalescence, but is, fortunately, very rare.

Treatment.—The treatment of enteric fever may be divided into:—

A. The treatment during the attack.
B. The treatment during the convalescence.

A. **The Treatment during the Attack.**—This may be subdivided into:—

I. Treatment of a simple uncomplicated case.
II. Treatment of special symptoms.

I. The treatment of a SIMPLE UNCOMPLICATED CASE may be considered under the following headings: (1) General hygiene; (2) nursing; (3) diet; (4) medicines.

1. *General Hygiene.*—A well-ventilated, airy, and well-lighted room should be chosen, and all superfluous furniture, hangings, belongings, etc., removed, except such few things as may be desirable to render the general appearance cheerful. Special attention should be paid to the bed, because the patient is to remain in bed for about one month after reaching a permanently normal temperature. The bed should not be too broad or too narrow, and should have a wire-woven mattress, which is part of the bed. Over this a soft horsehair mattress should be placed, and a reserve mattress should be kept handy. Over the horsehair mattress two folds of blankets should be placed, and then the sheet, and in the middle third there should be the draw-sheet, with its waterproof sheeting. The bed should be provided with an easily movable mosquito-net. The whole room should be thoroughly cleansed once a day by means of damp cloths dipped in Jeyes' fluid. All motions and urine should be protected against flies, and, after being inspected by the physician, should be disinfected with Jeyes' fluid or crude carbolic acid, which is allowed time to act before the contents are thrown away. A separate set of feeding appliances should be reserved for the patient, and these should be sterilized after use. All fomites should be soaked in Jeyes' fluid or carbolic lotion for some hours immediately after use and before being washed. A large piece of ice is very useful to keep down the temperature of the room in the tropics.

2. *Nursing.*—The most important feature of the treatment of a case of enteric fever is the nursing. Two nurses, one for the day and one for the night, are absolutely necessary, and their work may be rendered easier, and the patient considerably benefited, especially if he is over the average weight, by the use of a Skeffington lifter, or, failing this, by some simple apparatus based upon the plan of this ingenious lifter. The temperature should be recorded every four hours, and as hæmorrhage is so common in the tropics, both nurses should be warned, and should be instructed to be on the watch for the slightest suspicion of this symptom. Moreover,

they should be instructed how to act when it occurs, in order that there may be no delay. The nurse should also be warned to be careful as to the disinfection of her own hands. Nurses who are to attend enteric fever cases should be selected from among those who have been vaccinated, in order to prevent the possibility of infection; failing this, a course of intestinal disinfection at the end of nursing a case of enteric fever is not without its benefits, as many nurses contract the disease.

The patient should be sponged all over with tepid water twice a day, in the morning and in the evening, and this may be repeated if the temperature rises above 103° F. An excellent plan is to add to the water a little of a lotion of thymol 40 grains, spirits of lavender 2 ounces, rectified spirits of wine 3 ounces, dilute acetic acid 3 ounces, in 16 ounces of rose-water. The patient generally finds this admixture to be most refreshing.

From the first the back should be carefully inspected and dried, and dusted with a powder composed of boric acid, zinc oxide, and starch, or some similar powder. Any irritated region should be bathed with rectified spirits.

The mouth must be carefully attended to, and a mouth-wash of glycothymoline, listerine, or other antiseptic mouth-wash, must be used, while the teeth should be carefully cleaned by the nurse by means of a small stick carrying a little cotton-wool.

The bed-pan or slipper and the urine-bottle must be used throughout the illness and the early part of the convalescence.

When the temperature is high, a *light* ice-bag to the head is useful.

3. *Diet.*—With regard to the diet, the patient should not be unduly starved, but should be given liquid food in small quantities at stated intervals. The best basis for the dietary is good chicken-broth and milk, and special attention should be paid to the fact that the liquid actually given to the patient is chicken-broth, and not some greyish warm water, with yellow fat floating on the surface. To this broth some Plasmon may be added, if desired. With regard to the milk, it should be boiled and diluted in the proportion of 1 to 2 with either soda-water, Perrier-water, lime-water, or barley-water, and attention should be paid as to whether it is properly digested or not by examining the fæces. If it is not digested, it must be replaced by malted milk, zymonized or peptonized milk, or by whey. Junket and weak tea may also be used. The patient should be given plenty of water to drink, either plain or as albumen-water, and it is very soothing to occasionally rinse out the mouth with soda-water. But no very warm or very cold foods or drinks should be given.

4. *Medical Treatment.*—The less medicine given to a person suffering from uncomplicated and mild enteric fever the better for the patient.

Some mild medicine—*e.g.*, an intestinal antiseptic, or quinine in some form—is often given—*e.g.*, the quinine and chlorine made by pouring about 30 minims of strong hydrochloric acid upon 30 grains of chlorate of potash.

and dissolving the chlorine gas so evolved in 12 ounces of water, which constitutes the first bottle, and should be dispensed in a non-actinic bottle with a glass stopper. The second bottle contains quinine bihydrochloride 36 grains, syrup of lemons 1 ounce, also dissolved into 12 ounces of water. One tablespoonful from each bottle is mixed and taken three times a day. A thin slice of orange is sucked after each dose to remove the unpleasant taste. Some authorities prefer giving tincture of iodine 2 to 3 minims in an ounce of water every three to four hours; others prefer β-naphthol 2 to 3 grains mixed with bicarbonate of soda 2 to 3 grains, or eucalyptus oil or cinnamon oil 2 to 3 minims in a suspension.

Constipation must be counteracted by a simple enema or an enema with a little turpentine if there is some tympanites every other day.

After the second week urotropine may be given in 10-grain doses three times daily in order to disinfect the urine and gall-bladder.

Serums and Vaccines.—Serums have not been successful: somewhat better results have been recorded by a number of authorities by the use of vaccines. We do not use the vaccine treatment except in some protracted cases with low fever and fairly good general condition.

Tchikana, Fagiuoli, Micheli, Quarelli, and others, give the enteric vaccines by intravenous injection. Kraus, De Castello, and Lucksh, claim to have had good results in enteric by the intravenous injection of heterologous vaccines, as, for example, a *B. coli* vaccine. Intravenous injections of a peptone solution have also been used.

II. The Treatment of Special Symptoms.—The special symptoms which require treatment may be considered under the following headings:—

1. Tympanites.
2. Hæmorrhages.
3. Perforation.
4. Diarrhœa.
5. Cholecystitis.
6. Hyperpyrexia.
7. Delirium.
8. Cardiac failure.
9. Phlebitis.
10. Bedsores.
11. Abscesses.
12. Bone lesions.

1. *Tympanites.*—Tympanites is to be treated by fomentations, turpentine stupes, by the administration of 15 minims of turpentine every three hours, or 3 to 5 minims of cinnamon oil at the same intervals, or by a hypodermic injection of $\frac{1}{50}$ grain of eserine.

2. *Intestinal Hæmorrhage.*—The nurse should be prepared on the onset of this complication to stop all food and drink except a few sips of cold water, to apply an ice-bag to the abdomen, and to raise the bedclothes on a cradle and to administer either the enema mentioned above or to give a capsule of 3 minims of turpentine, or both. This is of the utmost importance, as then time is not wasted in getting the treatment under way. When the physician is certain that a perforation has not occurred, a hypodermic injection of morphia is very useful, but this should not be given so as to hide the signs of a perforation. The turpentine capsules may be continued three or more times a day, and calcium lactate in 10-grain doses may also be given.

3. *Perforation.*—The only chance is to perform a laparotomy, and deal with the perforation surgically; but this must be done as soon as possible. After the operation the Fowler-Murphy after-treatment should be carried out, and the patient placed as nearly in an upright sitting position as compatible with comfort. This position is maintained for four days. At the same time a continuous administration of salt solution *per rectum* is carried out, and so arranged that the patient obtains 2 to 6 litres per diem for a week, and Wainwright's special apparatus for this purpose may be employed.

4. *Diarrhœa.*—This may be checked by tannalbin, 10 to 20 grains, three times a day, or tannigen in the same dose. A very useful adjunct is an enema containing Dover's powder, 5 grains; tannin, 10 grains; mucilage of gum, 1 ounce; and thin starch solution, 1 ounce. Bismuth preparations should, if possible, be avoided, as they are apt to obscure traces of blood, which may be valuable hints of a possible hæmorrhage.

5. *Cholecystitis.*—This should be treated by urotropine, and when chronic by antityphoidal vaccination, or a surgical treatment may be advisable.

6. *Hyperpyrexia* must be combated by tepid, cool, or even iced sponging, by immersion in baths of a temperature between 75° to 85° F. Antipyretic drugs should not be given.

7. *Delirium.*—Acute mental symptoms require sedatives or relief of intracranial pressure by lumbar puncture.

8. *Cardiac Failure.*—This may require to be combated by hypodermic injections of digitalin or camphor in ether, or by strychnine and by saline injections.

9. *Phlebitis.*—This usually occurs in one of the legs, which must be wrapped in cotton-wool after applying ichthyol in lanoline (2 per cent.).

10. *Bedsores.*—These are usually quite preventable, but great care is necessary to dry and to disinfect the back and to harden the skin with spirit lotion. When the sores have developed they should be disinfected twice daily with hydrogen peroxide, and a xeroform or zinc oxide powder applied. In some cases a protargol ointment (5 per cent.) or a balsam of Peru ointment (1 to 2 per cent.) are useful.

11. *Abscesses.*—Local inflammations should be treated with ice-bags, and when pus has formed incisions must be made.

12. *Bone Lesions.*—A stiff jacket may be necessary to relieve the pain of a typhoid spine, and the osteitis or periostitis may require surgical treatment.

B. **The Treatment of Convalescence.**—This may be subdivided into—(I.) The treatment of a simple case; (II.) the treatment of sequelæ; (III.) the treatment of the acute carrier.

I. THE SIMPLE CASE.—The most important factor is to keep the patient in bed without any change of diet until twenty-one days after the temperature has permanently reached normal, and then to gradually increase and modify the dietary. The patient should not be allowed to sit up or to get out of bed until the temperature has remained normal for about four weeks. In the meanwhile the urotropine treatment should be carried out, and, if possible, a bacteriological examination of the urine and fæces should be made six weeks after the permanent return to a normal temperature.

II. THE TREATMENT OF THE SEQUELÆ.—The phlebitis has been mentioned, and as it is followed by œdema will require a bandage or elastic stocking. Post-typhoidal neuritis requires massage and electricity. Nervous sequelæ are not very uncommon, giving rise to a temporary form of mental weakness, or to types resembling disseminated sclerosis, myelitis, etc.

III. THE TREATMENT OF THE ACUTE CARRIER.— If a patient has become an acute carrier, he should be treated by antityphoid vaccination, as already described, and urotropine should also be administered, for this drug, in addition to its action on the kidney, is excreted during twenty-four hours by the liver cells and by those of the gall-bladder. A dose of 15 grains per diem is said to be sufficient to destroy the *B. typhosus* in a gall-bladder in ten days, but the complete cure of carriers is very difficult, even having recourse to surgical measures.

Prophylaxis.—The essential features in the prophylaxis of enteric fever are a pure water-supply, a good system of drainage, and sewage and dust disposal, a pure food and milk supply, the destruction and prevention of fly-breeding grounds.

Another essential feature is the watering of the streets with antiseptic solutions when there is much dust, and lastly, and by no means least, the search for, discovery, isolation when possible, and treatment of the typhoid carriers.

VACCINATION.—At the present time Castellani's triple vaccination (typhoid, para A and para B) has come into general use. The triple vaccine can be prepared according to various methods: broth cultures killed by heat, carbolic salt solution emulsions, oily emulsions, sensitized vaccines, etc. In a general way, it may be stated that, whatever the method of preparation, the results are satisfactory. We generally use a vaccine consisting of an emulsion of typhoid, para A and para B bacilli in normal salt solution, to which ½ per cent. carbolic acid has been added. The details of preparation may be found in various papers by one of us. Each cubic centimetre contains typhoid 500 millions, para A 250 millions, para B 250 millions. Half a cubic centimetre is inoculated the first time and 1 cubic centimetre a week later. Certain authorities recommend a double dose, 1 c.c. the first time and 2 c.c. the second. The triple vaccine gives a certain amount of immunity for the three varieties of enteric—viz., typhoid, para B, and para A; the immunity for typhoid and para B seems to be more marked than that for para A.

The inoculation of the triple vaccine gives rise to a local and general reaction, which is not more marked than after the old typhoid monovaccine: some infiltration and pain at the point of inoculation; fever with headache and rheumatoid pains. The inoculated persons are generally fit to resume their duties twenty-four to forty-eight hours after inoculation.

In countries where cholera is endemic in addition to enteric, the tetravaccine, typhoid, para A, para B, cholera, should be used. Certain observers describe a 'vaccine disease' in analogy to a 'serum disease,' and state that the human organism becomes sensitized by a previous injection of vaccine. This phenomenon, however—at least with marked features—is, in our experience, extremely rare.

Until 1916, in the British Army and practically in every other army—with exception of the Serbian Army, which adopted Castellani's tetravaccine (TABC) in 1915—the vaccine used was the Wright-Leishman typhoid monovaccine, which, as regards prevention of typhoid, gave good results, but naturally was of no efficacy in the prevention of the paratyphoid fevers.

Vaccination by a Single Inoculation.—This has been attempted with a certain degree of success by using oil emulsions of the various bacteria (lipovaccines), as done by Le Moignic and Pinoy, or by using 2 per cent. glycerin emulsions, as done by Castellani.

As regards the results of simple typhoid vaccination, Firth's figures worked out by Pearson's methods showed that out of 55,368 inoculated persons in the army in India, 61 were attacked by typhoid, and out of 12,074 non-inoculated 45 were attacked; while another series of figures showed 58,481 inoculated and 34 attacked, as against 10,927 non-inoculated and 22 attacks.

The vaccine used in the army was the Wright-Leishman, made from cultures not more than forty-eight hours old, which were sterilized at 53° C., and to which, when cold, 0·4 per cent. of lysol was added. This vaccine was to be used during the period extending from three weeks to three months after its preparation, and was to be injected under the skin opposite the insertion of the left deltoid.

The first dose was 500 million bacilli, and the second, given ten days after, was 1,000 million bacilli, and sometimes a third dose of 1,000 million was also given. Inoculation takes place at 4 p.m., and the soldier goes to bed at 8 p.m., when the reaction begins, and is on light duty for two days. There is practically no negative phase, and the reaction consists of a localized hyperæmia with œdema and some slight fever, malaise, and chilliness. Occasionally the symptoms are more severe, but usually disappear in forty-eight hours. The typhoid monovaccine was prepared according to many other methods: the Pfeiffer-Kolle vaccine, the Vincent vaccine, the nucleo-proteid vaccine of Lustig and Galeotti, etc. An attenuated live vaccine was prepared by one of us, and a non-attenuated sensitized live vaccine was prepared by Metchnikoff and Besredka, and extensively used by Alcock.

PARENTERIC.

Synonyms.—Typhoid-like and paratyphoid-like fevers; Enteric-like fevers; Fevers due to intermediate germs.

Definition.—The term 'parenteric' indicates a group of fevers clinically hardly distinguishable from one another, and from enteric, but due to intestinal bacteria specifically different from *B. typhosus* Eberth, *B. paratyphosus B* Schottmüller, and *B. paratyphosus A* Schottmüller.

Historical.—Since the discovery of the paratyphoid bacilli cases of clinical enteric, but apparently due to germs different from those of the enteric group (typhoid, para A, para B), were placed on record by a few observers. These cases were generally viewed with much scepticism, which was to a certain extent justified, as in a number of cases the germ believed to be the cause of the fever represented in reality merely a secondary infection. After our work, that of Balfour, and of Archibald, the fact that there is a group of fevers due to so-called intermediate intestinal germs began to attract more general attention, and is now accepted by most authorities.

Geographical Distribution.—Parenteric occurs apparently in every climate, but is of much more frequent occurrence in tropical and subtropical countries. Cases have been reported from Ceylon, India, Egypt, the Sudan, the Balkans, Southern and Central Europe.

Ætiology and Classification.—Parenteric is caused by a large number of intestinal bacteria, excluding *B. typhosus*, *B. paratyphosus A*, and *B. paratyphosus B*. Ætiologically one might differentiate a variety of parenteric for each species of intestinal germ capable of becoming the ætiological agent of a fever, but such a procedure would differentiate several scores of parenteric fevers, and we therefore consider it simpler, for the time being, to classify parenteric according to six types, corresponding to the six principal groups in our classification of intestinal bacteria (Chapter XXXVI., p. 932), as follows:—

A. Parenteric due to bacteria of genus *Eberthus* Castellani and Chalmers, excluding *B. typhosus*, and of genus *Alkaligenes* Castellani and Chalmers.

These cases do not seem to be very rare. Among the germs found we may mention *B. fæcalis alkaligenes* Petrowsky, *B. fæcaloides* Castellani, *B. meta-alkaligenes* Castellani, *B. para-alkaligenes* Castellani, *B. vivax* Archibald, *B. pritnitzi* Castellani, *B. kandiensis* Castellani, etc. It would appear that these germs are usually non-pathogenic, but under certain circumstances, of which very little is known, may become so.

B. Parenteric due to intestinal bacteria of genus *Salmonella* Lignières *emend.* Castellani and Chalmers, apart from *B. paratyphosus A* and *B*. These cases seem to be the most frequently met with. Among the bacteria found we may mention *B. psittacosis* Nocard, *B. columbensis* Castellani, *B. archibaldi* Castellani and Chalmers. These three germs seem to be constantly pathogenic, while many other members of the group are often non-pathogenic, representing when found only secondary infections, although it is not excluded that at times they may become pathogenic.

Two very important germs of the genus Salmonella are *B. aertryke* De Nobele (= *B. suipestifer*) and *B. enteritidis* Gaertner, but these two germs very seldom give rise to an enteric-like fever; usually they give rise to acute enteritis.

C. Parenteric due to germs of genus *Enteroides* Castellani and Chalmers. Cases of parenteric seem occasionally to be caused under certain circumstances by such germs, which as a rule are not pathogenic fæcal bacteria. The following germs have been found capable at times of becoming pathogenic: *B. entericus* Castellani: *B. khartoumensis* Chalmers and MacDonald; *B. parentericus* Castellani.

D. Parenteric due to germs of genus *Lankoides* Castellani and Chalmers. These seem to be rare, though a few cases have been recorded due to *B. ceylonensis A* Castellani and *B. ceylonensis B* Castellani.

E. Parenteric due to germs of genus *Balkanella* Castellani and Chalmers and genus *Wesenbergus* Castellani and Chalmers. These cases appear to be very rare, the germs of this group apparently seldom becoming pathogenic.

F. Parenteric due to bacteria of genus *Escherichia* Castellani and Chalmers. Cases of parenteric due to bacteria of this group (so-called coli group) are in our experience very rare. True, germs of this group are comparatively often found in the blood of cases of fever, and, moreover, are often agglutinated by the blood of the patient, but repeated bacteriological examinations very frequently show that these germs play only the rôle of secondary or associated infections, and that the cases are often true cases of enteric (typhoid, para A, or para B), the coliform germs having entered the general circulation through the intestinal ulcers. One should also keep in mind the frequent invasion of germs of this group in the pre-agonic period.

Parenteric due to germs of the tribe *Proteæ*, such as *B. cloacæ*, *B. pyocyaneus*, *B. proteus vulgaris*, etc., is rare, these germs generally acting as secondary infective agents.

Morbid Anatomy.—Very little is known. Intestinal ulcers do not seem to be present. The mesenteric lymph glands may be larger than normal, and the spleen and liver may be enlarged, and the latter organ may show cloudy swelling and fatty degeneration. The heart is flabby, and may be in a condition of fatty degeneration.

Pathology.—This seems to be somewhat similar to the pathology of enteric.

Symptomatology.—Parenteric is clinically very similar to enteric, the onset being at times slow, the fever subcontinuous or continuous, ending by lysis.

At times, however, the onset is sudden, and the fever may have a most irregular course. The duration varies between ten days and several weeks, or occasionally months. The patient in some cases takes the 'typhoid look,' being apathetic and expressionless; at other times he does not appear to be very ill. Intestinal symptoms may be present or totally absent, but a certain amount of meteorism is often noticeable. The spleen may be palpable, but this is of much less frequent occurrence than in enteric. Roseola is extremely rare and intestinal hæmorrhages practically unknown, the germs of the parenteric group giving rise very seldom to intestinal ulcers.

Frequency of Parenteric.—It is well to keep in mind that parenteric is on the whole much less frequent than true enteric (typhoid, para A, para B). The observation has been made that persons inoculated against enteric (typhoid, para A, para B) seem occasionally to become more prone to contract parenteric, in the same manner that persons inoculated against typhoid only, seem at times to develop a tendency to contract paratyphoid A and paratyphoid B more frequently than non-vaccinated individuals. This, however, cannot be used as an argument against vaccination by the enteric or triple vaccine (typhoid, para A, para B), because, although individuals vaccinated therewith may develop a slight tendency to contract parenteric, still the total number of enteroidea fevers (enterica and parenterica) observed in such individuals is greatly less than in non-vaccinated people or in people vaccinated only with typhoid monovaccine.

Diagnosis.—When a patient is suffering from enteric-like symptoms, while all serological and bacteriological investigations for enteric remain constantly negative, the practitioner is justified in suggesting the possibility of parenteric. The diagnosis, however, should always be confirmed by a complete and repeated bacteriological examination of the blood, stools, and urine, with the object of isolating the causative organism and of determining from what variety of parenteric the patient is affected. We should like to emphasize here that the mere presence of an intestinal germ in the blood is not sufficient to come to the conclusion that this fever is due to that germ. Repeated examinations may show that it is present in association with true *B. typhosus*, *B. paratyphosus A*, or *B. paratyphosus B*, and may have little or no part in the causation of the symptoms, quite a number of fæcal bacteria being capable of entering the general circulation through intestinal ulcers. If, however, the germ not only is found in the blood, but the blood contains specific agglutinins for it, while hæmocultures and serum reactions are constantly negative for enteric, the probabilities are that the germ isolated is the real ætiological agent of the fever.

Prognosis.—This is, on the whole, much more favourable than in enteric (typhoid, paratyphoid A, paratyphoid B).

Treatment.—This should be on the same lines as for enteric. Complete rest in bed and fluid diet are necessary. Drugs are of little or no use except occasionally. Urotropine may be given in doses of 10 grains three or four times a day. The vaccine treatment with autogenous vaccines seems to give better results than in enteric.

Prophylaxis.—As regards general prophylactic measures (sanitary improvements, destruction of flies), these are the same as for enteric. The usual enteric vaccination (TAB) does not, of course, protect against parenteric, and when certain forms of parenteric become frequent the bacteria causing them may be added to the enteric bacilli in the preparation of a prophylactic vaccine.

VARIETIES OF PARENTERIC.

In the general account we have given of parenteric we have stated (see Ætiology) that ætiologically very numerous varieties might be differentiated, but we have limited ourselves to distinguish six chief types in relation to the six principal groups of intestinal bacilli which may cause the condition. We consider, however, it advisable to give a brief separate description of certain varieties of parenteric which have been more completely worked out. These are:—

- Psittacosis parenteric.
- Alkaligenes parenteric.
- Columbensis parenteric.
- Archibaldi parenteric.
- Asiaticus parenteric.
- Khartoumensis parenteric.

PSITTACOSIS PARENTERIC.

Definition.—A very fatal specific epizoötic among parrots, which is capable of spreading to man and causing a febrile condition resembling typhoid fever in its characters, and which is very liable to be complicated with severe pneumonia.

History.—Ritter, in 1879, was the first to suspect that there was a connection between small epidemics of pneumonia limited to certain houses and an illness among parrots in the same houses. In 1880 Eberth obtained large numbers of micrococci from the bodies of grey parrots. Ritter's observations were confirmed by Ost of Berne, in 1882, and by Wagner of Leipsic, in 1885. In 1892, 500 parrots were shipped from South America for Paris, but no less than 300 died *en route* from enteritis. On arrival in Paris the surviving birds were divided into two lots, and sold to various people, with a result that within twenty-six days of their arrival an epidemic of psittacosis broke out, which resulted in forty-nine cases, with sixteen deaths. The epidemic was characterized by being of the *house type*, by which is meant that several persons in the same house were attacked by the complaint.

Smaller epidemics occurred in 1893 and 1894, and in the same year Banti, Malenchini, and Palamidessi reported an epidemic in Florence. In 1895 there were outbreaks at Prato, Cologne, and Paris; in 1897 at Genoa; in 1898 at Cologne; in 1901 at South Elpidio, Ancona, and Hull; in 1904 at New Hampshire, one of the Eastern United States of America. Beddoes in 1914 reported several cases in England. We have seen epidemic enteritis of this nature develop in parrots in the Sudan, but prophylactic measures being immediately instituted it did not spread to man.

Ætiology.—The disease is apparently due to a bacillus belonging to the genus *Salmonella* Lignières of our classification, first isolated from the wings of parrots which had died from the disease by Nocard in 1893, and subsequently found by Gilbert and Fournier in 1897 in the intestine of the sick birds, and also in the heart-blood of a man who died from the disease. The bacillus in question is pathogenic for parrots and other birds. It is possible that this bacillus exists normally in parrots, and only becomes pathogenic under circumstances of bad hygiene, when it causes an enteritis. The feathers, becoming contaminated with fæcal matter, are cleaned by the parrot with its tongue in the usual way, so that its mouth and bill become infected, and by this means the disease is spread to persons who feed or caress the bird. Very rarely the disease spreads from man to man. According to Bainbridge, *Bacillus psittacosis* is identical with *B. aertryke* (p. 954).

Pathology.—In parrots the disease causes a very fatal form of enteritis. In man it produces a septicæmia, often complicated by a pneumonia, brought about as a rule by the pneumococcus.

The post-mortem reveals lobular pneumonia in the lungs, fatty degeneration of the heart-muscle and liver, enlargement and softening of the spleen, and congestion of the kidneys, with swelling of the tubular epithelium.

Symptomatology.—The incubation period varies from seven to twelve days, after which the disease may begin suddenly with a chill, but more usually commences insidiously, like typhoid fever, with headache, malaise, etc., and a rise of temperature from 102° to 104° F., with a pulse-rate of 100 to 120 per minute, quickened respirations, cough, and muco-purulent expectoration. Râles may be heard over the lungs, while the spleen is enlarged, the tongue dry and furred, and diarrhœa or constipation may be present. Rose-coloured spots appear on the skin, and the patient becomes dull and stupid, in which condition he may remain for several days, and as a rule will recover in about fifteen to twenty days if no pneumonic complication intervenes. If, however, pneumonia sets in, the patient becomes much worse, and as a rule dies.

Diagnosis.—The diagnosis is to be made by the discovery of sick parrots in houses in which people are suffering from typhoid-like fevers and pneumonia. Bacteriologically, attempts may be made to obtain cultures of the bacilli from the blood.

Prognosis.—The prognosis is grave in old people and when pneumonia sets in, the mortality being stated to be about 35 to 40 per cent.

Treatment.—The treatment must be conducted on the lines usually laid down for typhoid fever and pneumonia.

Prophylaxis.—Th[illegible]ted parrots appear always to come from South America; therefore [illegible] should be taken that only healthy birds are allowed to be shipped, and that these are kept in good hygienic conditions during the voyage. On arrival at their destination, they should be quarantined for about a couple of weeks, and, if found to be infected, should be destroyed, and their dead bodies and cages burnt. The places in which they were kept should also be thoroughly disinfected. Parrots should not be allowed to take food out of people's mouths, and should always be kept in good hygienic conditions.

ALKALIGENES PARENTERIC.

Remarks.—*B. fæcalis alkaligenes* Petruschky—which belongs to the genus *Alkaligenes* of our classification—is generally a harmless fæcal germ, but researches by various observers have demonstrated that it may occasionally become pathogenic for man, and produce fever. Cases have been recorded by Straub and Krais (1914), by Rochaix and Marode (1916), by Shearman (1916), by Hirst (1917), and others.

Symptomatology.—The fever often resembles a mild type of enteric, and is generally of short duration, twelve to fifteen days, though protracted cases are occasionally met with. At times the temperature is very irregular, subcontinuous or intermittent, and even a tertian periodicity is said to be occasionally present, though possibly some of these cases may have been associated with malaria. The spleen is seldom enlarged, roseola is not present, and intestinal hæmorrhages have never been recorded.

Diagnosis.—This is based on the isolation of *B. fæcalis alkaligenes* from the blood, and the presence of specific agglutinins for this germ, while all bacteriological tests for enteric and other intestinal germs are negative. The bacteriological examination of the blood is carried out as in enteric, either using Castellani's dilution method, details of which have been given when discussing the bacteriological diagnosis of enteric, or one of the modifications of Drigalski-Conradi's bile method. The technique which, in the hands of Shearman, has given good results is the following:—5 c.c. of blood drawn aseptically from a vein is placed in 50 c.c. of a 2 per cent. solution of taurocholate of soda in distilled water, incubated at 35° C. for twenty-four hours, and then plated out on MacConkey's plates. These are incubated for twenty-four hours, and any white colony present is further investigated.

Prognosis.—This is favourable.

Treatment.—The treatment is symptomatic. Vaccines have been tried in a few cases, but no definite results have been so far obtained.

COLUMBENSIS PARENTERIC.

Synonym.—*Febris columbensis.*

Historical and Geographical Distribution.—The disease and its causative germ were described by Castellani in Ceylon in 1905. Spaar published a case in 1914. Recently cases have been recorded in India by De Mello, in Europe, in the Balcanic Zone by Lurie, and in the South of Europe by Conte. It also occurs in the Anglo-Egyptian Sudan.

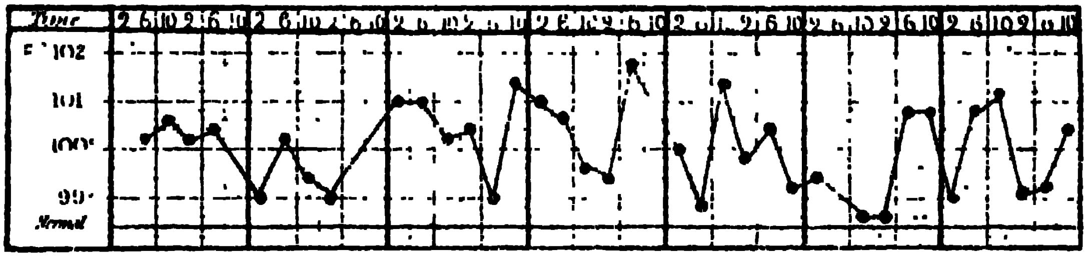

FIG. 663.—TEMPERATURE CHART OF COLUMBENSIS PARENTERIC.

Ætiology.—The causative germ is *B. columbensis* Castellani, 1905. This germ is somewhat peculiar in that occasionally when recently isolated its action on lactose may not be constant, the same strain having at times no action whatever on lactose, at other times slightly fermenting it. After several subcultures all the strains become non-lactose fermenters. It is not agglutinated by typhoid, paratyphoid A and paratyphoid B sera. Its biochemical characters can be found in the table of intestinal bacteria on p. 946. It differs from *B. paratyphosus A* and *B* in producing gas in glycerine and other

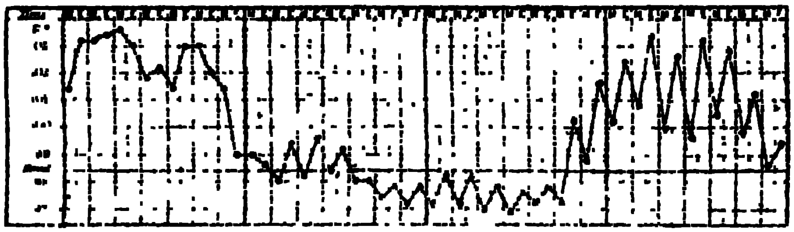

FIG. 664.—TEMPERATURE CHART OF COLUMBENSIS PARENTERIC FEVER.

minor characters. It is not agglutinated by either paratyphoid B or paratyphoid A serum.

Symptomatology.—Two types of the fever may be differentiated, one closely resembling typhoid, the other characterized by numerous relapses. Enlargement of the spleen and meteorism may be present, but are not constant symptoms. Roseola has not been recorded, nor intestinal hæmorrhages. Urinary complications (cystitis, etc.) are not rarely met with. All the cases recorded have ended in recovery.

Prognosis.—Appears to be favourable *quoad vitam*, but in the relapsing type the disease may last for four to six months, the patient having several attacks of fever, each lasting a couple of weeks.

Treatment.—This is on the same lines as for enteric, including complete rest in bed and fluid diet. Urotropine is useful, especially when there are urinary complications.

Prophylaxis.—Castellani has used in Ceylon a *B. columbensis* vaccine in the form of a combined *B. columbensis*, *B. typhosus*, *B. paratyphosus A* and *B. paratyphosus B* vaccine.

ARCHIBALDI PARENTERIC.

This fever and its ætiological agent were described by Archibald in the Sudan in 1912. The bacillus was believed by Archibald at one time to belong to the *B. cloacæ* group. It seems to us probable that the germ belongs to the genus Salmonella of our classification, and that it is related to *B. columbensis* Castellani.

Symptomatology.—As a rule the symptoms presented by the patient are not unlike those of the second week of enteric fever. There is high fever, ranging from 101° to 103° F., associated with drowsiness and perhaps delirium, but this is often absent, with furred dry tongue, but without diarrhœa or tympanites, and with or without some very slight enlargement of the spleen. Sometimes the temperature falls to normal after a week, but this intermission is followed by a prolonged fever of a remittent type, or, instead, the fever may be more or less remittent from the commencement.

Complications.—Complications in the form of pneumonia, abscesses, femoral thrombosis, etc., may occur.

ASIATICUS PARENTERIC.

This fever was differentiated by Castellani in Ceylon by obtaining the specific bacillus from the blood and motions. There are two varieties of the bacillus, which may be called *B. asiaticus* Nos. 1 and 2. (For the specific characters see table in Chapter XXXVI., p. 944.) Culturally these bacilli are identical, but the biological reactions are slightly different. The possibility of a double infection of one of these bacilli or other parenteric germs with those of enteric fever must not be forgotten. The diagnosis will then depend upon the absorption test.

Symptomatology.—*B. asiaticus* No. 1 is associated with a long, protracted, rather low fever of medium severity, which shows usually a remittent or an intermittent character (*vide* Fig. 665). *B. asiaticus* No. 2 produced a fever resembling certain types of protracted enteric fever, but without any enlargement of the spleen, without roseolæ, but associated with rather severe abdominal pains of long duration, though as a rule there is no diarrhœa and the stools never contain blood or mucus.

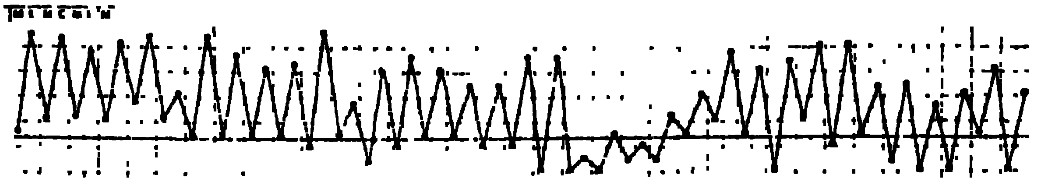

FIG. 665.—PORTION OF TEMPERATURE CHART OF A CASE OF ASIATICUS PARENTERIC FEVER.

One case due to *B. asiaticus* No. 1 was associated with a severe ancylostome infection, while one due to *B. asiaticus* No. 2 was associated with a heavy ascaris infection. The fever did not stop when the patients got rid of the parasites.

Diagnosis.—The only possible method of diagnosis is the early bacteriological examination of 5 to 10 c.c. of the blood taken aseptically from the median basilic vein, and examined as already described for enteric fever, while an attempt may also be made to isolate the bacillus from the fæces. The specific bacillus will be agglutinated by the patient's serum in high degrees of dilution.

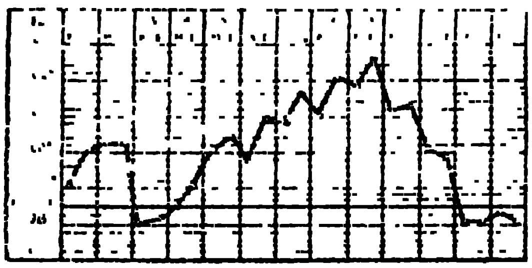

FIG. 666.—TEMPERATURE CHART OF KHARTOUMENSIS PARENTERIC.

Treatment.—The cases must be treated on the lines already laid down for enteric fever, but the most suitable special treatment is the injection of autogenous vaccines prepared like the typhoid vaccines, provided the acute symptoms are over and the fever is of very low type.

KHARTOUMENSIS PARENTERIC.

This fever and its ætiological agent have been described by Chalmers and MacDonald in the Sudan. The germ *B. khartoumensis* Chalmers and MacDonald, 1915, belongs to our genus Enteroides of intestinal bacteria, and is closely related to *B. entericus* Castellani, 1911, and *B. parentericus* Castellani, 1914.

Symptomatology.—After a preliminary period of one to three days, during which the patient suffers from headache, constipation, and malaise, with marked or slight fever, the febrile attack sets in with constipation, headache, and a disinclination for mental or bodily work. The heart, lungs, liver, and spleen remained normal, and, except for the usual febrile changes, the urine was also normal. Except for headache, the nervous system was normal, and no skin eruptions were noticed. The cardinal features of the illness were constipation, fever, relatively slow pulse, headache, malaise, and a general feeling of illness.

After about seven days from the commencement of the true rise of temperature the fever, which had gradually risen to a maximum lying between 101° and 103° F., subsided quickly, and in about another three days fell to normal, when the disease ended, or to nearly normal, and was followed by a relapse of a more irregular and prolonged nature. When the temperature subsided all symptoms gradually disappeared and the patient felt quite well, but if the relapse occurred the headache, lassitude, constipation, etc., returned. At no time was any patient seriously ill, and at no time did a purgative produce other than good effects.

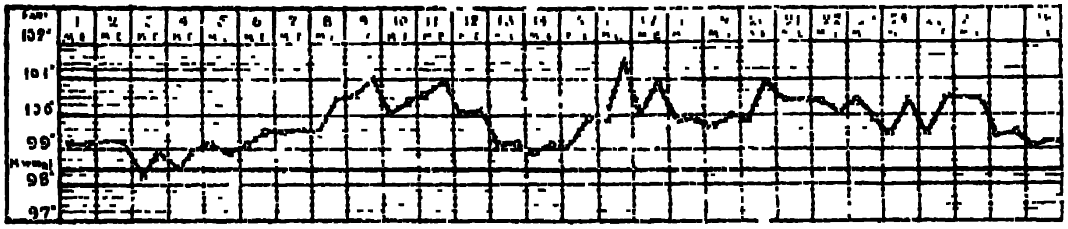

FIG. 667.—TEMPERATURE CHART OF KHARTOUMENSIS PARENTERIC.

The condition somewhat resembles a case of enteric, but the spleen is not enlarged and roseola is not present.

The **diagnosis** is made on finding *B. khartoumensis* in the fæces and by the serological reactions, while all the tests for enteric are negative.

The **prognosis** is favourable.

The **treatment** is symptomatic, but vaccines might be tried.

CHAPTER LIV

PLAGUE

Synonyms — Definition — History — Climatology — Ætiology — Pathology — Symptomatology — Diagnosis — Prognosis — Treatment — Prophylaxis — References.

Synonyms.—Black Death, Pestis, Lues. *French*, La Peste; *Italian*, Peste Bubbonica; *German*, Die Peste; *India*, Mahamari; *Japan*, Yeki; *China*, Kota-wen; *Uganda*, Kaumpuli.

Definition.—Plague is a septicæmia caused by *Pasteurella pestis* Kitasato and Yersin 1894 (usual name *Bacillus pestis*), which produces an epizootic in rats, from which it spreads to man and other animals by the agency of fleas.

In man it causes an acute specific fever, characterized by an inflammation of the lymphatic glands; a secondary septicæmia, with hæmorrhages, skin necrosis, and often a secondary pneumonia; or it may give rise to a primary pneumonia or a primary septicæmia. The pneumonic forms are highly infectious, spreading from man to man by aerial convection.

History and Epidemiology.—Plague, because of its epidemicity and its high mortality, is much feared and has been noticed from early times to be associated with a mortality among rats. Thus, the Bible contains an account of an epidemic disease in the Philistine country which produced buboes in human beings and killed rats ('mice of the field'), and there is also reference in Simpson's work on plague to the fact that Sennacherib's army was attacked by a pestilence in which field-mice were in some way concerned.

But it was not until the outbreak in Pelusium, a great Egyptian market, in A.D. 542, that the disease was seriously considered, for it spread to Byzantium, at that time the city of the world and then passed into Asia, and through North Africa into Western Europe as far as Ireland, lasting in epidemic form for about 200 years.

The next outbreak is in the eleventh century, when it spread as a pandemic, reaching a maximum in the fourteenth century, and gradually declining, until suddenly, in the seventeenth century, it left Western Europe, and in 1844 it vanished from Eastern Europe, and practically from Asia Minor, remaining, however, in the district of Assyr, in West Arabia.

This great pandemic stirred Governments to take prophylactic measures, and Count Bernabo, of Reggio, is found impressing stern quarantine laws in 1374, while the Venetians, in 1403 and subsequent years, laid the foundations of modern prophylaxis by erecting the first lazaretto, or depot for the isolation of the sick, by instituting the quarantine for forty days (hence the term), and by the disinfection of clothing and merchandise. Further, they compelled the ship coming from an infected port to hoist a yellow flag, and to allow an inspection of the crew and passengers before it was given pratique

In the meanwhile plague occurred in India, where the first records are t be found in a sacred Hindu book, the 'Bhâgavat Purana,' believed to be 800 years old, which describes a disease in man associated with death among rats, and advises the vacation of a house in which dead rats are found. Plague is known to have formed epidemics in the eleventh, twelfth, fourteenth, fifteenth, sixteenth, and seventeenth centuries, after which, apparently, it disappeared, only to reappear in Gujurat and Sindh in 1812. In 1823 it was discovered that plague existed in the districts of Garhwal and Kumaon, but no one has been able to determine from whence it came, or how long it had existed in those places. It is now said to be endemic there, and to form the focus for the epidemic of Delhi in 1825, and Rohilcund in 1836. In 1836 plague broke out in Rajputana—the so-called Pali Plague, from the place first infected—and lasted two years. Since then plague has been introduced into India from China, and has spread therein, as will be explained later. With regard to China, it is difficult to obtain any exact information, but it is possible that plague may have been introduced at some time by Mohammedans returning from Mecca via Burma to the province of Yunnan, where, according to Minakata, it was known some time between 1736 and 1809, for a Chinese author who lived during this period gives an account of a disease which caused death in men and rats. From that time plague has been endemic in Yunnan, from which it appears to have spread southwards, reaching Pakhoi on the southern coast, about 1867, where it disappears and reappears at intervals without apparently affecting other regions, until 1894 when, after an absence of ten years, it again reappears and, infecting the district of Kaochao, spre[illegible] Canton to Hong-Kong. In June, 1894, the causative bacillus was discovered by Kitasato in cases in Hong-Kong, and a little later by Yersin in the same town. In 1896 plague spread from China to Bombay, from which it has gradually extended over the larger portion of India, causing an enormous number of deaths.

In 1897 a most important international conference was held at Venice, when protective measures were agreed to, and regulations framed to combat the disease, based upon the view that the sick person and his personal effects were the chief source of danger, and a quarantine of ten days from the last infected port was placed upon healthy ships. In 1898 the pandemic spread from India to Madagascar, and from there to Lorenzo Marquez and Mauritius. In 1899 it affected the Malay States, the Philippine Islands, New Caledonia, the Sandwich Islands, Australia, San Francisco, New York, Asunçion, Rosario, Buenos Ayres, Rio de Janeiro, Oporto, Lisbon, and Alexandria. In 1900 it passed from Rosario to Cape Town, and also appeared in Glasgow.

In 1900 Clemow pointed out that the disease had existed endemically in Mongolia, Southern China, the Himalayas, Mesopotamia, Persia, Arabia, Uganda, Transbaikalia, Russian Central Asia, and Tripoli, between 1850 and 1894.

In 1903 a Second International Conference was held in Paris, which issued a series of regulations confirming those of the Venetian Conference, except that the quarantine of ships was reduced to five days, and that the agency of the rat in the disease was clearly recognized, and regulations for its destruction framed. Further, this Conference established an International Sanitary Office in Paris for the purpose of collecting and transmitting sanitary information to the different countries. In 1904 Johannesburg was attacked, in 1905 Persia and Russia, in 1906 Leigh, and in 1907 Accra, on the Gold Coast, in which year the disease was widespread throughout the world occurring in India, Persia, Arabia, Egypt, Tunisia, Algeria, West Africa, South Africa, East Africa, Russia, Glasgow, Argentina, Brazil, Chili, Paraguay, Peru, Uruguay, United States, Australia, New Zealand, Japan, China, and Indo-China.

Turning to Africa, which has already been mentioned to have been often infected, it is now known to possess two infected endemic areas—viz., Benghazi, in Tripoli, and Buddu, Koki, and Nkole, in Uganda, from the latter of which an epidemic is supposed to have spread into the Kissiba district of East Africa.

Such a pandemic as the one just described could hardly exist without numerous careful inquiries into its causation and spread, for Governments were interested in its prevention. Therefore Austrian, German, and Russian Commissions were appointed, and did excellent work. In 1898 the first Plague Commission of India was appointed, and was followed by an Advisory Committee of the India Office, Royal Society, and Lister Institute, appointed in 1904, and, finally, in conjunction with this committee, the Second Indian Commission was appointed in 1907, and has done excellent work in tracing the ætiology to the rat-flea.

In the meanwhile individual observers had also studied the disease—*e.g.*, Haffkine of India, and Lustig of Florence, had brought forward protective vaccines, while Verjbitski, of St. Petersburg, showed in 1908, the importance of the bug as a carrier of the disease.

Of great value have been the researches carried out in various colonies by Professor Simpson

According to Nicolas, plague is almost constantly present in New Caledonia, where the bacillus is believed to exist in a latent form.

During 1909-10 in Manchuria there was a very severe epidemic of pneumonic plague with a few cases of the bubonic type It was studied by Strong, Kitasato, Teague, Galeotti, and others

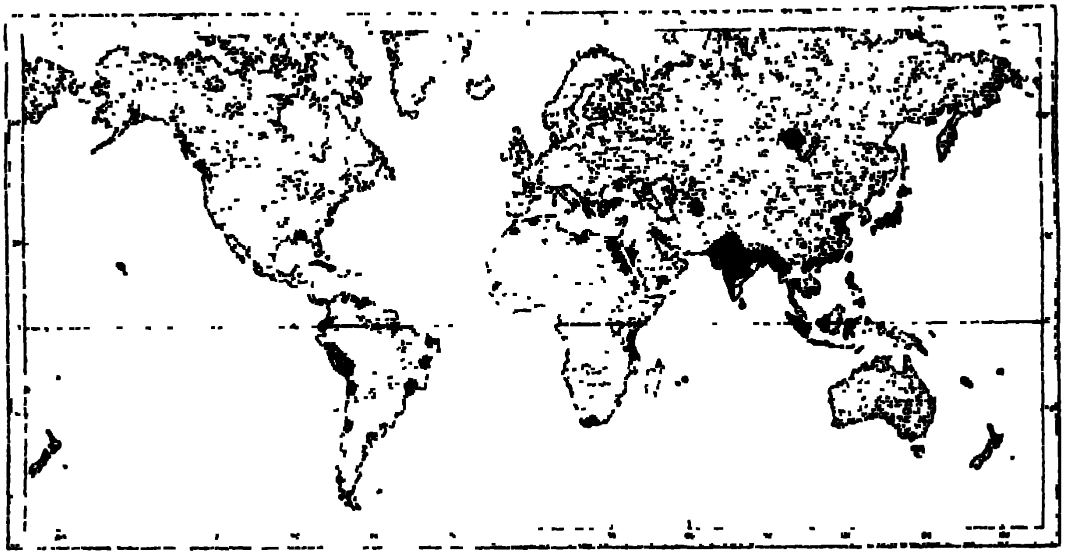

FIG. 608.—DISTRIBUTION OF PLAGUE IN 1914

In 1914 plague appeared in Colombo, Ceylon, where the epidemic was studied by Castellani, who isolated the bacillus, Philip, and Hirst. Several features of the onset were of interest:—

1. The human epidemic was certainly not preceded by a diffuse rat epizoötic, as for years the bacteriological examination of rats had been carried out by the Municipal Health Office with negative results, and it was several weeks after the onset of the human epidemic that the first infected rats were discovered.

2. Practically all the cases were of the acute septicæmic type, and were associated with an extremely high mortality without distinctive features, either clinically or post-mortem; and it is interesting to note that when infection was found in the rats it was also of the septicæmic type, and in them also the post-mortem findings were non-characteristic of plague, there being no buboes, no mottled appearance of the liver, no pleural effusion.

3. The strain of plague bacillus isolated (*B. pestis* Yersin-Kitasato *var. metapestis* Castellani) differed in some minor points from the typical one.

4. The commonest rat flea, as noted by Hirst, was different from that found on rats in the majority of plague-infested areas, such as Bombay, but it is the same as that found in Madras and Rangoon.

Climatology.—At the present moment the so-called endemic regions are an area in the Kurdistan Hills, with a secondary area in Irak, in Mesopotamia; another area about the Himalayas—*i.e.*, Kumaon and Garhwal, in India, Thibet and Yunnan, in China—and four lesser areas—viz., Benghazi, in Tripoli, Uganda, in Central Africa, Azeer, in Arabia, and the trans Baikal Province of Siberia—but only the first two are of real importance as far as we know. On the strength of these two different regions an attempt has been made to differentiate two distinct types of the disease: the first, the Western Asiatic, being mild, and pneumonic cases rare, while it is often self-limited, not capable of wide distribution, and not associated with an epizoötic in rats; the second is the Indo-Chinese plague, or the disease as it is known to-day. It seems, however, hardly likely that such a distinction will be supported when the disease in the first area is carefully studied. Climate appears to have but little influence on the distribution of the disease, and soil apparently none. In India an excessive rainfall seems to favour the spread and virulence of the malady. The hot season of the tropics and the winter season of the Temperate Zone are deleterious to the spread of the disease. The reason for this appears to be the effect of temperature on the bacilli in the flea, which disappear rapidly from its stomach above 85° F., and are very ineffectual at that temperature, while at 70° F. they are virulent. Moreover, as has already been stated in the chapter on Fleas, high temperatures restrain the adults from laying eggs and the larvæ from developing. When temperatures below 50° F. are reached, it is found that rats die before the bacilli pass into the blood, and therefore the fleas do not become infected when sucking the blood. A temperature of about 70° F. is therefore best for the propagation of an epidemic.

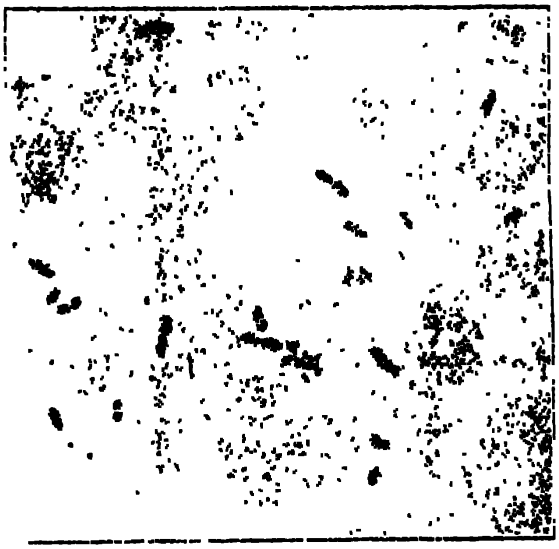

Fig. 669.—Plague Bacilli in the Blood. (× 1,000.)

(From a photograph by J. J. Bell.)

Ætiology (*vide* also pp. 909 and 913).—The ætiology of plague has been placed on a sure footing by the labours of Kitasato, Yersin, Cantlie, Simpson, Thompson, Ogata, Kolle, Martini, and the Special Committee already mentioned, together with the Second Indian Commission.

It is caused by the *Pasteurella pestis* (usual name, *Bacillus pestis*) of Kitasato and Yersin, which is found in the fluid of the initial cutaneous vesicle, the buboes, the spleen, the blood, and the sputum in cases of pneumonia. When inoculated into monkeys, cats, rats, guinea-pigs, squirrels, mongooses, bats, jerboas, etc., it causes the typical disease, while in bovines and equines it only causes local reactions, while camels are insusceptible. Canines, birds, and reptiles appear to be immune. It causes a natural epizoötic in rats which apparently is the true disease, from which that of man must be looked upon as an offshoot. In typical outbreaks there should be, firstly, the *enzoötic;* secondly, the *epizoötic;* then the *endemic*, followed by the *epidemic* in the affected country; and finally *pandemic*. In rats it produces either an acute or a chronic attack, the post-mortem appearances of which are different (*vide* Chapter XXXV.).

In the acute type a bubo is found in 85 per cent. of infected rats, being present usually in the neck or axilla. If the bubo is absent, a plague rat can often be recognized by the subcutaneous congestion, the purplish-red appearance of the muscles, the waxy, mottled, or finely granular appearance of the liver, the hæmorrhages, and the pleural effusions. The diagnosis can be confirmed by finding the bacilli in the bubo, the spleen, or the blood.

The chronic type of the disease consists of encapsuled caseous foci, or abscesses containing bacilli, and found in the spleen and other organs. This form plays no part in the spread of the disease.

The epizoötic does not continue with equal virulence all the year round, for it appears to be profoundly altered by the temperature, being diminished in the hot weather of the tropics and the cold weather of the Temperate Zone. Thus in Bombay the Plague Commission found 1,766 plague infected rats in one week in the season December to May, and only 20 to 30 in the season June to November. The cause of this variation has already been given.

But all rats are not equally infected, for it was found in Bombay that there were two principal species, *Epimys norvegicus* and *E. rattus*, and that during the epizootic period no less than 1,331 of the 1,766 belonged to the former species, while in the non-epizoötic period it alone carried on the disease. The reason assigned for this difference was that the numbers of the flea population of the two rats were very different, *E. norvegicus* possessing about double the number of *E. rattus*. Further, it was noticed that the curve of *E. norvegicus* infection began to rise about ten days before that of *E. rattus*, which points to the origin of the infection of the latter from the former in the first instance.

In Ceylon also the percentage of infected rats was higher in *E. norvegicus* than in *E. rufescens*, the local representative of *E. rattus*, but the septicæmic type was more frequent in the latter.

E. norvegicus, which is not nearly so numerous in Bombay as *E. rattus*, lives outside houses, for the most part in sewers, drains, and stables, and has a great facility for burrowing, and is a good climber. It, however, has never been found above the third floor of a house. It forms its nest in one of its burrows, and breeds all the year round, but has two special seasons, one in March and one from June to October, the average family being eight.

E. rattus is more common in Bombay than *E. norvegicus*, especially in houses, where it increases, relatively to the other, up to the third floor, but above that level it alone infects the house. It is not so common in gullies, compounds, stables, go-downs, and food and tea shops as *E. norvegicus*. The common meeting-ground of the two species appears to be the lower floors of houses, gullies, and go-downs. Though a domesticated rat, it can climb and burrow. It forms its nest in cupboards, heaps of firewood, etc., and breeds all the year round, but especially from June to October, the average family being five.

The spread of the plague from *E. norvegicus* to *E. rattus*, according to the experiments of the Commission, is neither by direct contact nor by air, soil, or food, but solely by the flea. Contact was excluded by placing healthy rats in the same room with plague-infected animals from which the fleas had been removed, when it was found that none of them developed plague. The experiment was kept up for a long time, replacing dead infected rats with freshly infected rats, and, further, the room was never cleaned out, so that the healthy animals lived in contact with the infected urine and fæces, and even ate food polluted therewith, and yet not one contracted plague, thus excluding transmission by contact, soil, and food.

Again, when healthy animals were suspended in cages 2 feet from the ground, so that the fleas could not get to them, or placed on the ground, and surrounded by 6 inches of tangle-foot, over which a flea cannot pass, as it is said to be incapable of jumping more than 4 inches, or surrounded by a curtain of wire gauze so fine that a flea could not penetrate it, and exposed to infection, they escaped, though others not so protected became infected, thus disproving aerial infection. Further, the transmission by the rat-flea was proved by constructing a glass box, inside which two wire cages were placed at a little distance, but side by side, each standing in a tray filled with sand. Each cage had a lid, through which rats, food, water, etc., could be introduced, and the whole apparatus was covered in with fine muslin to prevent the escape of the fleas. A plague-infected rat and a number of rat-fleas were placed in one cage. When this rat died, a healthy rat was placed in the other cage, and after some time the dead body of the infected rat was removed, when it was found that the new rat became infected with plague, and fleas containing bacilli were found upon it. This experiment was repeated many times, 15 per cent. of the exposed rats taking the disease. Further, fleas infected by biting plague rats, when placed upon healthy rats, produced the disease in 55 per cent. of the experiments.

The Commission calculated that the blood of an ordinary plague rat in two-thirds of the cases contains more than 100,000,000 bacilli per cubic centimetre, and that a flea's stomach could hold 0·5 cubic millimetre of blood. Therefore, when the flea gorged itself on the average plague-stricken rat it received at least 5,000 bacilli. These bacilli are found only in the stomach and in the alimentary canal posterior to that viscus, especially the rectum, and escape from the flea solely with the fæces. It was proved, however, that the bacilli multiplied in the body of the flea by allowing infected fleas to feed solely on uninfected rats, a fresh one being supplied each day, when abundant bacilli were found up to the twelfth, and once to the twentieth day, thus proving that multiplication must have taken place, otherwise the original number of bacilli would have become much diluted by the feeds with fresh blood. Further, it was discovered that the proportion of fleas in whose stomach multiplication took place was six times greater in the epidemic than in the non-epidemic season. In the former season the bacilli could be found easily up to the fourth and even to the twelfth day, while in the latter never after the seventh day. Infected fleas were found to transmit the disease for seven to fifteen days.

The method of infection probably is in one of two ways—either fæcal pollution of the proboscis, or else fæcal pollution of the wound made by the proboscis, which was found quite large enough for the purpose of introducing the bacilli into the skin. Martin's experiments tend to show that regurgitation often takes place, due to plugs of bacilli in the œsophagus (see Chapter XXXV.). Both males and females can transmit the disease, but it was found that one infected flea alone was unlikely to do so. The flea most commonly found on rats, and the one by which the infection in these experiments was usually spread, was *Xenopsylla cheopis* Rothschild, but others—*e.g.*, *Ceratophyllus fasciatus* and *Pulex irritans*—were found also capable of causing the disease.

With regard to the spread of the disease to man, the Commission believes that the infection generally comes from *Epimys rattus*, because the habits of that rodent bring it into close relationship with man, and because the curve of its epizoötic begins to rise ten to fourteen days before that of the epidemic. This period is calculated to be made up of three days, during which the flea leaves the dead rat, to which is added another three days, which is the incubation period of plague in man, and five and a half days, which is the average duration of the fatal illness in man.

Xenopsylla cheopis appears to be the flea by which plague is spread from *Epimys rattus* to man. This rat-flea will not merely bite man when it cannot get rat's blood, but is capable of living for three to four weeks on man's blood, and is often found on human beings after inspection of plague-stricken houses.

Further, it is believed that the spread of plague is due, not to migration of rats, but to the carriage of infected rats on ships, and of fleas in merchandise or on human beings. The Commission apparently consider the last to be the most important method.

In Ceylon, as observed by Hirst, the commonest rat-flea is *Xenopsylla astia* Rothschild, which seems to bite man with great reluctance at temperatures over 80° F.

Pneumonic plague, which occurs only in 2·5 per cent. of cases during bubonic epidemics, spreads from man to man by bacilli carried by the air, for Strong and Teague demonstrated that the sputum in invisible droplets containing viable plague bacilli was frequently to be found in the air near a patient. Teague and Barber have shown that the fine droplets of sputum disappear very quickly unless there is a considerable amount of aqueous vapour in the atmosphere, as is found in very cold climates, and hence the tendency for pneumonic plague to spread in those rather than in warm climates. On the other hand, the bubonic or septicæmic is not spread from man to man, but from rats to man. The epizoötic is the real disease, and the epidemic is only an offshoot.

The above ætiology explains fully the predisposing causes of sex, women staying more in the house than men; of house, of season, of climate, and also the carriage of the disease from one place to another by people, fodder, grain, bales of cotton, and clothing, rags, etc.

Verjbitski in 1908 showed that bugs could act as carriers of the bacilli, and this has been confirmed by Jordansky and Kladnitsky, while Walker considers *Clinocoris rotundatus* to be one of [illegible] carriers of plague [illegible] India, having found 22 per cent. infected with *B. pestis* when collected from infected native huts. Moreover, he successfully transmitted the disease from man to the rat by means of *Clinocorus rotundat*

The possibility of lice acting as occasional carriers should not be forgotten. Lice caught on patients suffering from plague have at times been found infected with *B. pestis*.

In California Wherry, McCay, and others have shown that the ground-squirrel (*Citellus beecheyi*) is subject to plague, and that its commonest flea, *Ceratophyllus acutus* Baker, is the vector from squirrel to squirrel, and, further, that this flea will bite man. Further, they record a subacute case of plague in a boy where the infection was believed to be acquired by contact with ground squirrels. With regard to the outbreak in Manchuria and North China, Gray has shown that it started among men who handled the tarbagan (*Arctomys bobak* Müller), which is susceptible to epizoötic plague, and that these men on returning to their homes introduced the disease into three provinces, as pneumonic and septicæmic plague, while it was spread by the agency of the breath and personal contact of clothes and belongings by coolies travelling in parties and sleeping together in overcrowded insanitary inns, especially as the cold of the winter induced an indoor existence. These travelling parties infected adult males who stayed at the inns or were travelling, and so it spread to the ordinary population. No infected rats could be found, in 20,000 examined, while isolation of the patients and their contacts, together with efficient disinfection, were sufficient to diminish the death-rate This shows how important the pneumonic form of plague may be in epidemics, especially in cold weather, but it is also to be noted that, although it starts from association with an epizoötic, it tends to die out without being succeeded by a bubonic outbreak, but it may infect rats and so cause a bubonic epidemic. There has been an epizoötic in Suffolk, in

England, but only a few cases of bubonic plague in man. The tarbagan suffers at times from plague, but the epizoötic is not extensive, and its direct relationship to human plague is negligible. *Spermophilus citellus*, the marmot, is susceptible to plague.

Attention may be called to epidemic diseases in the lower animals due to bipolar staining bacilli, somewhat resembling the plague germ. We have observed one such epidemic in cats in Ceylon in 1904 A bipolar staining bacillus was found to be the cause (*Bacillus felisepticus* Castellani), but the cultural characters were somewhat different from those of the true plague bacillus.

Pathology.- Plague is a hæmorrhagic septicæmia in the rat, which is communicated to the human being by flea-bites. The site of inoculation is sometimes marked by a vesicle, the contents of which contain the *Bacillus pestis* in considerable numbers. The bacilli then travel via the lymphatics to the nearest lymphatic glands, which they may traverse, and, passing through the thoracic duct, enter the blood stream, and cause a septicæmia. More usually they remain and grow in the peripheral lymph sinuses of those glands in which they or their toxins cause degenerations of the cells, periglandular serous infiltration, and, later, degeneration of the walls of the bloodvessels and hæmorrhage. The lymphatic glands are matted together by the exudation from the primary bubo. The glands usually affected are the femoral, inguinal, axillary, iliac, or cervical, which may briefly be classified into the groin, the axillary, and cervical glands.

The Indian Commission points out that the reason why the groin glands are so frequently attacked is simply because they drain the largest skin area, for they say that the areas drained by the glands of the neck, axillæ, and groin are in the proportions of 1 : 1·8 : 5, while the number of cervical, axillary, and inguinal buboes are in the proportion of 1 : 1·[illegible] : 5·[illegible], and that therefore there is no seat of election as to where the plague bacillus enters.

From the primary bubo the bacilli may travel along the lymphatic to the next chain of glands, in which they produce the secondary bubo, and from this they may enter the blood stream via the lymphatics. The bacilli, however, may gain direct access to the blood stream through the injuries to the walls of the veins in the primary bubo. Once the blood stream is reached the disease becomes a septicæmia, and affects the lymphatic glands, forming tertiary buboes: the lungs, causing bronchitis and secondary pneumonia; the spleen, liver, kidneys, skin, and other organs: and, finally, leaves the body through the kidneys, skin, and mucosæ, escaping in the urine, fæces, and sputum (if there is pneumonia), as well as by any discharges or hæmorrhages from the skin. The excretion, via the sputum and saliva, can proceed for a period of at least forty-eight days after the temperature is normal. Further, as in chronic plague in rats, the bacilli may be found in abscesses some two and a half months after an attack. The chemical pathology of the disease is not well known.

Strong, Crowell, and Teague, from a study of the pathology of Mukden plague, have concluded that epidemic pneumonic plague results from inhalation of the bacilli. The primary infection appears to be the bronchi, while it extends along the bronchioles by continuity into the infundibula and air-cells, or through the walls of bronchioles into the lung tissue, causing a peribronchial inflammation. From these centres the infection spreads to the adjacent pulmonary tissue and to the visceral pleura, the bacilli growing rapidly, and causing first a lobular pneumonia and later a lobar pneumonia, while the blood becomes quickly infected, causing a septicæmia. Secondary pathological changes take place in the spleen, bronchial glands, heart, bloodvessels, kidneys, liver, and tonsils, which may at times become primarily affected. No sign of any intestinal plague was found, although plague bacilli must have been repeatedly swallowed in the bronchial secretions and saliva by the patients.

Morbid Anatomy.—The characteristic features of a plague post-mortem are the hæmorrhages and the buboes, which have been studied in detail by Dürck. The skin in the region of buboes and on the head, arms, neck, and shoulders may show hæmorrhages, which arise from the action of the toxins upon the endothelial cells of the vessels. These cells increase in size, and perhaps in number, and some macrophages arise, after which they degenerate, and allow hæmorrhages by rhexis to take place. These hæmorrhages, therefore, may be petechial or diffuse, and will contain bacilli. Besides these, however, vesicles, pustules, or carbuncles, may be seen.

The vesicle arises from the irritation caused by the bacilli in the skin, producing inflammation with exudation, which may go on to pustulation, or, the vesicle drying up, the cutis may become much inflamed and degenerated, forming the so-called carbuncle, which in no respect resembles a true carbuncle.

The primary bubo shows a periglandular infiltration, which may spread from the site of the enlarged glands in all directions. When this gelatinous exudate is cut into, the enlarged glands can be seen matted together, grey or yellowish-grey in colour, with a soft centre and numerous hæmorrhagic spots, or perhaps large hæmorrhages. The secondary buboes are seen to consist of degenerated glands without the œdema, but with endo- and peri-glandular hæmorrhages. The tertiary buboes contain hard hyperæmic glands marked by hæmorrhages.

The muscles of the body, but especially those of the abdominal wall, will be seen to be hæmorrhagic. The spleen is enlarged and congested, and shows hæmorrhages and contains bacilli. The liver may be slightly enlarged and hæmorrhagic, with cloudy swelling and fatty degeneration of the cells. The lungs usually show some bronchitis, and often patches of secondary broncho-pneumonia. The right heart is usually dilated, and the musculature shows fatty degeneration, cloudy swelling, and hæmorrhage. Primary broncho-pneumonia may, however, exist, and be followed by a septicæmia and bubo formation. The stomach is hyperæmic and hæmorrhagic, while the solitary glands and Peyer's patches of the intestine are swollen and the mesenteric glands enlarged. The kidney may be normal, or show hæmorrhages. The nervous system seldom shows any changes, but hæmorrhages and meningitis may occur.

The post-mortem appearances of plague in rats are:—

Bubonic Type.—Lymphatic glands enlarged and hæmorrhagic, liver and spleen enlarged and congested; the former shows granular degeneration of a peculiar nature, and the latter is speckled with whitish spots as seen on section. There is often fluid in the pleural sacs. These features have been found useful in diagnosis of plague rats when microscopical examinations cannot be carried out.

Septicæmic Type.—There are no characteristic macroscopic features, and the diagnosis is solely based upon microscopic findings of the splenic juice and heart blood.

Doell and Warner have applied to the diagnosis of plague infection in rats Ascoli's thermoprecipitation method

In cases of *acute septicæmic type* there is no post-mortem characteristic feature on which the diagnosis of plague may be made or even suspected. The lymphatic glands are not enlarged, though the spleen may be of larger size than normal.

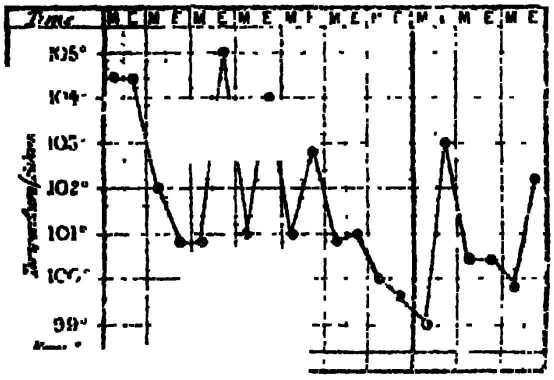

FIG. 670.—TEMPERATURE CHART OF PLAGUE.

Symptomatology—*Incubation.*—The incubation period varies from two to ten days, the average being three days. During this period there may be prodromal symptoms in the form of general malaise, headache, gastro-intestinal disturbance, pain, or feeling of discomfort in the site of the future bubo, chilliness, giddiness, and mental dulness.

Onset.—The onset is usually sudden, with rise of the temperature to 103° to 104° F., pulse of 120, and respirations 30 to 40, and marked prostration, with an aggravation of the prodromal symptoms—*i.e.*, severe headache, furred tongue, vomiting, at times diarrhœa, pains in the back and limbs, and at the site of the future bubo, marked chilliness or a rigor, staggering gait, and marked mental dulness.

Course.—In a few hours the disease becomes properly established, when the patient presents a typical facial expression of fear or anxiety, the eyes being bloodshot, bright, and staring, the face drawn and the nostrils dilated. The temperature rises during the first day, but may remit a degree or so on the second day, but if so, it rises quickly again to the same or a higher degree than at first. As a rule, however, the temperature is most irregular. Towards the end it may fall by lysis, if recovery is to take place, or fall rapidly to normal or subnormal, and then as rapidly to rise about 107° F., or may simply rise directly to about 107° F., and death ensue. There is much thirst, and the tongue is coated at first with a whitish fur, but later it becomes covered with sordes, as do the teeth and lips. Vomiting is frequently met with, as well as diarrhœa; but the abdomen is not tender, unless there are enlarged abdominal glands. The spleen is always, and the liver often, enlarged. Cardiac dilatation is an important feature of the disease, and systolic murmurs may be heard. The pulse is rapid, reaching 120 to 180 early in the disease, and later becoming, in bad cases, not countable. At first it is full and of moderate tension, but later it becomes small, weak, and intermittent.

The coagulation of the blood is diminished. Plague bacilli can be found culturally in about a third of the cases examined. The number of erythrocytes and the amount of hæmoglobin are distinctly increased above the normal, and there is a great leucocytosis—*i.e.*, 90,000 to 100,000 and more—but in the septicæmic form there may be a leucopenia. The leucocytosis is almost entirely due to an increase in the polymorphonuclear leucocytes.

The breathing is rapid, and the breath sounds harsh, with moist râles, but signs of lobular pneumonia and pleuritis may also occur. The sputum in this type of pneumonia is very hæmorrhagic and full of bacilli.

Buboes of varying sizes may be noted in the groin, the axilla, or the neck, and are very painful, respectively causing the patient to lie with the leg drawn up close to the chest wall, or the head bent towards the affected side. They usually appear during the first twenty-four hours, and they may decline or suppurate.

The skin is hot and dry, and may show vesicles, pustules, or areas of necrosis, often called 'carbuncles' (they are, of course, not true carbuncles). Hæmorrhages, in the form of petechiæ or ecchymoses, may be seen under the skin, and epistaxis, hæmatemesis, melæna, and hæmaturia may occur.

The quantity of urine is usually diminished, the specific gravity is high, and plague bacilli may be found. If hæmorrhages have occurred in the urinary tract, there will be erythrocytes and leucocytes, with albumen and globulin, though, apart from this, there is often a trace of albumin present, while anuria is generally present before death. Pregnant women always abort.

Termination.—As the disease progresses the patient becomes weaker and weaker, the mind wanders, and a wild delirium may occur; but later a low muttering delirium passes into coma, and death ensues from the third to the fifth day. In favourable cases the tongue becomes moist and clean, the temperature declines by lysis, the pulse-rate diminishes, and convalescence begins, but may be much prolonged by suppuration of the buboes or by a secondary septicæmia. Even now death may occur from cardiac failure, suppuration, septic infection, or secondary hæmorrhage.

Varieties.—Four variations of the disease are recognized: (1) The ambulatory type; (2) the bubonic type; (3) the acute septicæmic type; and (4) the pneumonic type.

The Ambulatory Type.—This is the mildest form of the disease, and is characterized by but little fever, with slight enlargement and tenderness of a group of lymphatic glands. If the area of skin drained by these glands is carefully investigated, a primary vesicle will often be seen at the site of the inoculation, and considerably helps in the diagnosis, for its fluid contains typical bacilli. The symptoms of this type resemble those already described as prodromata.

The Bubonic Type.—This type agrees with the general description, the bubo being usually in the groin, less commonly in the axilla, and least commonly in the neck. The fever reaches its maximum on the fourth to fifth day, and lasts till the seventh to tenth day, when it falls by lysis, though it may rise again if suppuration is taking place in the buboes. The attitude of the patient depends upon the position of the bubo, as described above.

The Acute Septicæmic Type.—Here the onset is sudden, and the temperature very high, with very rapid pulse, marked prostration, and delirium. There may be severe vomiting, and occasionally diarrhœa. No enlarged lymphatic glands are found, and the diagnosis on clinical grounds may be impossible. Hæmorrhages may at times occur in the skin and from the regions indicated above, and death rapidly takes place in from eighteen hours to three days. This type of the disease is often common at the onset of an epidemic.

The Pneumonic Type.—There are two distinct types of pneumonia in plague—a pneumonia secondary to bubonic plague and a primary pneumonia. This latter begins suddenly without prodromata, after an incubation of two to five days, with chilliness, high fever, headache, anorexia, and rapid pulse. Within twenty-four to thirty-six hours the temperature is 103 to 104 F., and the pulse 110 to 130 beats per minute. Cough and dyspnœa appear within twenty-four hours, when the expectoration is at first scanty, but soon becomes abundant. At first it is only composed of mucus, but it soon becomes tinged with blood and later very hæmorrhagic, and is full of bacilli. The conjunctivæ become injected, and the tongue coated with a white or brownish fur. The breathing is very rapid, and dulness may or may not be present over the bases: the breath sounds are usually tubular and crepitant, and sibilant râles are heard, while the vocal fremitus may be increased. Dyspnœa and cyanosis are early marked features, as is the fluid bloody sputum which is found by the second or third day, and is full of bacilli. Pleuritis, with its usual symptoms, may also occur. Prostration is extreme: the heart becomes very weak and the pulse rapid, while the spleen is usually not palpable. A marked leucocytosis may occur. This is a very fatal type of the disease; delirium and coma appear, and cases die at the end of sixteen hours, two or three or, much more rarely, four days.

Sequelæ.—Cardiac weakness, with proneness to syncopal attacks, paralyses, septic infections of the buboes, or a general septic infection, or gangrene of the lung, may occur.

Diagnosis.—This, in the *bubonic type*, which is commonest, is based on the acute onset with high fever, great prostration, and the presence of a bubo. Difficulty may arise in the diagnosis between the bubonic type of plague and climatic, venereal, and symptomatic buboes; between pneumonic plague and ordinary pneumonia; and between septicæmic plague and various fevers.

In venereal bubo there will be found ulcers on the genital organs, or, at least, the patient will give a history of such. In climatic buboes and various symptomatic buboes due to small ulcerative lesions on the legs, etc., the general condition of the patient is usually far from being so grave as in plague. In any doubtful case bacteriological methods should be employed. A little of the fluid from the suspected bubo is withdrawn, under aseptic precautions, by means of a sterile syringe, and films are made and stained with methylene blue, diluted carbol-fuchsin, or Leishman's stain. The presence of bipolar staining bacilli is sufficient, for all practical purposes, to diagnose the case as one of plague, though it is desirable, whenever possible, to complete the investigation by cultural methods followed by inoculations into animals.

In *pneumonic plague* the expectoration is generally fluid and greatly hæmorrhagic, and is not purulent, as it frequently is in catarrhal bronchitis or in bronchial pneumonia, nor is it tenacious, as in croupous pneumonia: the examination of the sputum—instead of the sputum, the lung juice, obtained by puncture with a sterile syringe, may be examined—will reveal the presence of numerous plague bacilli, easily distinguishable from the pneumococcus by their being Gram-negative.

Acute Septicæmic Plague.—The diagnosis is most difficult, as there are no characteristic symptoms and no glandular enlargements. In a country where plague is endemic any case of sudden high fever, with extreme prostration and blood examinations negative as regards malaria and relapsing fever, should be viewed with suspicion. The fever is generally higher than in dengue or pappataci fevers, often reaching 105° F., while the prostration is much more marked. The microscopical examination of the blood for *B. pestis* is unfortunately often negative, and the cultural examination requires time, and hence the diagnosis may be made too late, as by that time the patient may be dead. It may be distinguished from malaria by the absence of Laveran's parasites, from relapsing fever by the absence of spirochætes, but it is to be noted that cases of mixed infection occur. In India, as observed by Polverini and others, cases of mixed infection of plague and relapsing fever are not rare. The diagnosis between septicæmic plague and cryptogenic septicæmias due to the pneumococcus and other germs, as well as occasionally the differential diagnosis from pernicious malaria, typhus and typhoid, may be impossible without a complete bacteriological examination of the blood.

The simple microscopical examination of thick films of blood (Manson-Ross method) for the presence of bipolar staining bacilli is often a failure. The so-called *dilution method* introduced by Castellani for the search of the *Bacillus* *typhosus* in the blood of typhoid patients is useful also for the search of the plague bacillus, as proved by Kolle and others: 10 c.c. of blood are collected, under aseptic precautions, with a sterile syringe from a vein, and immediately distributed into several flasks of slightly alkaline broth, each containing 300 cubic centimetres of the medium. In this way the bactericidal substances of the blood are greatly diluted, and the growth of the plague bacillus facilitated. Agglutination tests are not of much use in the diagnosis of plague.

In places far from bacteriological laboratories Broquet recommends that a gland or a portion of a gland obtained as soon after death as possible should be placed in a vial containing 125 to 175 c.c. of a mixture of neutral glycerine (30° B.) 20 c.c., distilled water 80 c.c., and carbonate of lime 2 grammes. The mouth of the vial or flask is flamed and sealed with paraffin. On arrival at the laboratory the glycerine is wiped off the gland, which is made into an emulsion with normal saline, and injected, half into a guinea-pig and half into a rat. It is stated that by this method virulence is maintained for thirteen days, which is of great importance in the tropics. A dead animal should be immersed in a solution of strong disinfectant, such as carbolic 5 per cent., in order to kill the fleas, and should then be placed in sawdust or other packing in a hermetically sealed air-tight metal case, and forwarded for examination, if the distance is not too far, to the laboratory.

Prognosis.—Simpson quotes Procopius of Cæsarea as saying, with regard to the plague in Byzantium, that many whose death the physicians predicted recovered, while those who were supposed to be about to recover often quickly died, from which it may be inferred that the prognosis in cases of plague has to be most guarded, for dangers are numerous even in convalescence—*e.g.*, cardiac failure.

The prognosis varies with the character of the epidemic, some being milder than others, and is better when the number of cases is declining. It also varies for the type of the disease, being best for the ambulatory and worst for the pneumonic. As 75 per cent. of the deaths occur before the sixth day, after that time the prognosis improves.

A good pulse, a clear mind, a normal quantity of chlorides and no albumen in the urine, are good signs. High fever, rapid, thready pulse, violent delirium, sudden fall in the temperature, disappearance of the buboes on the fourth or fifth day, and anuria, are bad signs. But in all cases be cautious about the prognosis, and remember the physicians of Byzantium. In pneumonic plague the prognosis is most unfavourable—*e.g.*, in the Manchurian epidemic of pneumonic plague no case in which the bacteriological diagnosis was positive was known to recover.

Treatment.—The treatment should aim at killing the bacillus and neutralizing its toxins, and naturally one hopes to find those requirements supplied by sera. Unfortunately no such serum has as yet been found, though encouraging reports have been recorded by Choksy and Polverini concerning Yersin's and Lustig's sera, and by others concerning Cruz's serum. Whatever the serum, it should be given in large doses (30 to 50 c.c., and even more) by subcutaneous injection. A second and a third injection can be given during the course of the disease, but one should keep in mind the possibility of anaphylactic symptoms in people previously inoculated with serum. Several such cases have been recorded by Darling. The serum may be given also by intravenous injection.

Yersin's serum is prepared by the inoculation of horses with fresh agar cultures, and is such that 0·1 c.c. should protect a mouse from a dose of bacilli, which otherwise would kill it in two to three days. The dose for man is 60 to 300 c.c., given intravenously and also subcutaneously near the buboes. Lustig and Galeotti's serum is prepared by injecting a horse with a vaccine which contains nucleo-proteid from cultures. The mode of action of these sera is said by some not to be bactericidal, but to encourage phagocytosis.

Though admitting that the serum treatment is far from being perfect, we advise its use at the very beginning, as it gives somewhat better results than the ordinary symptomatic treatment or the so-called antiseptic treatment, such as the internal administration of carbolic acid.

As regards the symptomatic treatment, the first indication is to keep the patient in bed, because of the danger of syncope, and to give him good nursing and fresh air. Fever must be treated by sponging and cool or cold applications; buboes by cold applications and ichthyol, and when they suppurate an incision must be made and the wound treated aseptically. Not much good is to be obtained by excising the glands even in an early stage, though several authors—*e.g.*, Terni—have recommended it. The heart's action must be maintained by digitalis, strophanthus, and strychnine. Restlessness may require a hypodermic of hyoscin; hæmorrhage will require treatment by calcium chloride; the so-called carbuncles must be treated antiseptically; pneumonia and bronchitis require the ordinary treatment; and if there is constipation, calomel and a saline purge may be given; while vomiting is to be treated as described under Malaria. A sufficiency of fluid should be given, so as to keep up the action of the kidneys.

The diet should consist of broths and milk, while stimulants are usually required.

Tincture of iodine has been recommended, and is given by oral administration, a few drops at a time, diluted with cinnamon water, and may be given also by intravenous injection, 5 to 7 minims once or twice daily. Eusol has been recommended by Brayne.

Prophylaxis.—*Bacillus pestis* being conveyed by the rat-bite from rats to man as a rule, and more rarely from man to man, it is obvious that prophylaxis must include methods directed against rats and fleas, and methods for the protection of human beings.

The spread of the disease from place to place is thought to be mainly by the flea being carried by human beings on their person, or in their clothing, or by means of the merchandise, or by rats.

The prophylaxis will be considered under two headings—Public Prophylaxis and Personal Prophylaxis.

PUBLIC PROPHYLAXIS.—It is necessary, in order to prevent a country from being infected with plague, to institute a Sanitary Service, which should consist of a central authority for collecting and dealing with information on a large scale, and to which will be attached bacteriologists, who will carry out the necessary bacteriological examinations and prepare prophylactics; and a Port Sanitary Branch, for investigating and disinfecting ships.

It is as well, if possible, to limit the communication with infected areas to as few ports as possible, and to provide isolation hospitals for the sick and for the healthy coming from infected areas. The length of quarantine is fixed at present at five days, but this appears to be too short, if the findings of the Indian Commission with regard to fleas are considered.

Attempts can be made to prevent the disease crossing land frontiers by the medical inspection of persons coming by rail, road, or river, but this method of prophylaxis is liable at any time to break down.

It would appear most necessary to disinfect the clothing and persons of all people coming from infected areas, as they may carry fleas, and this is most difficult to effect, but it is not so difficult to disinfect merchandise by the Clayton apparatus.

In addition, rats must be caught regularly in places situated in danger zones, and inspected to see if any are becoming diseased, for the epizootic begins before the epidemic as a rule.

But of all things the most difficult, as well as the most important, appears to be the recognition of early cases, and pneumonia, buboes, and sudden deaths must be regarded with the greatest suspicion.

When an epidemic begins there are two periods, as Simpson points out, at which the populace takes fright, and has to be firmly handled: one at the beginning, and the second when the deaths begin to increase rapidly in number. Riots and assassinations of magistrates, medical officers, and inspectors may occur, and must be foreseen.

As diagnosis is so difficult at first, a house-to-house inspection by competent medical officers will be necessary to find out the number of cases, and in no instance must a body be allowed to be buried without being viewed by a medical officer. If this is not done, it will be impossible to gauge the extent of the disease.

Rats must, of course, be regularly and systematically examined, and their mortality curves constructed. The sick must be isolated, and the persons and clothing of contacts disinfected to kill the fleas. Every infected house must be disinfected by filling the adjoining houses with the gas from a Clayton apparatus, and after this the house itself. If this method is not carried out, the rats will simply pass from the infected to the non-infected houses, and spread the plague. Village houses might be burnt, which is cheaper and a fairly effective method, though, of course, measures should be taken to prevent the rats escaping. The gas in question is generated by burning sulphur at a very high temperature in a special apparatus, when SO_2 and SO_3 and some unknown gases are evolved, which are passed into the ship, house, warehouse, etc., and drawn through by an exhaust-pipe until a 3 per cent. mixture of gas and air comes out, when the exhaust is stopped, and gas passed in until 10 to 12 per cent.

is reached, at which it is allowed to remain for four hours. For the fumigation of ships it is found to be much more satisfactory if the gas is made to circulate and to penetrate better by means of electric fans and similar devices. This gas kills rats, rat-fleas, and other insects, and plague bacilli, and, if dry, will not injure food-stuffs, except fruit and some vegetables, nor will it harm merchandise or machinery. A mixture of equal parts of cyllin and petrol constitutes a reliable pulicide and bactericide.

Rats may also be killed by means of Danysz's virus, which is a bacillus easily recognized from *Bacillus pestis*, and kills the rat by a septicæmia, causing œdema of the intestinal walls, infiltration of Peyer's patches, and enlargement of the spleen, with sometimes peritonitis, and only then enlargement of the lymphatic glands. Danysz's virus is administered, by Simpson's method, on bread, and is said not to affect human beings, though recently complaints of illness of persons living in places where some sort of virus was being used has been recorded. Danysz's and similar viruses are very often inert and inefficacious in the tropics and require to be exalted by passage through animals before being used.

Bannerman has strongly advised cats as a method of rat extermination, but it must be noted that cats are not refractory to plague.

It appears to us that Black's methods of dealing with an outbreak of plague are the best. First of all, he localizes the outbreak, and begins his prophylactic measures in a circle well outside this area, and works towards the centre. This is of great importance, because beginning in the centre and working towards the periphery merely disseminates the disease. Secondly, he has recognized the fact that rats will not eat food handled by human beings, and therefore the people who handle and cut the bread into cubes prior to dipping it into poison have their hands smeared with oil of aniseed, as is also the board on which the bread is cut. The poison which he has used with great success is phosphorus paste. The phosphorus is mixed with glucose to prevent spontaneous combustion, and then a paste is made with a fatty base such as lard, but it is advisable to vary from time to time the fatty base. To our minds these little points make all the difference between failure and success. Liston advises the centralization and isolation of the stock of grain in villages, and an organization of the system of the refuse disposal, while the stabling of cattle in houses should be prohibited. He lays stress on the disinfection of the clothes of travellers coming from infected areas. Traps equivalent in number to 2 per cent. of the population should be used to catch rats.

With regard to the destruction of fleas in human habitations, washing the floors and walls with crude oil emulsion such as the one recommended by Burke will be found useful, as demonstrated by Jackson and others. Burke's formula is crude oil 80 parts, whale-oil soap 20 parts. The preparation is a jelly mixing freely with water, and a 10 per cent. solution of it will destroy fleas with certainty, as well as other insects. One gallon of the 10 per cent. solution is sufficient to disinfect a room 12 by 12 in a few minutes; the solution may be washed out afterwards with water. Tobacco and infusions of tobacco will also be found useful, as first demonstrated by Castellani and Low when studying the prophylactic measures to be taken against *Pulex penetrans* infections in Africa.

PERSONAL PROPHYLAXIS.—Ever since the middle of the eighteenth century there has been an idea that a vaccine should be obtained for the purpose of protecting the individual. Weszpremi and, later, Samoilowitz and Cerutti tried artificial inoculation, but the results were by no means satisfactory, persons dying from plague as the result of the inoculation. Recently a number of vaccines have been prepared for the purpose of personal prophylaxis, which may be classified into: (1) Vaccines composed solely of the chemical products of the bacilli; (2) vaccines composed of chemical products and dead bacilli; (3) vaccines composed of living attenuated bacilli; (4) polivaccines.

Chemical Vaccines.—In 1897 Lustig and Galeotti prepared a plague vaccine, composed of the nucleo-proteids of the bacilli obtained by shaking agar cultures with 1 per cent. caustic potash solution, and after two hours adding 0·5 per cent. acetic acid, and thus obtaining a precipitate of nucleo-proteids. It is administered by subcutaneous or intramuscular injections in doses of from 2 to 3 milligrammes. This method has been adopted in La Plata with success, and has been experimentally supported by Rowland.

Vaccines composed of Chemical Products and Dead Bacilli.—The most important is Haffkine's plague prophylactic, prepared by growing the bacillus for four to six weeks in broth, and then sterilizing at 65° to 70° C. for one hour, and then decanting into bottles, with or without the addition of a little carbolic acid. The dose for an adult man is 3 c.c., for an adult woman 2 to 2½ c.c., and children in proportion to their age (or size). The injection is made subcutaneously into the arm or loin under strict antiseptic precautions. Three or four hours after inoculation the temperature rises, and in twelve hours reaches 102° to 103° F., while tenderness and swelling may occur at the site of the inoculation, and malaise and general discomfort be felt, which disappear in one to two days, and the swelling in about a week or so. There is no doubt of the benefit of this prophylactic, which gives protection for a considerable number of weeks, and perhaps months, as shown by Haffkine and Simpson. Haffkine considers that the active principle lies in the liquid, but it appears more likely that it is in the dead bacilli. Haffkine's vaccine has been very extensively used in India and other countries since several years, and on the whole has given extremely good results.

The German Plague Commission used a growth of the bacilli on agar killed by heating to 65° C., and then suspended in normal saline, to which 0·5 per cent. carbolic acid was added.

Terni and Bandi used the sterilized exudate from the peritoneum of guinea-pigs inoculated intraperitoneally with plague bacilli, and killed some little time before they would have died naturally. The exudate is diluted with a solution of carbolic acid and sodium carbonate and chloride, and given in a dose of 1·5 to 2·5 c.c. By this method plague aggressins are produced and used.

Klein has advocated an ' organ prophylactic,' obtained by drying and powdering buboes, spleens, lungs, and livers of infected animals. The dose for an individual is from 5 to 7 milligrammes, made into an emulsion with warm, sterile, distilled water, and injected subcutaneously, but it has not yet been tried on man as far as we know.

Vaccines composed of Living Attenuated Bacilli.—Strong and Kolle have recommended the use of living virulent cultures, and Strong has practically shown that this method of vaccination can be carried out without danger. This vaccination consists of the intramuscular injection of one whole twenty-four hour agar slant of the living virulent culture in the adult, and one-quarter to one-half of such a culture in a child. The reaction is not excessive. About ten days after the inoculation Strong has observed a marked rise in the opsonic index, and that the phenomenon of complement fixation is given by the blood serum, thus proving the presence of specific antibodies.

Simpson, Strong, and Kitasato are of the opinion that Governments should unite to deal with plague by attacking it in the endemic centres by general vaccination of the population.

Polyvaccines.—During the contemporaneous epidemics of plague and cholera in Ceylon, in 1914, Castellani used with satisfactory results a mixed bivaccine plague + cholera, using the local strain of *B. pestis*. He also prepared and used a pentavaccine plague + cholera + typhoid + para A + para B, and an hexavaccine containing in addition Malta fever.

The double vaccine plague-cholera consisted of a carbolized emulsion of *B. pestis* and *V. choleræ*, containing per c.c. 1,000 million plague and 2,000 million cholera organisms. One c.c. was given by subcutaneous injection the first time, and 2 c.c. a week later. The pentavaccine consisted of a carbolized saline emulsions of *B. pestis*, *B. typhosus*, *B. paratyphosus A*, *B. paratyphosus B*, *V. choleræ* containing per c.c. 500 million plague, 2,000 million cholera, 500 million typhoid, 250 million para A, and 250 million para B; ½ c.c. was given the first time and double the dose a week later. The reaction was severe, but not more than after Haffkine's monovaccine. The inoculated persons developed immune bodies for the five diseases. The penta- and hexavaccines have recently been further investigated by Castellani and Taylor, *Journal of Tropical Medicine*, November 1, 1917.

Masks.—These used to be worn in the Middle Ages as a prophylactic measure, the use of which has been demonstrated by Strong and Teague, and by Barber and Teague, in epidemics of plague pneumonia. The best mask is a hood of heavy Canton flannel-cloth covering the entire head and tied round the neck, and provided with a window in front composed of sheet celloidin.

CHAPTER LV

UNDULANT FEVER

Synonyms—Definition—History—Climatology—Etiology—Pathology—Symptomatology—Diagnosis—Prognosis—Treatment—Prophylaxis—Para-undulant fever—References.

Synonyms.—Mediterranean fever, Malta fever, Melitensis septicæmia, Melitococcæmia, Bruce's septicæmia, Goat fever, Mountain fever, Slow fever (Texas), Gibraltar fever, Neapolitan fever, Cyprus fever, Munhinyo (Uganda). *Latin:* Febris Undulans, Febris Sudoralis, Septicæmia Melitensis. *French:* Melitococcie, Fièvre Caprine, Fièvre Cipriense. *Italian:* Febbre Mediterranea, Febbre Maltese. *German:* Malta Fieber.

Definition. Undulant fever is a chronic, rarely an acute, febrile disorder, with many undulatory relapses, caused by *Micrococcus melitensis* Bruce, 1893, and probably other closely allied germs, and usually spread by the agency of goat's milk.

Remarks.—It seems certain that, like enteric, the term 'undulant fever' may cover in reality a group of infections due to very closely allied germs. Nègre and Raynaud have described a *Micrococcus paramelitensis*, and previously to them Sergent and Zammit a *M. pseudomelitensis*. These germs have been proved to differ biologically from the common type of *M. melitensis* by means of agglutination and absorption tests.

History.—Undulant fever has probably existed in the neighbourhood of the Mediterranean for centuries, and passages are cited from Hippocrates recounting cases of long-drawn-out fevers, with short apyrexial intervals lasting as long as 120 days, which may perhaps refer to the disease.

In the eighteenth and the early part of the nineteenth centuries references were made to protracted fevers occurring in Malta by various observers—*e.g.*, Howard in 1786, Hennen in 1816-25, Davy in 1842-62—but it is difficult to be certain what disease is referred to. During the Crimean War there appears to have been a very large temporary increase of the fever incidence in Malta, much of which was undoubtedly enteric, but some of it was not. The change in the type of fever appears to have been so marked that some people thought that a new disease had been imported from the Crimea by the returning troops.

In 1859 Marston, who personally suffered from the fever, first gave an accurate account of its clinical history and post-mortem appearances under the term 'Mediterranean remittent' or 'gastric remittent fever,' distinguishing it clearly from enteric and what he called 'Maltese fever.'

From this date there seems to have been much confusion, for it was often diagnosed as some form of rheumatism, but the disease appears to have been clearly recognized by Boileau, Chartres, Thomas, and others. In 1879 Veale gave an account of it as seen in invalids at Netley, as did Fazio in Naples, who not merely described the disease, but suggested that it might be found to be of bacterial origin.

In 1886 it was proved to be a separate pathological entity by Bruce, who discovered a micrococcus in the spleen. In 1887 he found the organism several times, and was able to cultivate it on agar-agar, and to reproduce the disease by inoculation in monkeys, from which he again obtained the organism in pure culture. In 1889 he published the first full account of the clinical symptoms, and in 1891 he grew the micrococcus from blood aspirated from the spleen during life. Thus, Bruce proved that this organism, which he called *Micrococcus melitensis*, was the true cause of the fever.

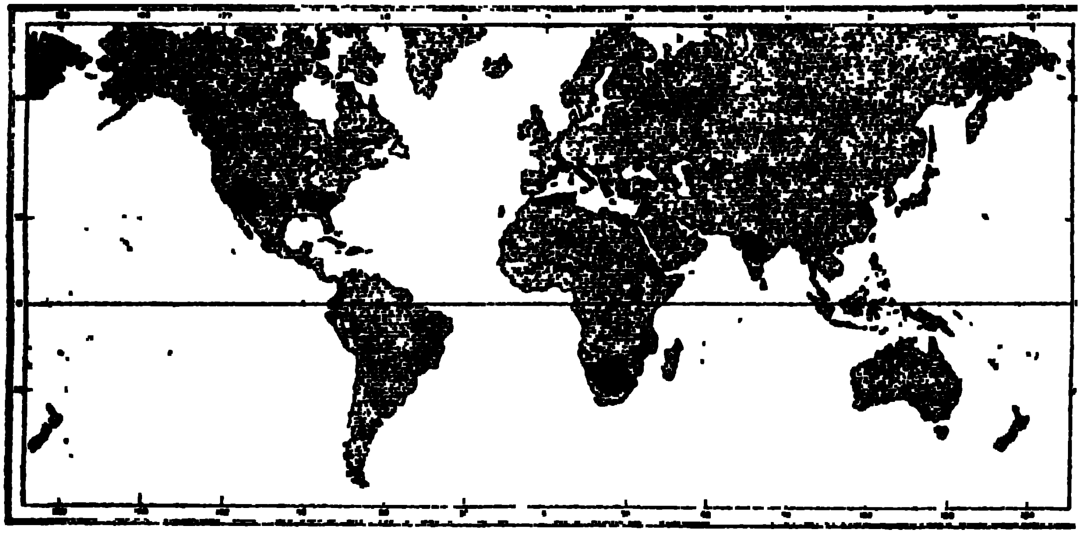

FIG. 671.—DISTRIBUTION OF UNDULANT FEVER.
(After Bassett-Smith.)

In 1897 Wright and Semple showed that the disease could be diagnosed by the agglutination of the micro-organism by the serum of patients, and in the same year Hughes published a full historical and clinical account.

In 1904 a Commission was appointed by the Admiralty, the War Office, and the Civil Government of Malta to investigate the disease. This Commission (J. C. Kennedy, Zammit, Horrocks) demonstrated that the micrococcus leaves the body mainly in the urine, and is then capable of existing for a long period outside the body. Zammit discovered that the milk of many goats agglutinated *M. melitensis*, and Horrocks isolated the germ from such goats. It does not appear to affect injuriously such animals living in the blood-stream, and also occurring in the milk, by means of which the disease is conveyed to man.

Eyre has made the suggestion that undulant fever was primarily a disease of the goat, which had its origin in the Persian hills, and has been carried by these animals all over the world.

Prophylaxis on the lines indicated by the ætiology has resulted in the reduction of the disease in British troops in Malta from 643 cases in 1905 to 7 cases in 1907, and 1 case in 1910. In 1906 Lamb and Pai proved that the organism existed in India in men, while Foster did the same for goats.

In 1912 Bassett-Smith drew attention to the fact that, though the disease has been reduced by prophylactic measures in some places, it had spread to (or been diagnosed in) Spain, Portugal, and France. In the same year Nègre and Raynaud described *M. paramelitensis*, and their findings have been confirmed by Bassett-Smith, who has fully described a case of para-undulant fever contracted in the South of France.

Climatology.—The endemic areas of the disease are, undoubtedly, firstly, the coasts and islands of the Mediterranean, Italy, France, Greece, Spain, Northern Africa, the Levant, etc.; and, secondly, India, especially the Punjab, where the causative organism has been obtained in human beings and goats. We have met with cases in Ceylon. Recently it has been reported from many other parts of the world—in fact, it may be said to be cosmopolitan, and to extend into the interior of the continents. A case contracted in Northern Nigeria has been reported by Low.

It is certainly a disease of tropical, subtropical, and temperate climates, and exists, in addition to the localities mentioned, in Russia, East and South Africa, Uganda, where it is called 'munhinyo,' the Sudan, Mauretania, China, the Philippine and Fiji Islands, North and South America, and the West Indies. It occurs all through the year, but is more common in the warm weather in Malta.

Ætiology.—The cause, as has been indicated in the history, is *M. melitensis*, and some extremely closely allied bacteria, *M. paramelitensis* Nègre and Raynaud, 1912, and *M. pseudomelitensis* Sergent and Zammit, 1908, which can be differentiated by agglutination and absorption tests. *M. melitensis* is found in the spleen, liver, kidney, lymphatic and salivary glands, the blood, bile, fæces (rarely), and probably in the alimentary canal (as Eyre's researches on rabbits indicate), the urine, and the milk. It does not occur in the expired air, the sweat, the saliva, or in scrapings from the skin.

It can be inoculated, and it may be found in the stomach of mosquitoes which have fed upon patients, but neither they nor any other biting fly, such as a *Stomoxys*, or a flea, have been proved capable of spreading the disease. It is, however, very resistant, and can live for eighty days in dust, or in water, fresh or salt, for a month, but has never yet been found naturally in air, dust, soil, or water, neither have any of these in a natural way been proved capable of spreading the disease. It is, however, true that dust, infected with damp organisms from a culture, has infected monkeys, as have suspensions of the organism when applied to mucosæ of the nose or throat. It appears, however, to be best conveyed to animals in food, especially milk.

The organism has also been found by the serum reaction to be present in 50 per cent. of the goats examined in Malta, and has also been obtained from the milk of 10 per cent. of the goats investigated, and, when looked for, it has been found in the blood of goats and other animals. The milk of such animals contains agglutinins for the germ (Zammit's lacto-reaction). Notwithstanding this infection, the animals are quite healthy, though a chronic mastitis, as observed by Neri, may occasionally be noted. It appears to be conveyed to man by infected milk, the best evidence in favour of which is the infection of a ship's crew by the milk of goats, which were being conveyed from Malta to America, 53 per cent. of which were found to be infected.

The distribution of the disease, therefore, depends upon the consumption of infected goat's milk, for people who use this milk will be more liable to infection than others—hence its occurrence in Malta and the Mediterranean districts, in South Africa and India. This is also the reason why the richer classes are more affected than the poorer, and why individual institutions are picked out. It also explains why there is no age or sex incidence, why infants rarely suffer, and why occupation and surroundings have but little influence.

How the disease spreads from goat to goat is not known. Brumpt states that they drink human and animal urine if deprived of salt, and in this way the infection may be kept up. The percentage of infected goats has been found to be 3·4 per cent. in Algeria, 29 per cent. in St. Marthal, 30·7 per cent. in Tunis, 34·2 per cent. in Marseilles, and 50 per cent. in Malta.

Mules, asses, horses, oxen, cows, dogs, rabbits, and fowls, are all apparently capable of spreading the infection, while often they do not show any sign of disease.

The question of the human carrier is only just coming forward with any degree of prominence as a factor to be considered in the spread of the disease, but Shaw has drawn attention to this possibility in Malta, where many of the dock labourers showed agglutinins in their blood for *M. melitensis*, and Missiroli has obtained the micrococcus from the blood of an apparently healthy man who subsequently developed the fever typically in fifteen days.

The carriers and ambulant human cases may pass the *Micrococcus melitensis* in the urine, infecting the soil, and in this way may convey indirectly the malady to other persons.

Four modes of infection are described: (1) By the alimentary canal, which is the usual method; (2) by the respiratory system, inhaling dust contaminated by goat's urine, which is rare; (3) by the cutaneous system, which is very rare; (4) by sexual intercourse, which is possible.

A variety of *M. melitensis*, called *M. paramelitensis*, is described by Nègre and Raynaud as the cause of a variety of fever termed 'para-undulant fever' (see p. 1447).

Pathology.—The micrococcus enters the blood-stream via the mucosæ of the alimentary canal, and causes a genuine septicæmia, with enlargement and congestion of the spleen as the most marked feature; so that the disease somewhat resembles typhoid fever in many of its characters, without, however, producing such typical intestinal lesions as that disease. According to some authors (Ross, etc.), the germ can be conveyed by mosquitoes, but this has not been proved. For clinical and experimental reasons Bruce believes that one attack produces an immunity, but Manson and Bassett-Smith doubt this. The organism produces hæmolysins, while the reaction on the part of the body is shown by the formation of agglutinins, which may last from four to ten years, and a specific serum, which may be useful for immunization. There is also an immune body in the blood suitable for complement deviation, and this corresponds generally with the quantity of the agglutinins.

Morbid Anatomy.—The morbid anatomy shows an enlarged and congested spleen, some congestion of the liver, kidney, and mesenteric glands, duodenum, jejunum, large intestine, and lungs. The spleen is usually much enlarged, weighing from 10 to 44 ounces. It is dark red in colour, and may be soft and friable, and is very congested, with enlarged Malpighian bodies. The liver is congested and enlarged, and shows cloudy swelling, with a round-celled infiltration between the lobules. The kidney is congested, and may show a glomerular nephritis. The alimentary canal may not merely be congested, but the colon may also be ulcerated, particularly in cases of hæmorrhage. The lungs are congested, especially at the bases, and may show patches of consolidation.

Symptomatology—*Incubation.*—Monkeys fed with infected milk require an incubation of fifteen days, while in human beings the period, according to Johnstone, is fourteen days. The prodromata are usually malaise, chilliness, headache, muscular pains, and dyspepsia.

Onset.—The onset comes on gradually, and the patient continues his work though feeling ill, while the temperature rises in a ladder, being higher each evening, and remitting somewhat in the morning. About the fourth or fifth day of the illness a doctor is consulted for the headache, and pains in the body and limbs, which may have been thought to be rheumatic. The patient looks ill, and his temperature is found to be about 103° F., his pulse 80 to 90, and his tongue coated dorsally with a white fur, while the edges are red, and may be indented by the teeth. There is usually a slight sore throat and a tender epigastrium, with some bronchial catarrh or congestion of the lungs, and enlargement and tenderness of the spleen, which develop in the course of a week or so.

Course.—All these symptoms continue for about a couple of weeks, the temperature remaining high—103° to 105° F.—but at the end of this period the fever declines, and the temperature may become normal, while the patient feels much better. In a day or so, however, a relapse occurs with much the same symptoms as the attack. This relapse subsides, and another follows, relapses and intermissions recurring for months.

The temperature now becomes undulating, with a marked rise at night and fall in the morning, while the patient becomes more and more anæmic, weak, and wasted. The alimentary canal is irritated, as is shown by the dyspepsia and the constipation or diarrhœa. The throat may be sore, the gums spongy, and bleed on pressure; the spleen is often enlarged and painful, and the lung may show signs of bronchitis, and occasionally lobular pneumonia, while the heart is easily excited, and hæmic murmurs are heard. The patient shows signs of prostration and headache, and pains all over the body are felt. Insomnia and hysterical emotions are not uncommon, but actual delirium is not usual, and the memory may be impaired, while neuritis—*e.g.*, sciatica—may occur. The skin is pale but damp, due to local or general perspiration, which is very common, and occurs with each remission of the temperature, the sweat being of a peculiar disagreeable odour. Sudamina is not uncommon after the third week. Desquamation may occur, as well as prickly heat, boils, bedsores, subcutaneous abscesses, or hæmorrhages.

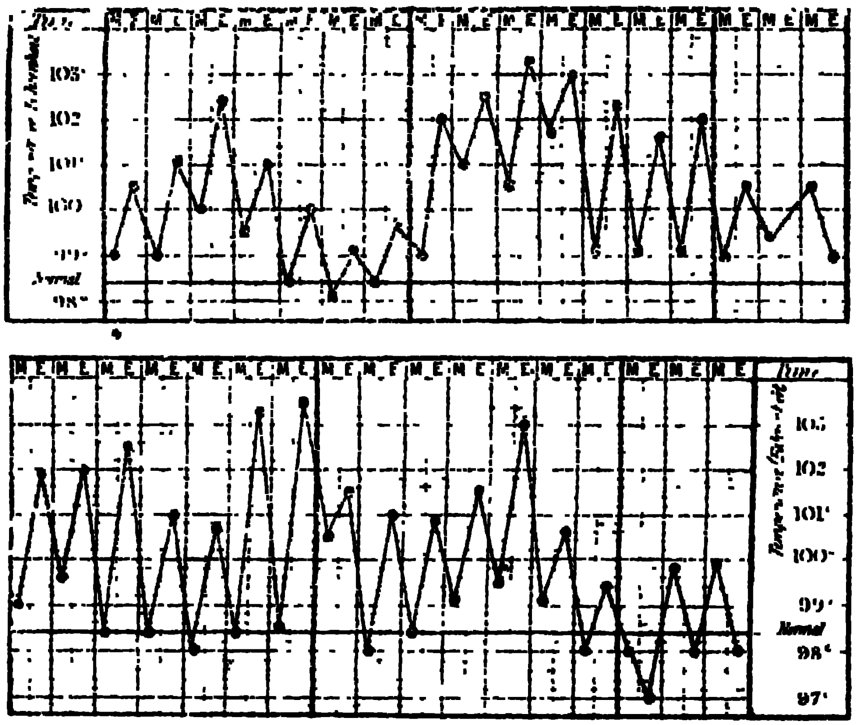

FIG. 672.—TEMPERATURE CHART OF UNDULANT FEVER.

The joints may become swollen and very painful, but the skin over them is seldom reddened. Of all the joints the hip, shoulder, ankle, and knee appear most commonly affected. Inflammation or neuralgia of the testes may occur, and at times the parotid also becomes inflamed.

The blood has been more particularly studied by Bassett-Smith and Gabbi, who find a secondary anæmia with a loss of 20 to 40 per cent. of the corpuscles, with some poikilocytosis and an even greater reduction of the hæmoglobin. The leucocytic count is normal, but there is a decrease in the polymorphonuclears, and an increase in the mononuclears up to as much as 80 per cent. in some cases. Phagocytosis is said to be diminished, as is also the bactericidal power of the blood.

The urine is passed in fair quantity, and has a slightly acid reaction, with a deposit of urates and phosphates, but there is very seldom any albumen, though bile may be present in severe cases, and the specific germ can be found in the urine even two years after an attack. Albuminuria and nephritis may occur, and very rarely hæmaturia.

The patient is now anæmic, and prostrated by the repeated attacks of fever, when gradually the symptoms begin to improve, the intermissions lengthen, the attacks lessen in length and severity, the temperature becomes normal or subnormal in the morning, rising a little at night. Gradually the evening rise diminishes until it stops, the tongue clears, the symptoms abate, and convalescence begins after an illness of from 20 to 300 days, with an average of 90 days.

Varieties.—Two varieties distinct from the typical description given above are recognized by Hughes viz., a malignant and an intermittent—to which a third or ambulatory variety may be added.

The Malignant Variety.—Suddenly, without warning, the patient is attacked with high fever, the temperature rising to 104° or 105° F., with severe pains all over the body, flushed face, and all the other symptoms already mentioned, but in an aggravated form, and often associated with basal pneumonia, and diarrhœa with offensive stools.

After a little the symptoms abate somewhat, but instead of improving, the pulse becomes intermittent, the breathing is laboured, and vomiting becomes serious, and the patient gradually passes into the typhoid state, when hyperpyrexia sets in, and death takes place from the fifth to the twenty-first day of the illness.

The Intermittent Variety.—The onset in this variety is very gradual. When the attack is fully developed, the temperature is about normal in the morning, but rises in the afternoon to 99° or much higher, up to 105° F., this rise being accompanied by malaise, irritability, and chilliness. During the night sweating occurs, and the temperature falls to nearly normal. This fever continues usually for about six weeks, but may be prolonged for about six months, and is usually unassociated with any serious symptoms—in fact, so mild may the attack be that it is not discovered until the patient's general health begins to be unsatisfactory, and he seeks medical advice.

The Ambulatory Variety.—Apparently at times the organism may produce such little effect that the infected person may be unaware that he is suffering from any complaint, and may pursue his daily vocation. Thus, out of 525 dock-hands examined by Shaw at Malta for the serum reaction, 79 gave positive results; and of 22 tested, 9 contained the organism either in the blood or urine, or both.

Complications.—Ulcers may, though rarely, occur in the small and large intestine, and give rise to hæmorrhage, while persistent vomiting, diarrhœa, hyperpyrexia, pneumonia, pleuritis, effusion, and cardiac failure all form serious complications. Orchitis is common. As shown by Frotta, the micrococcus may occasionally acquire a pyogenic action, and cases of suppurative localized periostitis have been recorded similar to those seen in enteric infections.

Sequelæ.—Paralysis, neuritis, common in Cairo, wasting of muscles, loss of memory, tremulousness, and neurasthenia are possible sequelæ.

Diagnosis.—The principal clinical signs on which to base a diagnosis are the prolonged undulant character of the fever, the profuse sweatings, and the articular symptoms.

Bacteriological methods of diagnosis should be always resorted to whenever possible. The agglutination reaction, if the blood is sufficiently diluted (at least 1 in 80), the test properly performed and carried out, using a known and reliable strain of the germ, is, in our experience, sufficiently certain. The agglutination test must be performed in a dilution of at least 1 in 80, otherwise errors in diagnosis will result. Bassett-Smith recommends a high dilution (1 in 1,000), but in our experience 1 in 80 is generally sufficient, with a time-limit of thirty minutes. This reaction is said to last for a very long time *i.e.*, two to seven years. Birt and Lamb have made this serum reaction the basis of prognosis, which is considered to be unfavourable if continuously low, or rapidly altering from a high to a low figure. Agglutinins are present also in the saliva (saliva-reaction of Polacci and others). Whenever possible the agglutination test should be carried out in various dilutions, to avoid results caused by a paradoxical reaction— viz., the possibility of the serum agglutinating in high dilutions and not in low or medium dilutions. In any doubtful case the blood should be investigated for the presence of *M. melitensis*, using nutrose media or Castellani's dilution method, as in enteric infections (see p. 1390). In case of a negative result, the examination should be repeated at least three times at different periods of the disease.

Nicolle and Conor consider that many of the errors are due, firstly, to leaving the serum in contact with the clot, and state that either the blood should be used at once or the serum separated from the clot; and, secondly, in order to prevent obtaining positive reactions with non-undulant fever serum, that sera, to be tested, should be heated to 56° C. for half an hour in order to destroy the non-specific agglutinins, as first recommended by Nègre and Raynaud.

symptom. The physical examination of the patient will reveal nothing abnormal, apart from, occasionally, signs of slight anæmia. The liver and spleen are not enlarged. In a few cases some superficial lymphatic glands may be slightly enlarged. In some cases the red blood cells are decreased. An interesting feature in most cases is the distinct increase in the number of eosinophile leucocytes, even when no evidence of intestinal worms can be found in the motions. The course of the fever is very long. We have seen cases lasting six months.

Diagnosis.—This fever may be diagnosed from *Malaria* by the absence of Laveran's parasites, and by the fact that the spleen is not enlarged; from *Malta fever,* a type of which it closely resembles clinically, by the absence of the *Micrococcus melitensis* in the blood, and the constant negative result of Wright's reaction: from trypanosomiasis by the absence of trypanosomes; from low fever of tubercular origin by the negative cutireaction.

Prognosis.—This is good—*quoad vitam*—but the patient feels weak, tired, nervous, and unfit to do his work properly for months.

Treatment.—A change of climate is always beneficial, and often quickly stops the fever. A long course of injections of quinine cacodylate is useful in many cases. The ordinary preparations of quinine by the mouth or by injection do not influence the fever in the least.

HIGH INTERMITTENT NON-MALARIAL FEVER.

Remarks. This fever has been described by Castellani in 1909 in children in Ceylon.

Symptomatology. Apart, perhaps, from slight anæmia, the child does not show any symptoms except the fever. He takes his food well, runs about and plays, and seems apparently in his usual health. The fever begins in the late morning, and lasts several hours every day, reaching 103° to 104° F. and more. There is no shivering fit at the onset, nor perspiration when the temperature falls to normal. The blood does not show anything abnormal, except, occasionally, a slight degree of anæmia. The course of the fever is very long, lasting at times several months.

Treatment.—Quinine does not influence it in the least. As a rule, a change of climate stops the fever almost immediately.

MOSSMAN FEVER.

Synonym.—Endemic glandular fever.

In 1910 Smithson described a fever, which he called Mossman fever, and which was characterized by an irregular remittent fever of three to twenty-one days' duration, accompanied by painless enlargement of the posterior or subscapular group of axillary glands, which were tender. The symptoms were mild, accompanied by a macular or vesicular rash. It almost exclusively affects sugar-cane cutters. The blood is normal and the death-rate is low, but it may end fatally, apparently from a form of septicæmia. It affects white and black people in the endemic area. The incubation period is six to ten days, and the onset is sudden or gradual.

The mortality is less than 1 per cent., and an attack confers a slight immunity. It is thought that it may be due to some insect on the cane. The dermatitis often found in cane cutters is described in Chapter XCIV. on p. 2163.

In 1913 Clarke described this disease more fully, and in 1914 Breinl, Priestley, and Fielding gave a longer account.

NASHA FEVER.

Synonyms.—Nakra fever, Nakhra Jawhur.

Remarks.- Under the above terms Fernandez, in 1894, described a fever characterized by swelling of the nasal mucosa as occurring in Bengal.

Climatology.—It is found mostly in the months of April to August, and is rare in the cold weather.

Ætiology.—The causation is unknown.

Symptomatology.—The illness is ushered in by a chill associated with high fever and hyperæmia, with swelling of the mucosa of the nose, and pains in the head, neck, shoulders, and small of the back. The face is flushed, the pupils contracted, and there is an eruption of small papules, often accompanied by bronchial symptoms.

The fever, which is usually remittent in character, disappears in three to five days, when the nasal swelling also subsides.

Relapses may occur in one to four weeks, and sometimes a severe relapse may end in delirium, coma, and death.

Treatment.—A saline purgative and a mild diaphoretic are first administered, and then the nose is sprayed with iced water two to three times a day, or the congestion is relieved by pricking the mucous membrane. Tannin and 10 per cent. cocaine solution may also be applied to the nasal mucosa.

TIENTSIN FEVER.

A somewhat similar fever has been reported by A. C. Fox from Tientsin, but in his cases the fever lasted from ten to fourteen days. He thinks it may have been a paratyphoid infection.

It is characterized by sudden onset, remittent fever for ten to fourteen days, frontal headache, constipation, slow pulse. The constitutional symptoms are slight, relapses are rare, and the mortality is nil, while convalescence is rapid. It occurs in persons inoculated against typhoid and having no malaria. It may be enteroidea.

WHITMORE'S FEVER.

Synonym.—Morphine injector's septicæmia.

Whitmore, in 1915, has described several cases of a glanders-like disease in Rangoon, characterized by intermittent fever, bronchopneumonic symptoms, and often multiple abscesses in various parts of the body. The bacillus isolated seems to be very similar to *B. mallei*.

In 1915 Knapp came to the conclusion that this fever might exist in other parts of India, and showed that the disease is due to the contamination of the hypodermic syringe.

WOOLLEY'S FEVER WITH JAUNDICE.

This fever was described by Woolley as occurring in the Andaman Islands. He thinks that it is separate from malaria.

Jaundice appears on the third to fourth day, and in bad cases there are hæmorrhages, delirium, and a rapid pulse, while 40 per cent. of the cases die.

It seems to us that it must be *Febris castrensis gravis*—*i.e.*, Weil's disease.

THE MACULAR FEVER OF TUNISIA.

Synonym.—La fièvre boutonneuse de Tunisie.

Definition.—An acute febrile disorder of unknown causation, characterized by a peculiar macular eruption on the abdomen, palms of the hands, and soles of the feet, which often persists for several days after the temperature has fallen to normal.

Remarks.—This fever was described by Conor, Bruch, and Havat in 1910 in Tunisia, and by other persons more recently.

Ætiology.—The causation is unknown, and inoculations into monkeys were negative.

Symptomatology.—The onset is sudden and accompanied by rigors, fever, pains in the joints, injection of the conjunctiva, nausea, vomiting constipation, and insomnia. The rash appears on the second to fourth day in the form of rose-red or dark red spots about the size of a lentil, which disappear on pressure. The blood shows a lymphocytosis of about 35 per cent. These spots appear upon the abdomen and the palms of the hands and feet. After lasting about two weeks the temperature falls to normal, and after a few days the rash dies away without any desquamation.

Diagnosis.—The characteristic feature of this fever is the distribution of the eruption and the fact that it frequently persists for several days after a normal temperature has been reached. It most nearly resembles Brill's disease—that is to say, a mild form of typhus fever—which, indeed, it may well be.

Prognosis.—This is good.

Treatment.—The treatment is purely symptomatic.

TACAMOCHO FEVER.

In 1918 Henao gave an account of five cases of a fever at Tacamocho, on the Antioquia Railway, Colombia. It was characterized by high fever, vomiting, intense headache, and diarrhœa. The vomit might have blood in it or might be bilious. The liver was not enlarged. There was temporary suppression of urine, followed by albuminuria in the cases which recovered. Two cases died. Microscopical findings did not confirm the idea that it was a form of yellow fever.

KYOTO FEVER.

A fever lasting for seven days in Kyoto, Japan, and described by Masuda in 1918. Ineda found a spirochæte in the blood. The peculiar feature was that adult males of the farmer class were the principal sufferers, and that it produced a cloudiness in the vitreous humour of the eye.

BAN BACH.

Synonym. *La miliaire cristalline fébrile.*

This fever was first described by Montel in 1912, and in 1916 by Saralhé in Cochin China. It is characterized by an insidious onset, followed by six to eight weeks' fever, terminating by lysis, and attended by pulmonary catarrh and a very abundant vesicular eruption, which is difficult to see unless looked for, and which comes out in crops. The skin is dry, conjunctiva yellow, and there is constipation, lassitude, and enlargement of the spleen and liver, with rapid compressible pulse and sometimes delirium. Convalescence is prolonged, and there is a complete loss of hair. Blood tests show no parasites, and are negative for the enteric fevers. It is thought to be infectious. This resembles in many particulars the cases described by Smith and Loughnan at Aden in 1914, but they do not mention the vesicular rash or the loss of hair. Both fevers probably belong to the enteroidea, and should be examined bacteriologically as to the blood and the fæces.

FEBRIS PALUSTRIS REMITTENS.

Described by Ludwig in 1917 as being characterized by an incubation of twenty-one days and a fever of seven to ten days, of a remittent type, with headache, pains in the muscles, weakness, jaundice, and nephritis. It sounds like *enteroidea.*

REITER'S DISEASE.

This was also described in 1917, and resembles the above, but there were pains in the joints, conjunctivitis, iritis, and cystitis, with enlargement of the spleen and fever lasting about seventeen days.

OVOPLASMOSIS.

A fatal fever described by de Raadt in an Annamese aged forty-four years, with enlargement of the spleen, but not of the liver, and with a temperature somewhat resembling subtertian malaria, without malarial parasites in the blood, but with pigment in the mononuclear leucocytes and resisting quinine therapy. The temperature rose very high, and the patient died. Small intraglobular rings were seen staining blue with Giemsa's mixture, and without any trace of chromatin. These were also seen in the mononuclear leucocytes, and were called *Ovoplasma anucleatum* de Raadt, 1913. This sounds like subtertian malaria.

HÆMOCYSTOZOON FEVER.

Hæmocystozoon brasiliense Franchini, 1913, is a flagellate which encysts in the peripheral blood, and was judged to be the fatal cause of a quotidian fever in an Italian physician coming from Brazil.

The fever came on after the removal of a tumefaction in the neck. Spleen and liver were enlarged, and there was great anæmia and emaciation. Brumpt considers that the organism is a *herpetomonas*, and compares the non-flagellate forms to *Schizotrypanum cruzi*, while the flagellate, he thinks, are contaminations, but Franchini does not agree.

He reports that he has found in smears from the liver--

(1) Oval and lanceolate forms 3-6 and 1-2·5 microns, without blepharoplast or flagella. (2) Oval or lanceolate forms, sometimes dividing, 16×3 microns. (3) Flagellate forms, with a flagellum arising near the blepharoplast. (4) Non-flagellate forms with a large nucleus. (5) Encysted forms with chromatinic masses.

The patient had enjoyed good health until three years previously, when he began to feel ill and lost his appetite, while his weight declined. One year later a hard indolent tumefaction appeared on the right side of the neck. This was removed, but the wound did not heal and discharged a white non purulent secretion. He now began to suffer from irregular quotidian fever, preceded by shivering and followed by sweating. The spleen became somewhat enlarged, but the liver gradually extended to the umbilicus, and a cyst formed in the right lobe, puncture of which gave a reddish fluid. The patient now became very anæmic and emaciated. The lymphatic glands were normal, the urine showed traces of albumen, the blood showed signs of acute anæmia, with leucopenia, no eosinophilia, and a few parasites. Puncture of the liver showed more parasites.

No malarial parasites, leishman bodies, spores, or fungi could be found by examination or by cultures. Wassermann's reaction was negative. Sections of the tumefaction showed granulomatous tissue and some parasites.

SEPTIC BILIOUS FEVERS.

A febrile complaint described by Gartan, in 1918, as occurring mostly in women, associated with enlargement and tenderness of the liver, and lasting five to thirty days. One death is recorded.

BUNGPAGGA.

This appears to us to be myositis purulenta tropica (*vide* p. 1975)

ROBB'S HEAT FEVER.

This is described as non-infective cerebro-spinal fever, occurring in East Africa.

NON-MALARIAL QUARTAN FEVER.

This fever, described by Castellani, is characterized by having a quartan periodicity and no malarial parasites in the blood, and quinine given in massive doses does not influence the course, which is prolonged, lasting several months.

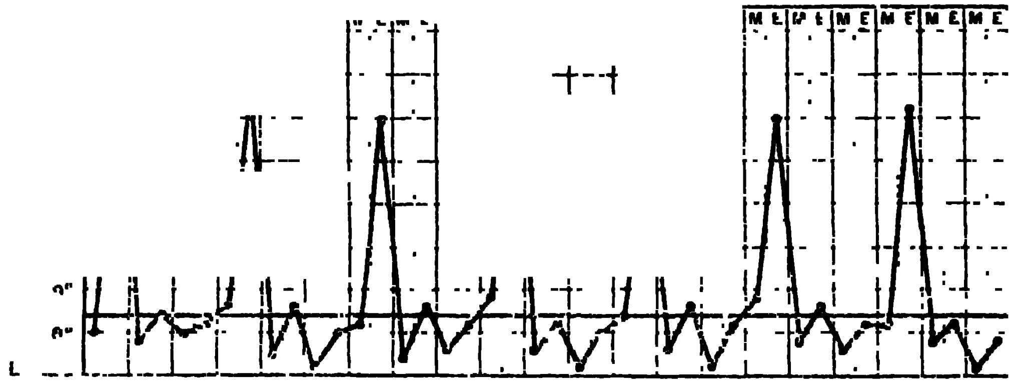

FIG. 677.—TEMPERATURE CHART OF NON-MALARIAL QUARTAN FEVER.

ANÆMIC LOW FEVER.

In young European and native women aged sixteen to twenty-two years there is a persistent low fever lasting for several months, reaching above 99·4° F. in the afternoon and associated with a certain degree of anæmia, which is met with at times. The patient may become extremely nervous and hysterical. This temperature may be due to the degree of chloranæmia, and has nothing to do with hysterical fever of certain authors, as it disappears on the anæmia being treated.

VESICULAR FEVER.

Definition.—A febrile disorder associated with acute pain in some region of the body, followed by the appearance of a vesicular eruption which becomes general.

Remarks.—This is a fever which at its commencement resembles an attack of chicken-pox, and when it is fully developed closely resembles modified smallpox. We have seen several such cases in Ceylon during the last ten years.

Ætiology.—The causation is unknown.

Symptomatology.—At no stage of the illness is the patient severely ill, but the commencement is ushered in with sometimes pain in some part of the body, followed in a day by a rise of temperature to about 101° F. and a quick pulse. The eruption may appear at first in the region of the pain, or may be general from the commencement, which, however, is not relieved, and may, on the contrary, have extended to other regions of the body. The pain gradually disappears, a scattered general eruption of vesicles appears, and the temperature becomes normal, while the patient feels better. The vesicles are discrete, dome-like, or flattened; later, a few may become umbilicated. The size is generally much less than those of chicken-pox, and a few may become umbilicated. There is little or no inflammation of the base. The contents are at first clear and then purulent. Superficial scabbing may occur, and, as a rule, no scars are left, though rarely some scars may be found.

Diagnosis.—The diagnosis is based upon the characters of the eruption, there being no true pustulation, with scabbing and scars, as in smallpox, and by the fact that during convalescence Jenner's vaccination is generally successful.

In chicken-pox the vesicles are generally larger, and often leave thick crusts.

In alastrim the eruption is often confluent, pustular, and clinically almost identical with smallpox.

Prognosis.—This is good.

Treatment.—The treatment is purely symptomatic.

PAPULAR FEVER.

Definition.—A slight febrile disorder, described by Castellani, of unknown causation, characterized by a maculo-papular eruption and rheumatoid pains.

Remarks.—We have seen an epidemic of this peculiar fever in Ceylon: it resembled measles in the appearance of the rash, but was without any catarrhal symptoms.

Ætiology.—This is quite unknown.

Symptomatology.—The disease begins with a prodromal period, during which the patient suffers from malaise, depression, and rheumatoid pains, especially in the back, which are associated with chilliness. After three or four days the rash comes out suddenly all over the body, but most marked on the arms, trunk, and legs, the face being least affected. The eruption is morbilliform, being composed of bright red pin head papules and red maculæ. It is, as already stated, visible on the arms, legs, and chest: while there may be a few maculæ on the palms of the hands and soles of the feet. The face is not much affected, and there the eruption is rather more macular than papular. Filatow's papules in the mouth are absent. There is generally slight fever lasting for a day or two. There are no catarrhal symptoms of the eyes, nose, or throat, no enlargement of the lymphatic glands. The eruption generally lasts between two to five days, and then fades without any desquamation and without leaving any marks. In most cases the eruption is associated with itching, especially on the arms, and in a few cases there is no fever.

Diagnosis.—It is to be distinguished from measles by the absence of the catarrhal symptoms, absence of Filatow's and Koplik's signs, from German measles by its longer duration and the diffuse type of the eruption, from toxic rashes of intestinal origin by the absence of any intestinal symptoms, and from dengue by the rash being frankly papular.

Prognosis.—This is good.

Treatment.—The treatment is symptomatic, small doses of aspirin or pyramidon being given to relieve the pains, and calamine lotion to alleviate the rash.

HÆMORRHAGIC FEBRILE GASTRO-ENTERITIS OF CHILDREN.

Synonym.—Fièvre à Vomissements noirs des Enfants.

Definition.—An endemic fever limited to 'Grande terre' in Guadeloupe, and characterized by black vomit and by occurring only in children.

Remarks.—This disease, which closely resembles yellow fever was first described by Dr. Guesde in 1891.

Climatology.—It is only known in 'Grande terre' in Guadeloupe.

Symptomatology.—The disease begins suddenly with an attack of vomiting, and is followed by an attack of febrile bilious vomiting. The child then becomes very ill, with remittent fever, slight icterus, obstinate constipation, and later black vomit. After lasting from two to five days the symptoms may improve, sleep returns, the fever disappears, and the child gradually recovers; on the other hand, the symptoms may become worse, and the child die. Convalescence is prolonged.

Diagnosis.—The disease seems to us to be indistinguishable from yellow fever.

Prognosis.—The prognosis is always grave.

Treatment.—This is symptomatic.

CHAPTER LVIII

COSMOPOLITAN FEVERS

General—Epidemic cerebro-spinal meningitis—The exanthemata—Vaccination—Alastrim—Vaccinia in natives—Vaccine rashes—Influenza—References.

GENERAL.

At the present time many so-called tropical diseases have become cosmopolitan, *e.g.*, amoebic dysentery, while others, such as malaria, probably have always been world-wide in their distribution. There are, however, some few fevers which, though they really belong to cool climates, nowadays are of importance in the tropics—for example, the exanthemata and influenza. We think it advisable to give a brief account of these.

EPIDEMIC CEREBRO-SPINAL MENINGITIS.

Synonyms.—Spotted fever. *French*, Méningite cérébro-spin épidémique. *Italian*, Meningite cerebro spinale, *German*, Epidemi Genickstarre.

Definition. An acute specific fever caused by sseria intracellularis Weichselbaum, 1887 (*Diplococcus intracellularis*), and d organisms, spread from man to man by aerial carriage, and characteriz a brief septicaemia, leading to a cerebro-spinal meningitis, and occasion y a more prolonged and dangerous septicaemia associated with a petechial eruption.

History.—The disease may have been known to the ancients, but to our minds the *phrenitis* of Hippocrates and of Celsus has nothing in common with cerebro-spinal meningitis. We have been unable to refer to the works of Aretaeus or of Paul of Ægina, and, therefore, are unable to state whether the disease which they are said by Kutscher to have described in Italy resembled cerebro-spinal meningitis or not, and the same remarks hold good with regard to the epidemic described by Aldere de Lucien.

On the other hand, we have carefully read Sydenham's 'Rise of a New Fever,' which Arnell considers to be identical with the disease which he saw in Connecticut in 1807; and which, he also says, is the same as Cullen's 'Typhus Petechialis' and the disease described in *Medicin. Novissimus*, published at the beginning of the eighteenth century. When superficially considered, Sydenham's new fever does, at the first glance, read like cerebro-spinal meningitis, but when the symptoms are carefully analyzed they will be observed to resemble those of the enteroidea group of fevers, and therefore we are convinced that Sydenham's new fever is not cerebro-spinal meningitis.

We have been unable to peruse Vieusseux's original account of the outbreak in 1805 at and around Geneva, but North's translation in 1811 of the article in the *Journal de Médecine de Paris* makes it quite clear that this was undoubtedly the disease in question, and the same author's verbatim account of Danielson and Mann's article published in the *Medical and Agricultural Register* of Boston, with its careful clinic and post mortem histories, leaves no doubt that these two authors were dealing with an epidemic of cerebro-spinal meningitis at Medfield in March, 1806. North's valuable little book containing all the early histories of the disease appeared in New York.

From this date onwards till about 1884 the whole ground of the history has been reviewed by Hirsch in the third volume of his classical 'Handbook of Geographical and Historical Pathology,' in which he divides the epidemics of cerebro-spinal meningitis in Europe and America into four cycles, viz.:—

(1) 1805-1830, Europe and North America.
(2) 1837-1850, Europe, North America, and Algiers.
(3) 1854-1875, Europe, North America, Africa (parts), Western Asia, and South America.
(4) 1876-1884, small epidemics in former areas, to which may be added:—
(5) 1885 to present time. Recognition of the disease in the tropics, West Indies, Fiji, Anglo-Egyptian Sudan, West Africa, Western Australia, Mexico. Severe epidemics in America and Europe—*i.e.*, this is the period of the first pandemic.

It will thus be seen that the area in which the disease is recognized has gradually extended, and that this has been quicker of late years, probably due to increased facilities for travel which has introduced it by the agency of carriers into lands in which it probably did not previously exist, as, for example, Fiji, the result being that at the present time it appears to be diffused all over the world and to occur as localized epidemics in different places in different years.

In the study of these epidemics certain important features were brought out—viz., the influences of over-exertion, starvation, overcrowding, and bad ventilation, which account for the prevalence of the disease among soldiers and poor people and for its increase in different countries in periods of bad weather—*e.g.*, during the winter and spring in cold climates and during the Haboub seasons of the hot Anglo-Egyptian Sudan, or to a less extent the cold weather of the Sudan, when the people huddle together into crowded, ill-ventilated huts and houses.

The historical portions with which we are mainly interested are those concerned first with its occurrence in the tropics, and secondly with its ætiology.

Occurrence in the Tropics.—The first record we have been able to find of the disease in a subtropical land is the occurrence of an epidemic in 1840-1847 in Algiers, in which country it has, from time to time, been reported. It is also said to have occurred in 1840 in Brazil and in Monte Video in South America.

In 1872 it was reported in Asia from Smyrna and in 1874-75 in Persia, according to Bruce Low in his paper on epidemic cerebro-spinal meningitis published in 1899.

It is believed to have been present in Central America and in the West Indies prior to 1884, but without trustworthy information.

Corney has given an excellent account of the invasion of Fiji by the disease. It would appear that the first cases were noted in 1876 in an immigrant labourer's depot at Levuka, and from that time onwards it was probably diagnosed as tetanus, sunstroke, or meningitis, until it assumed epidemic form in 1885, which he believed was due to the contagion being spread from man to man—a very advanced idea at that time.

Cerebro-spinal meningitis was reported from the West Coast of Africa by the Williams in 1900, and from then onwards from time to time. In 1905 there was a severe epidemic in Northern Nigeria, which was reported upon by Twomey and Davidson, and in 1906-08 in the northern territories of the Gold Coast, where it was ably investigated by Horn. In Northern Nigeria it was said that cattle were attacked, and in the Lorha district of the northern territories of the Gold Coast the natives are said to have noted a great mortality among fowls prior to the epidemic of the disease. According to Bargy and Horn, the disease was marked at this time in French West Africa to the west of the Black Volta.

In 1909 it was reported as being present in 1907 in the northern districts of Togoland by Jaffé, when it was known to cause 300 deaths. Jaffé obtained the true diplococcus of Weichselbaum from his cases.

Epidemic cerebro-spinal meningitis has been recorded in British East Africa since 1906, when Haran noted five cases, and has been ably described by Shircore and Ross in 1913.

In 1915 Butler drew attention to *a curious feature* of the disease, in that there are places in East and Central Africa where it has always been endemic and seldom epidemic, and he quotes Uganda in general, whilst in the highlands of British East Africa the endemic form is seldom seen, but epidemics of greater or less virulence are known. He says that in one tribe alone between 20,000 and 40,000 deaths are attributed to this disease, a mortality which sleeping sickness can hardly be said to rival.

In India it appears to have been first reported by Vandyke Carter as occurring in July, 1878, in Bombay, where he says that he is not aware that it had been previously recognized. He does not appear to have published this observation until 1882, and then only in his work 'Spirillum Fever,' p. 436, when he gives not merely a clinical but a post-mortem account of one case and clinical histories of three others. As he has been said not to have recognized the disease, it may be well to note that he heads the paragraphs in question *cerebro spinal meningitis*.

In 1884 Dimmock gave a full account of an outbreak in the preceding year in the Shikarpur Jail. Since then some cases have generally been reported year by year, and the whole subject of epidemic cerebro-spinal meningitis in India was ably reviewed by Robertson-Milne in 1906.

In 1905 Castellani described two cases which occurred in Singhalese natives in Ceylon.

In 1910 Chalmers and O'Farrell published a series of investigations upon the disease as seen in the Anglo Egyptian Sudan.

History of the Organism. In 1875 Klebs was the first to see cocci in the cerebro spinal fluid of cases of meningitis, and to assign to them a causal function. He was followed by Eberth in 1881, in which year Gaucher was the first to see micrococci in the blood and urine in a patient during life and in the exudate from the spinal canal after death; and in connection with these findings in the blood one may invite attention to the observation of Cole in 1915, who obtained films of the peripheral blood in which ten out of 2,000 leucocytes showed the organism, and also to Osler's statement that Gwyn in 1899 was the first to isolate the organism from the blood in pure culture. In 1883 Ughetti also found micrococci in the exudate and in the blood, and in 1884 Marchiafava and Celli wrote a short work on the occurrence of micro-organisms, and especially diplococci, in cerebro spinal meningitis. They were also seen in meningeal exudates by von Leyden in 1883, and by Leichstenstern in 1885, and the last mentioned observer noted that they resembled the gonococcus by being found in the leucocyte.

In 1886 Senger also noted them in the cerebro-spinal exudate, while Fränkel with Weichselbaum, Foà with Bordoni, Uffreduzzi, and Lemoine described the pneumococcus as the causal organism of a series of cases of cerebro-spinal meningitis unassociated with pneumonia.

In 1887 Weichselbaum published his paper 'Ueber die Ætiologie der akuten Meningitis Cerebro-spinalis,' in which he described eight cases of meningitis without pneumonia, two of which were due to the pneumococcus and six were caused by an organism which differed therefrom by being generally a diplococcus, more rarely arranged as tetrads, and resembling the gonococcus, being often contained in leucocytes and being Gram negative. He, however, distinguished this organism from the gonococcus by the fact that it produces in subcultures on agar agar slopes a flat viscous growth which is greyish when seen by reflected and greyish-white when examined by transmitted light. It only grew at incubator temperatures, and had but a slight vitality. This organism he called *Diplococcus intracellularis meningitidis*, and looked upon its action as being toxic in nature, while he hesitated to regard it as the causal agent of the disease.

Although Weichselbaum's observations were confirmed by Goldschmidt in 1887, and by Edler and himself in 1888, they produced comparatively little influence, and were almost unnoticed until a polemic was started in 1890, which raged till 1893, as to the identity of Bonomé's streptococcus of epidemic cerebro-spinal meningitis first reported in 1890, and Foà's meningococcus and the *Diplococcus pneumoniæ*, in which it was decided that Bonomé's organism was the pneumococcus, but the confusion was increased by Bordoni, Uffreduzzi regarding *D. intracellularis* as a variety of *D. pneumoniæ*.

This unhappy condition was accentuated in 1895, when Jaeger, while studying a regimental epidemic of fourteen cases occurring in Stuttgart, found the pneumococcus in two cases, a streptococcus in one case, and in eleven cases an intracellular Gram-positive diplococcus morphologically resembling the gonococcus, producing turbidity in broth, and forming short or even at times long chains, while it retained its Gram-positive character in cultures. It grew well on gelatine at the temperature of the laboratory, and preserved its vitality during fourteen days or more on artificial media. He concluded that this organism was Weichselbaum's *D. intracellularis*, and in this unfortunate conclusion he remained unopposed for years, and was supported by Heubner in Berlin in 1896, who not merely was the first to obtain a coccus from the cerebro-spinal fluid during life, but who produced a fatal meningitis in goats with this germ, which at the time was considered to be an important experiment, as an epizoötic meningitis was present in horses and horned cattle in Germany; further, he proposed the name meningococcus for this organism, notwithstanding the fact that Bonomé had already used it for the pneumococcus mentioned above.

This meningitis cerebro-spinalis enzootica, or epizoötic cerebro-spinal meningitis, is often called the *Borna disease*, because of the attention paid to a malignant outbreak in horses at Borna in 1894.

It is obvious that it must be of the greatest importance to definitely settle the question as to whether (as is generally believed) the two diseases are quite separate, or whether there is some relationship between the human and some undefined fraction of the animal complaint.

Thus we see that confusion has arisen not only between a disease seen in animals, but also between two human organisms.

Jaeger and Heubner's results were more or less confirmed by Holdheim, Petersen, Urban (1897), Rameny (1898), Vanzetti (1901), and many others, while Kiefer, Kister, Kischensky, and Berdach and Fioz supported Weichselbaum, and so great a confusion arose between the Gram-negative *Diplococcus intracellularis* Weichselbaum 1887, and the Gram-positive coccus of Jaeger and Heubner, which is also known as *D. crassus* von Lingelsheim, 1906, that every coccus found in connection with the meninges was considered to be a true meningococcus.

In 1898 Still showed that posterior basic meningitis was associated with an organism like *D. intracellularis*, and Councilman, Mallory, and Wright obtained Weichselbaum's coccus from thirty-one cases of the disease, while Faber in 1900 found the same organism in an epidemic in Copenhagen, and Canuet in the same year showed that it was an obligatory aerobe.

Pfaundler in 1899 recognized both the Weichselbaum type and the Jaeger-Heubner type, and in this he was supported by Hunter and Nuttall and by Lazarus-Barlow in 1901, in which year Albrecht and Ghon, reporting upon the 1898 epidemic at Trefail in Steiermark, not merely confirmed Weichselbaum's researches, but were the first to obtain the organism by cultural methods from the naso-pharynx of cases of the disease, an observation which is now of almost daily occurrence, although we are still uncertain as to the proportion of cases which become permanent carriers. They also obtained Gram-negative cocci in the throats of fifteen healthy persons who were contacts with cases, and in one such person the meningococcus was identified by cultural tests.

In 1902-03 Bettencourt and França, in Portugal, found the meningococcus to be present 271 times in 274 cases of cerebro-spinal meningitis, and Lepierre in 1903 described a meningococcus which, although originally Gram-negative, became Gram-positive, and the same year saw the *Meningococcal polemic* between Jaeger, as representing the German school, and Weichselbaum, Albrecht, and Ghon on behalf of the Austrian schools, as a result of which Weichselbaum's organism became firmly established.

In 1905 Kob and Weyl wrote on the subject of Gram-negative and Gram-positive diplococci, and in the same year Castellani described Weichselbaum's organism in cases in Ceylon, and Dunn and Gordon reported upon an epidemic simulating influenza in Hertford in which they obtained *Micrococcus catarrhalis* and forms resembling the meningococcus. It was during this investigation that Gordon brought forward the carbohydrate tests as differential agents for the meningococcus, a point which he further elaborated in 1907, in which year Buchanan introduced a modification of Loeffler's blood serum by adding neutral red in a proportion of 1 in 10,000.

The outbreaks of cerebro-spinal meningitis in 1905 in Prussia and New York produced excellent work, in the former by von Langelsheim and by Kolle and Wassermann with reference to the organism, which, together with the labours of other collaborators, was published in one volume in 1906. In this epidemic von Langelsheim found the meningococci to be present in 23·12 per cent. of the cases, but, as many of the samples came from a long distance, it is interesting to note that he obtained 70·0 per cent positive results from examinations in the hospital near the laboratory and taken during the first day of illness, and 60·0 per cent. in those taken from first to fifth day of the illness, while he obtained 24·5 per cent. from sixth to tenth day, 11·29 per cent. from eleventh to twentieth day, and only 4·39 per cent. after the twenty-first day. Thus in three weeks 90 per cent. of the cases were free from meningococci, but he found that 15 per cent. of the contacts became carriers. He also gave an account of *D. crassus* and, with Leuchs, of experiments on animals with the meningococcus.

The American epidemic was investigated by Elser, Durham, Goodwin, and Sholly, and produced results similar to those of von Langelsheim, and in the same year Robertson Milne reported upon cerebro-spinal meningitis as seen in India.

In this year Kutscher described a coccus in the naso-pharynx of carriers which agreed morphologically and culturally with the meningococcus, but which could be differentiated by Castellani's absorption test, and Westenhoeffer stated that the primary focus of the disease was in the pharyngeal tonsils, post-nasal region, and the nasal sinuses, in which in the early days of the disease he reported that it caused an inflammation. In 1907 Taylor investigated the opsonic index with a view to diagnosis. In 1909 Elser and Huntoon named Kutscher's organism the *Pseudo-meningococcus*. At first it was thought that organism was rare and had nothing to do with the disease, but, when Gordon and Murray's researches mentioned below are considered, it is obvious that it would agree with such of their groups as do not agglutinate with and absorb intracellularis serum; at the present it is only differentiated from the strains with which Kutscher and Elser and Huntoon were working, and may or may not be the same as Dopter's parameningococcus, which is mentioned below.

In 1908 von Langelsheim gave the following differentiation of the organisms found by him in the naso-pharynx of the contacts. —

(1) *Micrococcus catarrhalis*.- Frequent, colonies, dry crumbling; when seen under microscope granulated, generally with irregular borders. Attacks neither grape sugar, nor maltose, nor levulose.

(2) *Diplococcus flavus I.*- Colonies on ascitic agar very similar to those of meningococcus. Twenty-four hours' culture exhibits clear yellow pigment in thick layer.

(3) *Diplococcus flavus II.*- Colonies polymorphic, sometimes moist and glistening, sometimes dry and wrinkled. Twenty-four hours' culture exhibits yellow pigment in thick layer.

(4) *Diplococcus flavus III.* -At commencement difficult to cultivate, and therefore rarely coming under observation. All three species of *flavus* form acids in the presence of grape-sugar, maltose, and levulose; whilst the meningococcus ferments only grape-sugar and maltose, the latter regularly.

(5) *Diplococcus mucosus.*- Colonies more prolific and juicy than those of meningococcus. Grows also on gelatine at room temperature. According to many authors, markedly pathogenic for mice.

(6) *Micrococcus cinereus.*—Coarse, uneven granular. Colonies and cultures

delicate, reminding one of *D. crassus*. Does not attack grape-sugar, levulose, and maltose.

He also considered the possibility of the spread of the disease by insects, by dwellings, and by clothing, food, and water, and concluded that none of these were effective agents in the propagation of the disease.

In 1909 there appeared a most important work by Elser and Huntoon in which they described most carefully the cultural, biochemical, and serum reactions of the meningococcus and its allies, as well as its viability, and especially its selective affinity for the cerebro-spinal fluid, a point little considered by the majority of investigators. They also considered the subject of mixed infections, which was dealt with by Specht in the following year.

In the same year Dopter described his *Parameningococcus*, which was not agglutinated by meningococcus serum (a fact confirmed by Gordon and Murray in 1915), but showed complement fixation. Two years later he described seven cases of cerebro-spinal meningitis as being due to this organism, and in 1912 used Castellani's saturation test to differentiate it from the meningo-

The agglutination reactions of the meningococcus are unsatisfactory, as may be gathered by a study of Elser and Huntoon's careful work, as well as by the discordant results obtained by numerous observers. In 1915 Hine instituted a rapid method of preparation of a high titre agglutinating serum in rabbits, and Gordon and Murray investigated genuine strains of meningococci obtained from the cerebro-spinal fluid of cases, and found that by agglutination tests and by Castellani's absorption method they could split up thirty two strains into the following groups:—

(I.) With serum from No. 1, 19 strains.
(II.) With serum from No. 20, 8 strains.
(III.) With serum from No. 28, 4 strains.
(IV.) With serum from No. 32, 1 strain.

They also distinguished by these sera Dopter's paramenigococcus from all the other groups, and they noted that one strain absorbed the specific agglutinins from two groups, while out of ten carriers one belonged to Group (I.) and five to Group (II.), while the others were not classified.

In the same year Crowe attempted to meet the difficulties met with in the agglutination tests by devising a simpler method.

We have now given a rough sketch of the history of Weichselbaum's organism, and we might well pause, as Crowe has done, and ask where do we stand as regards its recognition.

It is admitted on all sides that there is a close resemblance between the gonococcus and the meningococcus, except as regards the human diseases which they produce, and, indeed, many years ago it was suggested that the latter might be the former adapted to the cerebro-spinal nervous system and the naso-pharynx, but to-day it is admitted on all sides that they are separate, mainly because of an experiment in which the meningococcus was found not to cause gonorrhœa when injected into the human urethra.'

As regards the meningococcus, we can aptly quote Crowe, who, writing in 1915, says:—

'The present state of our knowledge so far as it bears on the carrier may be summed up:—

'No Gram-negative organism isolated from the naso-pharynx can be proved to be a meningococcus.

'No Gram-negative organism which resembles even faintly a meningococcus can be regarded with certainty as incapable of producing meningitis.'

Hence we have not improved our position since the days of the meningococcal controversy, but are actually in a position of greater uncertainty as to the differentiation of Weichselbaum's *Diplococcus intracellularis*, and, this being so, we will now briefly review our position as to the causal relationship between this organism and epidemic cerebro-spinal meningitis.

Indeed, this is exceedingly necessary at the present time, because, firstly, a certain amount has been written with regard to the so-called pleomorphism of the meningococcus—*e.g.*, the papers in 1915 by Lundie, Thomas, and Fleming, and by Donaldson in the same year, while in 1915 and 1916 Hort, Lakin, and Benians have doubted the causal action of the meningococcus, and in the last publication Hort has stated:—

'In order to discover the true infective agent, whether biologically related to the meningococcus or not, further research is imperative, attention being particularly directed to filtrable organisms in the naso pharnyx and cerebro-spinal fluid of acute cases.'

With regard to the question of filtrable organisms, Chalmers and O'Farrell have performed an experiment of this nature with a fresh cerebro spinal fluid, but the result was negative.

With regard to the meningococcus being the causative factor in epidemic cerebro-spinal meningitis, the above observations make it sufficiently clear that it has been regularly found in the cerebro spinal fluid of persons suffering from the disease, and that it has been found in the blodd and also in the urine when looked for at the correct time or in suitable infections. It is also generally present in the naso pharynx of the cases, and was found by Sophian, Westenhöffer, and others in such complications as arthritis, pyelitis, pneumonia, endo carditis, and in purulent conjunctivitis from a virulent [illegible] ie disease.

Epidemiological studies easily convince anyone associated with the disease that some contagion can at times pass from the sick to the healthy, causing an attack of the disease, and, moreover, as we have pointed out above, many of the contacts show the meningococcus. It is true that, as a rule, but few attendants on cases acquire the disease, [illegible] here are marked exceptions.

It is also true that the accidental infec[illegible] Sicler of his own nose with a culture from the laboratory pro[illegible] a severe rhinitis, but he did not develop meningitis, and one of us accidentally infected his thumb from some cultures, with the result that hæmorrhagic granulation tissue formed from which the germ was recovered, cultivated, and tested biochemically, and agreed with the meningococcus in these details. Although the lymphatic glands enlarged and a mild chronic fever lasting for months ensued, with almost constant and sometimes very severe headache, no meningitic symptoms developed, although the opsonic index varied from 0·8 to 1·3, until meningococcal vaccine therapy cured the condition.

In the first case it is possible that the coccus never got into the system, and in the second that it never entered the blood-stream, and hence the lack of meningeal infection.

Turning now from man to experiments upon animals, von Lingelsheim and Leuchs, followed by Flexner in 1906, reported successful inoculations of monkeys subdurally. They were followed in 1908 by M'Donald, but neither he nor Davis in 1905, nor any of the above experimenters, were able to infect animals by injections into the blood-stream, although M'Donald produced an acute toxæmia by this method, nor were Kolle and Wassermann or Davis able to reproduce the disease in the same animals via the nose. Elser and Huntoon consider that the value of these experiments is questionable when the *peculiar affinity* of the meningococcus for the leptomeninges is taken into account. They point out that other organisms injected subdurally will cause a meningitis, but no other common pathogenic organism shows a similar *selective action* for the meninges of man.

Further, it is to be remarked that Bettencourt and França and Kolle and Wassermann were unable to infect monkeys even by means of subdural injections, and this has happened to us both with fresh cerebro-spinal fluid from which growths were subsequently obtained and with cultures, although we have also had successes.

Only Councilman, Mallory, and Wright have succeeded in infecting a goat when dealing with the true meningococcus, and Vansteenberghe and Grysez produced meningitis in rabbits and guinea-pigs, but it seems to us to be doubtful whether they worked with a true meningococcus.

We have been unable to peruse Flexner's original papers, but according to Batten the general circulation became infected in his monkeys.

We shall give below reasons why carriers do not become infected, and it is possible that monkeys may be resistant except when damaged by an operation like trephining or otherwise below par; moreover, the meningococcus is often damaged in the drawn fluid and degenerated on cultivation, for we have seen it fail to infect a monkey after five generations of growth of the same organism which was infective during the second generation.

We now turn to inquire in what way the human body reacts to the organism. Davis showed in 1907 that at the end of the first week agglutination up to 1 in 50 could be obtained, and in the eighth week up to 1 in 200, and pointed out that the agglutinins were thermostable, resisting a temperature of 65° C. for an hour, while they appear to be practically absent from the cerebro-spinal fluid, but many observers, including ourselves, have found this test uncertain.

Davis in 1905 showed that the coccus multiplied in two normal defibrinated bloods, but in four other bloods it was killed, as it was by the blood from patients after the tenth day. He noted that the meningococcidal power of the blood serum of patients which seemed to be greater than that of normal blood serum was diminished by heating to 60° C. for thirty minutes. He found that the phagocytic index was 13 for normal human serum, 0 for serum heated to 60° C. for thirty minutes, while in meningitic serum from cases between the second and seventh week of convalescence it was 11·1. Normal cerebro-spinal fluid did not contain opsonins.

Houston and Rankin in 1907 found that opsonins were exceedingly low in normal serum, and lower still in cerebro spinal fluid, while in cases from the sixth day onwards they rose remarkably, except in two fatal cases, while in one relapse the rise was postponed till the eleventh day.

MacGregor observed that the highest indices occur in the second and third week of the disease, but that the degree of immunity after recovery, as measured by the opsonic index, was variable, and concluded that a high opsonic index was a sign of forcible reaction to a fairly severe infection.

Meakers and Dopter have shown the presence of immune bodies in the blood of meningitic patients by means of complement-fixation, and McKenzie and Martin have also demonstrated the presence of these bodies by injecting the serum of recovered cases intraspinally into other acute cases with fair results. It would therefore appear that immune bodies are formed in patients' systems, which is in support of the causal action of the meningococcus.

We now turn to see whether specific serum treatment and vaccine therapy will help the problem.

With regard to the serum treatment, Jochmann in 1905 experimented with a specific immune serum which was afterwards manufactured by Merck. He tested his serum by the opsonic test, the bactericidal test, and by agglutination.

Kolle and Wassermann also made an immune serum upon which they reported in 1907.

In 1906 Flexner wrote upon a specific serum which protected monkeys and small animals. Later this serum was made from immunized horses, and has been extensively used.

With regard to vaccine treatment, Davis in 1907 was the first to inject killed meningococci into normal persons and into patients suffering from the disease, and Collis in 1913 tried specific serum treatment together with vaccine therapy. In the same year Sophian reported on his experimental inoculation of eleven medical students, and eleven months after these inoculations Merck re-tested eight of them, comparing the results with those of a normal person and a recently recovered case, and concluded that a person *so vaccinated may consider himself to be immune for at least one year.*

In October, 1915, Surgeon-General Rolleston reported upon sixteen cases of vaccine treatment with four deaths and twelve recoveries; the vaccine, however, was never used alone, but combined with serum treatment in some form or with soamin. In his report lumbar puncture alone in thirteen cases resulted in four deaths and nine recoveries, serum intrathecally alone forty-three deaths and nineteen recoveries, or alone and combined with vaccine, soamin, or hexamine, sixty-four deaths and forty-one recoveries, while symptomatic treatment gave ten deaths and four recoveries.

In 1916 Chalmers and O'Farrell, studying an outbreak of cerebro-spinal meningitis in the Anglo-Egyptian Sudan, came to the following conclusions:—

1. The important causal agent is *Neisseria intracellularis* (Weichselbaum, 1887), and only once has *Diplococcus crassus* von Lingelsheim, 1906, been found acting in this capacity, and so far no other organism.

2. Only *man* has been found to be the host of *Neisseria intracellularis*, and he acts in this capacity as *the true carrier* of the germ, and as such does not acquire the disease because of an *immunity* conferred by autovaccination.

3. In order to acquire the disease, two factors at least are required, viz.:—

(*a*) Infection with *Neisseria intracellularis*.

(*b*) Lack of capability on the part of the body to produce the necessary *immunity*.

The infection takes place from the nose of a carrier or a case to the nose of an uninfected person, and is favoured by overcrowding and bad ventilation. The lack of power to produce the necessary immunity is favoured by poor and insufficient food, bad hygienic conditions, and over-exertion.

4. In susceptible persons the germ passes into the mucous membrane of the nose and of its connected cells, and multiplies therein, and then entering the blood-stream forms in the early days of the disease a bacteriæmia. Normally, however, it does not long remain in the blood-stream, and therefore normally does not produce a prolonged septicæmia, which, when present, should be considered as a complication. Apparently the organism is strongly attracted to the cerebro-spinal fluid, into which it quickly passes via the choroid plexus of the lateral ventricle, and perhaps other vascular structures of the brain and spinal cord, and so causes the disease.

The reason why the cocci as a rule do not pass in relays day after day from the mucous membrane of the nose into the blood is because the patient is either dead or the resistance is raised in a short time, but if this resistance again becomes lowered it is possible that relays may again pass from the nose, and in this way a relapse or recurrent attack ensues.

5. There are various strains of *Neisseria intracellularis*, and to be successful in treatment a *polyvalent serum and a polyvalent vaccine made from local strains* are necessary. Vaccine alone will cure many cases, but requires time to act, which may not be available, and hence the value of the serum in such cases, especially when followed by subsequent vaccine therapy.

6. Prophylaxis depends upon

(*a*) The search for, isolation of, and treatment of cases and carriers, and here vaccine therapy is of use in helping to cleanse cases and carriers.

(*b*) The increase of the immunity of the general population, which can probably be done by prophylactic vaccination in doses of 5, 50, and 100 millions, but further experience is required of this when given on a large scale. There is little doubt that a negative phase is produced, at all events at times, in the first stages of the vaccination, and this may possibly be aggravated by fear, poor or insufficient food, and bad hygiene. It also appeared to them that vaccine prophylaxis ought to be tried on a large scale, as it causes no general or local symptoms if the germs are killed at 50° C., and the vaccine is aseptic and isotonic with the fluids of the body, and if the site of injection is the subcutaneous tissue just below the angle of the scapula, which in their opinion is the best place for prophylactic and other subcutaneous injections.

7. There are a great many questions with regard to epidemic cerebro-spinal meningitis which are at present unsolved, and one of the most important appears to be the question as to whether any animal or animals act as host of the germ.

In 1917 the Medical Research Committee of the National Health Insurance issued a report on bacteriological studies, and in 1918 upon serum treatment in connection with the disease.

Ætiology. The causal agent in the large proportion of cases is *Neisseria intracellularis* (common name: meningococcus) or one of its immediate allies.

It lives in the naso-pharynx of healthy people whose opsonic index for the germ is abnormally high, and it passes from these carriers to healthy people, who may, according to their resistance, become carriers, temporary or permanent, of the germ, or victims to the disease.

Its ætiological relationship depends upon.—

1. Its presence in all cases of the true epidemic disease.
2. Its pure culture from these cases, and the reproduction of the disease in monkeys by inoculation of cultures.
3. The sera of persons suffering from the disease can agglutinate and give positive complement-fixation with meningococci obtained from other patients.
4. It produces a protective mechanism in carriers which is lacking in susceptible persons.

Pathology.—The meningococcus appears to enter the blood via the mucosa of the nose and air sinuses, but it quickly leaves this fluid and enters the cerebro-spinal fluid via the choroid plexuses, and perhaps by other routes. Arrived in the cerebro-spinal fluid, it causes a cerebro-spinal meningitis.

Morbid Anatomy.—In fulminating infections meningitis is absent, and little is to be seen beyond hæmorrhages in various parts, while the cerebral vessels are intensely congested and the perivascular subarachnoid spaces show scattered patches of pus.

In ordinary fatal cases there is considerable amount of purulent exudate in the subarachnoid, the most intense being over the uppermost part of the vertex.

In chronic cases there may be but little sign of pus and no vascular congestion, but the ventricles are distended by a quantity of fluid, the pressure of which causes flattening of the convolutions.

Symptomatology—*General Remarks.*—As seen in the tropics the disease is of sudden onset, with or without a rigor, but with marked headache, vomiting, and fever. The next day there is often some remission in the symptoms, but with stiffness in the muscles of the neck and sometimes Kernig's sign. On the third day vomiting returns, with headache and a condition of *resistant stupor*, retraction of the head and Kernig's sign, and from this time onwards the symptoms in fatal cases go from bad to worse and the patient dies within four to six days of the commencement of the attack. If the case is to recover, the symptoms begin to abate about the seventh to eighth day, the temperature falls to normal, and convalescence begins.

Slightly fuller details of this usual type may be given.

Incubation Period. Judging by persons who have left an uninfected area, visited an infected and returned to the uninfected area, the incubation period is short, varying from two to five days, and more usually about four days, but there are obvious fallacies in this calculation, and it may perhaps be better to admit that the length of time of the incubation period is only approximately known.

Attack. The onset is sudden and may begin with a rigor in an adult or convulsions in a child, but these may be absent. The patient feels very ill and exhibits three so-called cardinal symptoms, viz., fever rising to 102° to 104° F., vomiting, marked headache, which may be associated with severe giddiness. As the first day progresses there may be pain and stiffness in the neck and some retraction of the head. If the blood be examined at this early stage of the disease, only a moderate amount of leucocytosis, amounting to about 10,000 cells per cubic millimetre, will be found, while the differential count will show an enormous preponderance of polymorphonuclear leucocytes, amounting to over 90 per cent. in some cases.

Blood cultures are usually very successful at this early stage of the disease, but not later in uncomplicated cases. By direct examination of blood films Gram-negative diplococci can be seen in about 1 per cent. of the polymorphonuclear leucocytes examined, while a very few similar organisms may be found outside the cells. Even at this early stage of the disease the cerebro-spinal fluid is usually more or less turbid, and shows a variable number of white cells, which may amount to 20,000-30,000 per cubic millimetre, and of which some 98 per cent. are polymorphonuclear leucocytes, while the remaining 2 per cent. are generally mononuclears. As the day goes on there may be pains in the limbs and some slight catarrhal symptoms in the nose and throat.

Slight Remission.—On the second day there is often, but not always, a slight remission of the symptoms, which may be assigned to the treatment, but which is really part of the disease.

Course.—On the third day, if there has been some slight remission the symptoms all return, as violent as before, the temperature continues to be high, but the pulse varies—it may be quick or it may be slow—the respirations are irregular, vomiting returns, and there is an intolerance of light and noise, while the stiffness of the neck, the retraction of the head, and Kernig's sign, become well marked, and headache, insomnia, restlessness, and delirium may be present, or the patient may be huddled up in a state of *resistant stupor*, from which he can be temporarily roused.

This is about the time at which a rash should appear, but this must be extremely rare in the tropics, as we have never yet met with it in this ordinary acute type of the illness. Flushing may be present and herpes of the lips may develop, but the petechial rash is extremely rare. The leucocytosis is now more marked.

Terminations.—During the fourth and fifth days death is not uncommon, but the symptoms may persist and death occur later on, somewhere about the sixth to eighth day or later, the temperature may decline, the symptoms abate, and the patient become convalescent.

Varieties.—Such is the common course of the disease, but there are other types—*e.g.*, the fulminating type, spotted fever type, chronic type, abortive type, infantile type.

The Fulminating or Septicæmic Type is associated with a sudden attack, rapid development of coma, and death in a few hours. It is often associated with a purpuric rash, with petechial or large hæmorrhages. The cerebrospinal fluid may be quite clear when first examined, but it contains a number of meningococci, and in a few hours has a typical appearance and shows polymorphonuclear leucocytes.

Usually by the time death has taken place there is sufficient evidence of pus at the vertex of the brain to support the diagnosis, even without microscopical examination. There are, however, cases which die before this pus is formed, and then the brain and meninges are congested, but the pia mater at the base shows patches of cloudiness due to pus cells.

Spotted Fever Type.—Somewhere between the first and the fifth day generalized petechial eruption may appear, which is most marked on the inner side of the knee, but it may also be found wherever there is pressure—*e.g.*, the great trochanter, the points of the shoulder, etc. It is a sign of severe toxæmia, and when exaggerated becomes the purpuric rash. *Other rashes* are:—A macular rash appears at times after the second day. It comes out in one crop, and is seen on the lower part of the abdomen and the thighs, but may occur on the forearms, legs, hands, or feet.

A fugitive erythema or blush has already been mentioned.

Chronic Type.—The acute symptoms of an attack pass away, the temperature may become normal, but the patient does not improve, and fever of an irregular type may or may not return, while opisthotonus may occur, wasting set in, and the patient slowly die of exhaustion, the amount of cerebro-spinal fluid obtained by puncture becoming less and less and thicker and thicker as time passes on.

Abortive Type.—These are cases which, though beginning with the ordinary symptoms, undergo the remission on the second day, are much better on the third day, and convalescent on the fourth day or thereabouts.

Infantile Type.—This is the so-called cervical opisthotonus of infants, a symptom which is *en evidence* by the fourth day, while as a rule there is little or no fever, but considerable and progressive wasting and marked vomiting. It is chronic and has a high mortality, death commonly ensuing in four to six weeks after the onset.

Mimicry.—At times the disease imitates enteric fever, broncho-pneumonia, gastro-enteritis, or rheumatic fever.

Relapses.—These are not uncommon, and are usually mild in type.

Sequelæ.—There is usually some permanent damage to the nervous system in cases which recover.

Diagnosis.—The cardinal early signs are:—(1) The sudden onset; (2) the headache and sense of general illness; (3) the vomiting; (4) the fever; (5) stiffness in the neck muscles; (6) the presence of the meningococcus in the cerebrospinal fluid as obtained by lumbar puncture.

The *Differential Diagnosis* has to be made from malaria, relapsing fever, typhus, enteric, influenza, and pneumonia.

From ***malaria*** it can be recognized by the absence of the leucopenia, the presence of the leucocytosis, and the absence of malarial parasites from the blood, as well as the absence of a large spleen. It may, however, occur in a malarial subject, but the leucocytosis will be present.

From ***relapsing fever*** it can be separated in the early stages by a blood examination revealing the absence of spirochaetes.

From *typhus* it can be distinguished by the vomiting, by the stiffness in the neck, and Kernig's sign.

From *enteric* it may be diagnosed by the headache and delirium occurring together, by the rigidity of the neck, Kernig's sign, and lumbar puncture.

From *influenza* it may be differentiated by Kernig's sign and by lumbar puncture, which may relieve some of the symptoms of a cerebral influenza.

From *pneumonia* by the irregular pulse-rate, the presence of Kernig's sign, and the absence of those of consolidation of the lungs.

Prognosis.—This is always serious—firstly, *quoad vitam;* secondly, with regard to after-effects.

Treatment.—Systematic daily lumbar puncture, with the withdrawal of a few cubic centimetres of cerebro-spinal fluid and the intrathecal injection of anti-meningococcal serum, in quantity to be judged by the amount of cerebrospinal fluid withdrawn at the time and by the blood-pressure and pulse-rate.

In cases where the pus is very thick an attempt to wash the spinal canal by intrathecal injections of warm sterile saline, followed by serum injections, may be tried.

In chronic cases or relapses vaccine therapy may be attempted.

Symptomatic treatment and careful nursing are also required.

Prophylaxis.—The proper method in prophylaxis is to avoid overcrowding, bad hygiene, and to provide ample space, good ventilation, and ample and good food for a community. When an attack has begun the sick and their attendants should be isolated, or the attendants should be constantly examined bacteriologically and have systematic naso-pharyngeal disinfection.

Contacts should be isolated and examined bacteriologically on three separate occasions, and have the naso-pharynx disinfected.

A search for carriers should be made in the immediate neighbourhood of the patient, and these carriers should be isolated and treated.

The nose and fauces should be sprayed with a solution of 1 per cent. iodine, 2 per cent. menthol in parolin, or if this is too expensive with ½ per cent. watery solution of formalin, which may be snuffed into the nose if an instrument is too expensive. This solution of formalin is especially useful for natives; it is rather too strong for Europeans.

If this fails and the carriers be isolated and placed under improved sanitary and dietetic conditions, vaccine treatment is beneficial, and may succeed when under other conditions the natural vaccination of contained organisms will fail. General vaccination of the population may be tried, but it is not certain as yet whether it will be successful or not, as the application so far has been limited.

THE EXANTHEMATA.

Scarlet fever has often been introduced into the tropics, but it does not spread. Thus we have seen cases introduced into Colombo from the steamers, but there has never been an epidemic of scarlet fever in that town to our

knowledge, nor have we seen an indigenous case. The tropical practitioner should be careful not to mistake for true scarlet fever, cases of scarlet fever-like eruptions such as *erythema scarlatiniforme*.

Measles is endemic in most tropical countries, but differs in no important details as a rule from the same disease in the Temperate Zone, except that when first introduced into Fiji it gave rise to a severe epidemic, and is still severe in Oceania.

FIG. [illegible] CHICKEN-POX: [illegible] DAY OF THE ERUP

Chicken-pox in the tropics is very often a disease of the adult, being most common in India in February to March. The majority of the cases are mild, but some are severe, and there may be great difficulty in diagnosing chicken-pox from smallpox. Varicella cannot be transmitted to man very readily by inoculation. Rabbits' cornea can be inoculated, and fine granulations have been described by several observers in the epithelial cells, which may be early stages of a cytoryctes arrested in its development, which would support the people who believe the two diseases to be closely allied.

VARIOLA.

Synonyms.—Smallpox. *French*, La petite vérole; *Italian*, Vajuolo; *German*, Blattern; *Spanish*, Viruelas; *Arabic*, Jadari.

Definition.—Variola is an acute specific fever of unknown causation spread by various agencies, but especially by air, and characterized by a more or less general eruption passing through the stages of papule, vesicle, pustule, crust, and often scar.

History.—There can be no doubt of the great antiquity of the occurrence of smallpox in India and Africa, but whether it arose *de novo* in these two centres we cannot say, but there is a suspicion that there are two varieties of the disease—viz., the ordinary smallpox, which may have had its origin in India and spread to Europe, and so to America, and later to the islands of Oceania; and an African variety variously known as South African Amaas, or milk-pox, which may have been imported by the negro slaves into the West Indies, where it is called West Indian modified smallpox. Apart, however, from conjectures of this nature, there are the facts that in India there was a special worship defined in the Atharvaveda, and there were special prayers to be said by the Brahmins when performing the operation of inoculation of smallpox virus. References in the Charaka-Saṁhitī and the Susruta-Saṁhitī make it almost certain that the disease was well known when they were written. It would appear that the disease was introduced into China perhaps from India, in the course of the third century B.C.

Equally ancient is the evidence of the existence of smallpox in Africa, for Ruffer and Ferguson have found an eruption on the skin of a mummy belonging to the period of the twenty-eighth dynasty (1200-1100 B.C.), which they believe to be suggestive of smallpox, and it is quite possible that there has existed from time immemorable an endemic focus in Africa, perhaps in Central Africa.

From these two foci in Asia and Africa it would appear probable that the disease has spread all over the world. With its introduction and spread in Europe we are not concerned, but with that into America a few remarks must be made, as it is very interesting. It would appear not to have been known in America until after the advent of the Spaniards, it is first recorded as occurring in the West Indies in the year 1507, when it was introduced from Europe, as has happened on many occasions since—e.g., into Chili in 1554—also by the agency of the Spaniards.

More interesting than this is the fact that it is recorded that importations of slaves from Africa were often followed by the appearance of the disease—as, for example, in Brazil, where, according to Piso, it appeared in 1560, being introduced in this manner.

With regard to Oceania, it has been introduced from Asia or America at various times—as, for example, Australia in 1838, from China to Sydney, the Hawaiian Islands in 1853, from San Francisco to Honolulu; while New Caledonia became infected in 1859, and Marquesas in 1863.

To-day the disease is widespread all over the world, but is especially common in the tropics, where institutes for the preparation of calf-lymph are urgently required in order that efficient vaccination, the only method of keeping the disease in check, may be successfully carried out.

Climatology.—It is believed that smallpox is perhaps most active at the present time in Central Africa, but if this is true certainly some portions of tropical Asia must come very nearly equal in endemicity, and briefly the disease, though world-wide in its distribution, is of the utmost importance in the tropics. When first introduced among peoples previously unaffected with the disease, it was most virulent—as, for example, its incidence on the Mexicans and the North American Indians.

Ætiology.—The causation is unknown, but various protozoal bodies have been described, of which the most important is *Cytoryctes variolæ* Guarnieri, 1892, minute spherical homogeneous bodies, to 4 μ in diameter, and staining well with Romanowsky, when it takes on a chromatin coloration, while Councilman and his colleagues have described a complicated life-history (p. 535).

Whatever the virus may be, it is usually spread by the air, and enters the body by means of the respiratory passages. Cases are on record of the infection being probably carried by cotton from Egypt to England, and there starting sporadic outbreaks, and this is possible if the cotton was handled by an infected person. Hence the request for the vaccination and revaccination of cotton-workers.

Symptomatology.—This is described in all books on general medicine, and need be only very briefly repeated here.

Briefly, a typical attack of discrete smallpox, after an incubation of nine to fifteen days, begins with a chill in an adult and a convulsion in a child, and continues with high fever, severe headache, lumbar pains, and vomiting, with or without a scarlatiniform or morbilliform rash on the second day, which may be general or local; or hæmorrhagic rashes, which are either petechial or petechio-erythematous, which appear from the first to the third day. If these latter rashes are associated with hæmorrhages from the internal organs, they indicate the onset of hæmorrhagic smallpox. Generally the initial stage of the disease lasts two days, but it may be shorter and milder than that recorded above, or more severe. The peculiar odour of a smallpox case may be noted in these early stages.

The typical rash appears on the second, third, or fourth day as papules on the face, arms, back of the wrists and hands, and, later, on the trunk and limbs; and at the same time on the mucosa of the mouth, nose, and throat, and more rarely on the vulva, vagina, and rectum. Generally it is more marked on the extensor surfaces of the limbs than on the flexor surfaces, and is often most marked in areas where there has been pressure. The papules are bright red in colour, but this may not be very evident in the dark skin, 2 to 3 millimetres in diameter, and have a hard, shotty feeling. As the rash comes out the temperature falls, and the initial symptoms improve. On the fifth to sixth day the papules become umbilicated vesicles, which turn into pustules when the umbilication disappears, and a surrounding areola of injection appears. During the maturation of the pustules the secondary fever appears, and the eyelids become swollen and closed. In the discrete form the fever disappears by the tenth to eleventh day, and convalescence sets in.

The confluent type of smallpox is more severe than in the above, and presents much less difficulty in its recognition, and need not be described.

Varieties.—There are, however, two varieties which are of importance in the tropics—viz., variola hæmorrhagica and varioloid—and these must be mentioned at greater length.

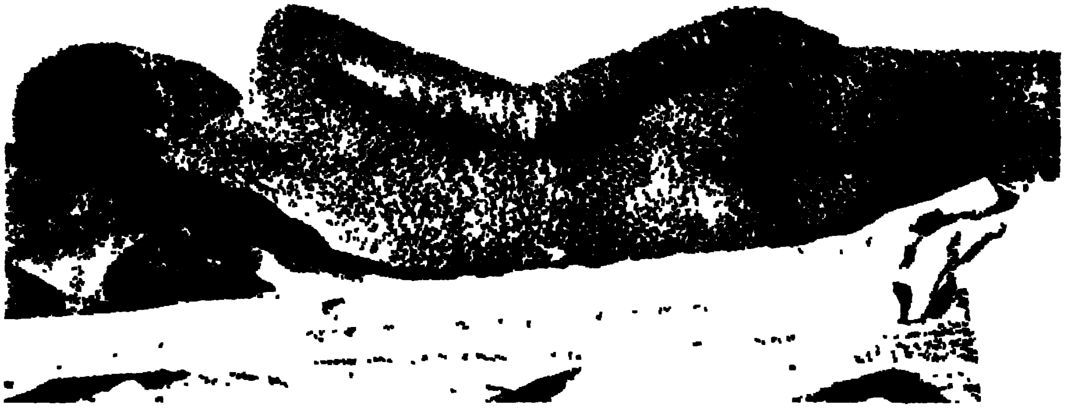

FIG. 679.—SMALLPOX.

(From a photograph by Balfour.)

VARIOLA HÆMORRHAGICA. Hæmorrhagic smallpox is, or was, by no means rare in Africa, and is met with in Asia, though by no means so frequently.

There are two varieties: *Purpura variolosa* and *Variola hæmorrhagica pustulosa*.

Purpura Variolosa. This variety commences with the same symptoms as ordinary smallpox, but they are much more severe. The fever is not considerable, and may be below 100° F., but the pains in the body, especially the backache, is very severe, and the vomiting may be very persistent and associated with severe epigastric pain. The pulse and the respirations are both much increased in frequency. At the end of the second or the beginning of the third day an erythematous rash appears in some part of the body, very often in the groins and flexure of the joints, but it may be absent, or it may extend and become general. At the same time and in the same places appear red and purple petechiæ, and about the same time subconjunctival hæmorrhages in one or both eyes, while purple spots appear on the forehead, eyelids, and face, and ecchymotic areas in various parts of the skin, and also on the tongue and pharynx. The patient now becomes pale and anæmic, except where the blotches are situate, and bleeding occurs from the mucous membranes and internal organs, of which the most common are oozing from the gums and hæmaturia, but epistaxis, hæmatemesis, hæmoptysis, melæna, and metrorrhagia, may one or all be present. Even retinal hæmorrhages may occur.

The temperature is now below normal, the patient is restless, with often a sensation of weight in the præcordium. The pulse is now soft and compressible. Sordes form on the gums, and the patient dies on the third to sixth day, with a clear mind and often without any sign of the typical smallpox eruption.

Purpura variolosa fulminans.—Very rarely the disease is more severe, with a temperature of 105° F. or more, associated with delirium, coma, and collapse, and followed by death in a few hours without any signs of external hæmorrhage.

Variola hæmorrhagica pustulosa.—In this variety the initial symptoms are severe, and delirium sets in early. Hæmorrhages appear from and under the mucous membranes and under the skin, and at the same time the typical smallpox eruption appears, into which blood also passes. The symptoms resemble those of confluent smallpox, with the addition of hæmorrhages.

A milder form is when the hæmorrhage occurs only into the eruption, and may or may not be associated with hæmaturia and some bleeding from the mouth.

Varioloid - Repeated vaccination is an excellent protective against smallpox, but if the disease does appear in a person who has been several times vaccinated, it is remarkably modified and is most difficult to recognize. Epidemics have been known to show such a mild type that the disease was mistaken for a length of time for chicken-pox, and have also been considered to be due to a new form of disease, to which such names as 'Cuban itch' and 'Philippine itch' have been given. Indeed, such epidemics have in some cases not been recognized until a fatal case has occurred, and Osler and McCrae have recorded a small outbreak in one of their wards for coloured patients in which the disease was at first mistaken for chicken-pox.

The varieties of 'Varioloid' are numerous. In the first place, there may be no eruption, and the usual initial symptoms may be slight, or they may be severe and accompanied by an erythema, but all symptoms disappear by the third or fourth day.

In other cases the disease begins with the usual symptoms, but at the end of the first day a few maculæ appear, which become vesicles in another twenty-four hours, when the constitutional symptoms begin to abate, and are full grown in about three to four days, when they are seen to be conical vesicles, often without any depression, surrounded by a very faint red line. On the third to fourth day they become somewhat opaque, and then shrink and desiccate forming small dry prominences on the skin, which finally desquamate, and the patient is convalescent. In other cases a few vesicles may become pustules by the sixth day of the eruption, which dry up and cast off their crusts in about a week.

Diagnosis. -The headache, the severe backache, the epigastric pain, the vomiting, the high temperature, and the rapid pulse, associated with an erythematous or petechial eruption on the abdomino-crural region, are important factors. The erythema, however, is apt to be irregularly distributed in blotches, but it does not affect the face. The petechial eruption is usually found about the flexures of the joints as small bright red petechiæ. Any acute febrile disorder associated with purpura should be suspected as being probably variola.

The typical eruption comes out on the second or third day of the illness as hard shotty papules on the forehead, face, arms, and legs, which have become papulo-vesicles and pustular, presenting umbilication, and *not* flattening on pricking.

From Varicella.—The first point in the differential diagnosis between smallpox and chicken-pox is to remember that it is very difficult, and that the most distinguished physicians have owned to not one mistake, but a series. No one point of absolute diagnostic value can be given, but the following table will indicate some of the points —

Sign or Symptom.	*Chicken-pox.*	*Smallpox.*
Initial symptoms ..	Absent as a rule, but may resemble smallpox.	Usually well marked, but may be absent.
Temperature ..	Does not fall with the appearance of the rash.	Falls with the appearance of the rash.
Situation of rash ..	Most marked on the trunk.	Most marked on the face and limbs.
Vesicles	Develop in twelve to twenty-four hours; are rarely umbilicated, collapse on pricking, all stages, papules, vesicles, and flattened scabbing, puckered pocks, appear together.	Papules hard and shotty; are slow in developing; vesico-pustules are more commonly umbilicated; eruption more uniform, and the scabbing margin is not puckered.

From Measles.—The diagnosis from measles may be made as follows.—

Sign or Symptom	*Measles*	*Smallpox.*
Catarrhal symptoms	Lachrymation, coryza, cough present from the beginning and marked	Usually absent, but there may be some conjunctival effusion.
Filatow or Koplik's spots	Usually present	Absent.
Eruption	Appears on the third to fourth day as minute pink papules behind the ears, on the forehead, chin, cheeks, neck, limbs, and chest. Papules not hard or shotty	Initial measly eruption on the first or second day on face, trunk, and limbs simultaneously. If partial, appears in the abdomino-crural area. Papules hard and shotty
Temperature ..	Reaches its height with the appearance of the rash.	Falls with the appearance of the rash.

From Influenza, etc.—In German measles the initial severe symptoms are absent, and in the fourth disease the face is free, while in influenza the typical eruption fails to appear.

From Typhus.—The diagnostic features are —

Sign or Symptom.	*Typhus.*	*Smallpox.*
Erythema	Appears on the third to fourth day of the illness.	Appears on the first or second day of the illness.
Typical eruption ..	Petechial. Appears on the fourth or fifth day, and is rarely seen on the face.	Papulo pustular. Appears on the third or fourth day, and is common on the face.

From Hæmorrhagic Diseases.—Any case of high fever of an acute nature associated with purpura may be smallpox. It is extremely difficult to separate hæmorrhagic measles and scarlet fever from hæmorrhagic smallpox, but in the former diseases there is not so much bleeding from the mucous membranes. The isolation for sixteen days and vaccination of all contacts, and the isolation of the sick are the most important.

Prophylaxis.—As smallpox is endemic in nearly all tropical countries, it is important that the natives should be taught concerning it, and the fact that vaccination is an excellent prophylactic measure, and this should be done by verbal instruction and by vernacular pamphlets, if possible illustrated; in this way the native prejudices, which are usually not strong, must be overcome. Secondly, vaccination should be made compulsory by law; and, thirdly, a vaccine service should be established. This vaccine service should consist of an institute for the preparation of lymph, with a reliable man to make the lymph, an inspector of vaccination, or more, according to the needs of the country, and a series of native vaccinators.

ALASTRIM.

Synonyms.—*African*, Varioloid varicella, Amaas, Kaffir milk pox, *American*, West Indian modified smallpox, Epidemic varioloid varicella; *perhaps* Pseudo-smallpox (Kersten), Sanaga smallpox (Plehn).

Definition.—An acute specific fever resembling in all its symptoms and pathological appearances a mild form of variola.

History.—As already stated in the history of smallpox, there is a possibility that there were originally two distinct endemic foci of variola—viz., Asia and Africa—and therefore, bearing in mind the different varieties of relapsing fever, it is hardly surprising that there should be at least two varieties of smallpox, even though the clinical symptoms are similar, and Guarnieri's bodies are found in both. Moreover, the disease is known in Africa and America, and there is no reason why it should not occur also in Asia when the considerable intercommunication between India, Ceylon, and China, with Africa, is considered. One of the earliest descriptions is by Anderson, in 1806, of an epidemic in 1805 in Jamaica, and there was another epidemic described by Dickson and Lasselle in 1903, while Korte gave an account of amaas, or Kaffir milk pox, in 1904. In 1905 Welch and Schamberg gave an account of it in their work on 'Acute Contagious Diseases' in 1908; Scheult described it as seen in Trinidad from 1902 to 1904; while Grant, in 1910 described 'amaas' as seen in South Africa, and in the same year Ribas describes it as seen in Brazil in 1900, and Carini as seen in the States of St. Paul, Minas, and Paranà.

Ætiology.—The causation would appear to be the same as that of ordinary smallpox, as it is generally agreed that Jenner's vaccination is protective, and Guarnieri bodies have been found, and the classical reaction in the inoculated cornea of the rabbit has been produced; after sixty hours the Guarnieri bodies have been recovered from the cornea, but it would appear to be due to an attenuated virus.

The question which has been much debated is whether it is smallpox, chicken-pox, or a new disease halfway between the two. In the first place, there are still some persons who disbelieve in the difference between variola and varicella, but their objection is usually disregarded. In the second place, alastrim differs from varicella because of—

1. Confluence of the vesicles in certain cases.
2. Its frequency among adults.
3. The partial protection by Jenner's vaccine.

It differs from variola vera by—

1. Its low mortality (1 to 2 per cent.).
2. Because it is less severe in children than in adults, and is often found among babies, in whom the vesicles are often small.

3. There is no secondary fever in children.

4. Though Jenner's vaccine is in some degree protective, the disease can occur after recent successful vaccination.

5. Jenner's vaccination can be successfully carried out shortly after an attack of alastrim.

6. According to some authorities, an attack of smallpox does give a lasting immunity to alastrim.

Provisionally we may conclude that it is probably a slightly different form of disease from true variola.

Symptomatology.—It begins with high fever, severe pains, and vomiting, with very often delirium. The rash comes out on the third day, when the temperature descends, the symptoms disappear, and the patient feels so well that he may resume his ordinary avocations. Secondary fever is usually absent, especially in children, but may occur about the eighth day. Papules become pustules and scabs, and these drop off, leaving little scarring, but only pigmentation.

FIG. [illegible] TRIM. (After Rib

Complications.—Hæmorrhagic cases are unknown.

Mortality.—The death-rate is remarkably low, about 1 to 2 per cent.

Prophylaxis.—The usual isolation, quarantine, and vaccination of contacts and cases must be adopted.

VACCINATION.

Vaccination from arm to arm is very dangerous in the tropics, as syphilis, yaws, relapsing fever, sleeping sickness, etc., may be inoculated. It should therefore only be performed when calf-lymph is not available, and only by means of children under eight years of age who are found to be healthy. These vacciniters can be sent to suitable districts if necessary; and if the amount of lymph required is considerable, two or three drops of glycerine may be placed on the vesicles, which are then punctured in several places, and the mixture used for immediate vaccination. With regard to the systematic work, *lanolated* seed-lymph can be obtained from many institutes at present, for example, from the Lister Institute in London.

Preparation of Lymph.—The vaccine institute requires an inoculating-room, a preparation-room for the lymph, an office, a store-room, a good stable for the calves—all of which should be rendered flyproof, and should have cement floors and be as cool as possible, and have a good supply of water. The special apparatus required are means for sterilization, Dornig's hand roller machine for trituration, and Entrican's machine, fitted with a small Geryk pump, for filling the tubes, as well as the ordinary glass and other materials of a laboratory.

The lymph should be obtained as lanolated seed-lymph from a reliable institute, and should be inoculated into fair-skinned heifers, not into black-skinned heifers, which should be specially fed during and after inoculation.

When tubes of calf lymph cannot be obtained, monkeys may be directly inoculated from cases of variola, and the calves may then be subinoculated from the monkeys, and if calves cannot be obtained rabbits may be used.

All animals should be carefully isolated and watched for a week before being used for inoculation. During this period the temperature should be taken and a tuberculin test applied.

When lymph first arrives in a tropical country from the temperate zone it requires to be acclimatized—that is to say, its virulence should be increased by passing it through about three calves before use, otherwise failures may occur.

The calves are vaccinated on the shaved abdomen, which has been washed with soap and sterile water, by linear incisions, about 1 inch apart, into which the lymph is gently and immediately rubbed, and a sterile cloth tied over the vaccinated area. No straw should be given for bedding, but a wooden grating should be used, and the calf's head should be secured by two tie-ropes to prevent it licking the inoculated area.

The lymph may be collected after 96 to 120 hours by first washing the area with soap and water, then with sterile water and a sterile gauze mop, and then removing the contents of the liver vesicles by means of a Volkmann's spoon.

The lymph is now weighed and mixed with an equal weight of sterile distilled water or glycerine, and after being worked into a paste is triturated until it is in an extremely fine condition, and if urgently required is treated with a stream of chloroform vapour for fifteen to thirty minutes, after which sterile air is bubbled through until no chloroform remains, and another part of sterile water and 2 parts of sterile glycerine, or 3 to 5 parts of anhydrous lanoline are added. The lymph is now filtered through a special fine sieve into test-tubes till nearly filled, and stored in cold climates for four to five weeks at a temperature of 15° to 20° C., when the number of micro-organisms is found to have decreased considerably. The chloroform method of purifying the lymph is to be preferred in the tropics, as it is much quicker. The technique is found in any modern work on the preparation of lymph.

A bacteriological examination is always necessary, especially to discover whether tetanus bacilli are present, and if these are found the lymph must be rejected. The lymph must be stored at temperatures at 5° to 10° C.; if this precaution is not used the lymph becomes inert very quickly in tropical countries.

The capillary tubes are filled in a vacuum in the Entrican filling-machine, and should be tested for vaccine activity before being issued.

Lanolated lymph, not being sterile, is more apt to contain a large number of micro-organisms. Dried lymph has been placed upon the market, and is now on trial on a large scale.

In vaccinating natives the left arm should be used about the middle, and not near the shoulder.

Vaccinia.—The only modifications in vaccinia between the Native and the European is the difference produced by the colour of the skin, and the greater risk of septic sequelæ; therefore the area of skin should be carefully cleansed before being utilized for vaccination.

The slight redness and swelling due to the scratches disappear in twenty-four hours, while the papules appear on the third to fourth day, and are succeeded by the vesicles, which become umbilicated pustules about the eighth to ninth day. These quickly begin to dry in the centre and form a scab, which falls off about the fourteenth to twenty-first day and leaves a scar.

VACCINATION RASHES.

Generalized Vaccinia.—This eruption is rare, but has been reported upon in natives by Hill and Ross in Natal, and by Chalmers and Archibald in the Anglo-Egyptian Sudan. It appears some twelve to twenty-two days after vaccination, associated with fever, in the form of a generalized papular rash, which as a rule comes out during several days. The papules form vesicles which become umbilicated, and then the case resembles closely a very mild attack of varioloid. The vesicles pass on to pustules, and these to scabs, which eventually leave small depressed scars.

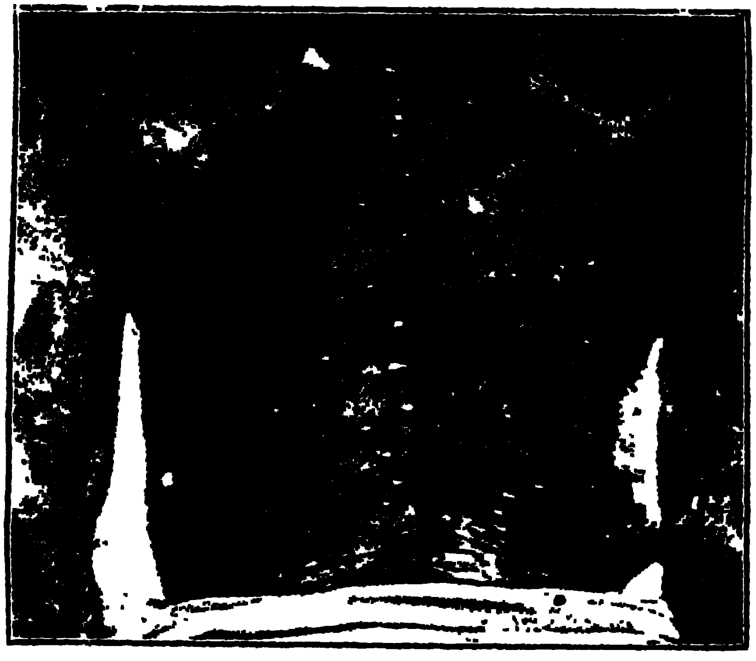

FIG. 681.—GENERALIZED VACCINIA.

In a typical case the rash appears twelve to twenty-two days after vaccination, requires some six days to reach its full development, and another eight days to decline to the stage when the scabs are thrown off and the patient is convalescent.

Localized Gangrenous Vaccinia.—Fortunately this is a very rare disease, but has been met in the tropics by Chalmers and Archibald. It occurs in cases in which no reasonable precaution has been omitted to guard against septicity in the performance of the vaccination, and, indeed, there may be no sign of septic infection in the disease, of which the following is a typical case:—

During the first three days after vaccination there was nothing to report, but on the third day the area became red and swollen, and on the fourth there was a number of small vesicles.

On the fifth, although there was only slight fever, the patient felt ill, while some of the vesicles ruptured and discharged their contents.

On the sixth day the vaccination area was covered by a yellow crust, and surrounded by a ring of vesicles and by a congested dark red area measuring about 1 inch in diameter. The temperature on this day did not exceed 102° F.

On the seventh day the crusted area became quite black, and extended until it measured some 2 inches in diameter. It was surrounded by a ring of umbilicated vesicles and by a dark red border measuring 1 inch in width, outside of which was a light red area of about the same depth. The whole region felt somewhat brawny to the touch, and the temperature rose to between 104° and 105° F.

On the eighth day the condition of the leg may be described as follows:—

In the centre there lay a black slough some 2 inches in diameter, surrounded by a ring of collapsed vesicles and by a raised dark red border, which, in its turn, was surrounded by a purplish area of skin some 3 inches in width, while, finally, the whole area was defined by a red zone of about an inch in diameter. On this day the temperature did not exceed 103° F., and the patient felt better, though the leg looked worse.

On the ninth day there was a decided improvement, the ring of vesicles had dried and formed a circular scab, the brawny resistance was softer and was beginning to disappear at the edges. The purple hue was lighter and showed signs of becoming reddish in places. The surrounding red area had, however, extended down to the ankle and up to the knee. The temperature did not exceed 102° F

From this date onwards the signs and symptoms began to steadily improve. The temperature fell slowly, remaining about 101° F. for two days, about 100° F. for another day, and then reached 99° F. The purple area became reddish and the reddish area white.

At this stage an attack of *acute gout* set in, beginning on the thirteenth day, when the temperature, which had never reached normal, rose to 100° F. The gouty symptoms were marked in the left hip, left arm, left side of the jaw, left wrist, the back, and the right ribs. These symptoms lasted some seven days, but gradually gave way to the usual remedies, and the temperature slowly sank to normal.

During this time the slough, mentioned above, came away, and a clean, healthy-looking, healing surface was left at the bottom of a depressed ulcer with raised, but not undermined, red edges, while the surrounding skin had returned to its normal colour.

There were no enlarged lymphatic glands, and no signs of sepsis. The urine was febrile, but did not contain albumen or sugar.

The patient made a good and rapid recovery.

Ætiology.- In attempting to define the causation of the above condition it is important to clearly distinguish between *localized gangrenous vaccinia* and the condition called *dermatitis gangrænosa infantum*, as the latter is a generalized eruption probably of septic origin, following *Varicella* and other pustular eruptions in children, and often assumed to have something to do with vaccination.

Localized gangrenous vaccinia, on the other hand, is quite different. It is not septic, but vaccinal in origin, and it is not generalized, but localized to the vaccination area.

Acland, Crocker, Balzer, and Hutchinson have met with similar cases, some of which are stated to have ended fatally.

In such cases as Chalmers and Archibald have been able to find any account of, there has been some latent infection or disease in the patient. Thus, for example, in Crocker's case there was *latent scarlet fever*, and in Chalmers and Archibald's case there was *latent gout*.

It therefore seems probable that *localized gangrenous vaccinia* can be produced by perfectly pure calf-lymph and by a satisfactory technique in persons suffering from any form of *latent constitutional disturbance* of severe nature, and that the severity of the local signs is caused by the lowered resistance of the tissues due to this latent infection, which, judging from this and other cases, makes itself sufficiently evident in the course of the illness which follows the vaccination.

Treatment.—At first the area should be merely protected from septic infection by pieces of sterilized lint lightly held in position by pieces of bandage. When the inflammatory symptoms appear, antiseptic dressings in the form of 1 in 80 carbolic lotion may be applied on lint, while the whole area is covered with cotton-wool, loosely held in position by first a bandage and then a handkerchief.

Closed dressings are not indicated, and the affected area should be simply exposed to the air in an elevated position, and treated at first by dry powders, later by lead and opium lotion, and finally by *calamine lotion*.

Papulo-Vesicular Vaccinia (Synonym, *Vaccine Lichen*).—This rash, which was first described by Crocker as vaccine lichen, has been observed in a number of cases by Chalmers and Byam in the Anglo-Egyptian Sudan. Some seven or eight days after vaccination the patient suffers from a mild attack of fever, which may reach 102° F., and may be attended with a slight sensation of itching in various parts of the body. The febrile symptoms subside as the rash appears, and do not return; but during the fever some of the patients suffer from a dry cough, which becomes worse as the eruption develops, and then slowly disappears. There is no vomiting or diarrhœa or other symptom worthy of record, while the vaccination pursues a normal course.

With regard to the rash, it appears, as already stated, some seven to nine days after vaccination in the form of dark coloured maculæ, which quickly become papules or papulo-vesicles, because, although no actual vesicles can be seen by the naked eye, still they produce a hard shotty sensation on palpation, and on microscopical examination show minute vesicles in the epidermis. A fully developed papule is about the size of a large pin's head, dome-shaped, and projects above the surrounding skin, which, as a rule, is quite normal, though in some cases it may be distinctly congested and may even be swollen. They appeared firstly upon the back of the hands and forearms, then on the back of the neck, then on the face, chiefly on the forehead, and then on the chest and back, and varied considerably in number from a few dozen to several hundreds.

The blood showed no parasites, but there was a leucocytosis and a marked relative increase of mononuclear and eosinophile leucocytes.

After lasting some four or five days, the rash slowly disappears, and is followed by a well-marked desquamation.

With regard to its ætiology, it was associated with vaccination because it occurred in two quite distinct detachments of Nuers and Nubas. The first detachment of twenty-four were vaccinated on February 10, 1914, and the eruption developed in eight, while the second detachment of thirty-six was vaccinated on February 23, 1914, and three developed the rash. It is to be noted that the vaccination in all was performed with lymph from one and the same calf. In every case the vaccination took well and developed normally, and in no case was there any sign of septicity or infection. No fungi or bacteria could be found in or cultivated from the papules; on the other hand, bodies which bore a resemblance to Guarnieri bodies were found in the vesicles.

The chief diagnostic points are:—

A papular or papulo-vesicular eruption beginning about eight days after vaccination and heralded by slight or no constitutional disturbance, but with moderate itching, and usually commencing on the arms, is most probably this eruption, which may be called a *vaccine lichen*, but which would be better termed a *papulo-vesicular vaccinia*.

The diagnosis should be confirmed by attempts at vaccination of a monkey from a papule or a vesicle.

The differential diagnosis may be made from:—

Lichen acuminatus by the fact that the hair follicles are not attacked.

From *craw-craw* (in the restricted sense of the word) by the absence of the horny consistency, and by the smaller size of the vaccinal papules.

From *lichen convex* by being non-follicular and by being an acute and not a chronic eruption.

From an ordinary *generalized vaccinia* by the main lesion being a papule and by the usually small size of the vesicles.

Prognosis.—This is invariably good, as all our cases and apparently most of Crocker's cases recovered very quickly without any scarring or pigmentation. Crocker has pointed out that it may go on to vesiculo-pustular formation, and in some of these cases fresh crops may continue to appear for months, or the vesicles may enlarge and become herpetiform or bullous, but it is possible that these exceptional forms are due to secondary infections and not solely to the lymph.

Treatment.—The essential treatment is rest and quiet. On quinine by the mouth and an antiseptic ointment—*i.e.*, carbolic ointment—for the skin, rapid recovery takes place.

Prophylaxis.—There is no explanation why eleven out of sixty persons vaccinated by the same lymph and belonging to the same African tribes, living under similar conditions, and about the same age and of the same sex, should develop an eruption while others did not. Therefore it is not possible to suggest any prophylactic measures.

INFLUENZA.

Remarks.—An acute specific fever, until recently believed to be caused by *Hæmophilus influenzæ* (Pfeiffer, 1892) (usual term: *Bacillus influenzæ*), spread from man to man aerially, and typically characterized by a sudden and severe onset, pains in various parts of the body, some catarrh of the respiratory passages, which typically subside in some two or three days and are apt to be followed by a prolonged convalescence. Recent researches by Charles Nicolle and Charles Lebailly tend to show that the malady may be due to a filter-passing virus. Bradford, Bashford, and Wilson state that the virus isolated in cases of influenza consists of minute Gram-positive, roundish, coccus-like bodies, varying from 0·15 μ to 0·5 μ, capable of passing through Berkefeld N and V filters. It is an anaerobe, and is not destroyed by heating to 56° C. for thirty minutes. They have isolated this organism from the blood and sputum of a number of cases.

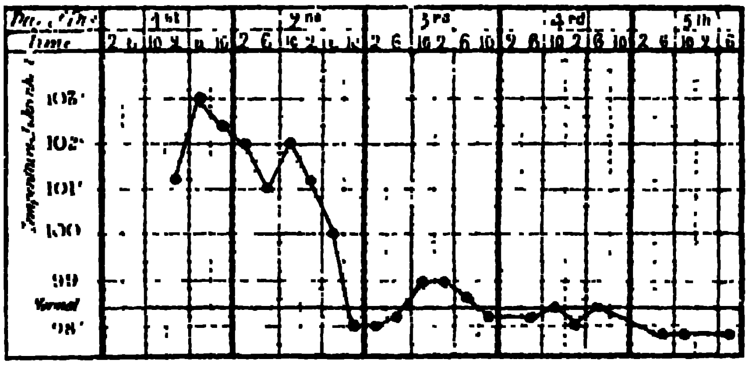

Fig. [illegible]52.—Temperature Chart of Influenza.

It is not our intent to discuss the ætiology or to enter upon a full description of influenza, which can be found in any textbook on medicine, but rather to attempt to impress upon the tropical practitioner the necessity of recognizing this complaint, which is very apt to be mistaken for pappataci and dengue fever, and *vice versa*.

Typical Attack.—Suddenly, without warning, the victim feels very ill; he may shiver, feel sick, or be giddy, but in any case he feels acute pains in various parts of the body, but especially in the lumbar region, behind the eyeballs, and in the muscles and bones, as well as a dry burning sensation in the eyes, nose, and throat, and sometimes also behind the sternum. His temperature rises quickly to 103° to 105° F., his pulse and respirations are increased, and he suffers from a troublesome cough, and herpes may occasionally appear on the lips.

After two or three days of these symptoms the temperature falls, slight catarrhal symptoms appear, the patient becomes convalescent, and may recover completely or may feel out of sorts for weeks or months.

In the *catarrhal type* there are the ordinary signs of a bronchitis, to which may be added those of a lobular pneumonia, and such cases are very dangerous. In the *gastro-intestinal type* there are the signs of gastro intestinal catarrh, which is rare, but more frequently there is a pseudo-enteric condition, with fever, lasting, however, about a week.

In the *cerebral type* the onset may be sudden or gradual, be with or without catarrhal symptoms, and is associated with pains in various parts, delirium, aphasia, hemiplegic or monoplegic symptoms, and, indeed, may at times simulate a cerebral hæmorrhage, especially in afebrile cases. These are very fatal cases, but at times recovery takes place, often with permanent mental disturbance.

Blood.—The blood practically shows no change. The total leucocytes vary from 8,000-12,000, while the differential count is within normal limits.

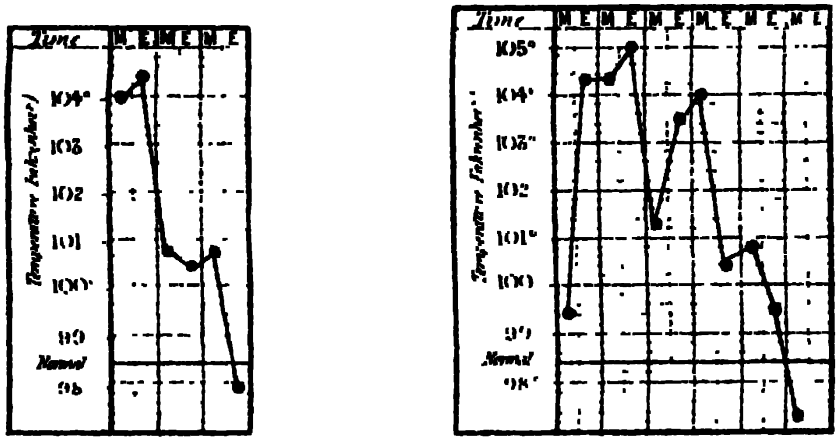

Fig 683 Fig. 684

FIGS 683 AND 684.—TEMPERATURE CHARTS OF INFLUENZA

Complications and Sequelæ.—These are numerous and frequent, but for them an ordinary textbook of medicine must be consulted.

Diagnosis.—The cardinal features of a typical attack of influenza are:—(1) The sudden and violent onset, (2) the high fever and quick pulse, (3) the violent pains in the muscles and bones; (4) the catarrhal symptoms, (5) the absence of any typical rash; (6) the presence of Pfeiffer's organism, whether it is the true specific agent or a nosoparasite; (7) the absence of a marked leucocytosis.

In the tropics the most important points in the *differential diagnosis* are the separation of the malady from malaria, dengue and pappataci fevers, and from plague. From malaria it can be recognized by the absence of the parasites in the blood, the absence of the mononucleosis and of the enlarged and tender spleen, and by the presence of catarrhal symptoms.

From *dengue* it can be separated by the absence of the leucopenia and of the rash, and by the presence of catarrhal symptoms.

From *pappataci fever* it can be diagnosed by the absence of the leucopenia, the quickness of the pulse, and as a rule the presence of the catarrhal symptoms, which in pappataci fever are absent or slight.

From *plague* by the absence of plague bacilli in the sputum in the pneumonic type, or in blood as demonstrated by hæmo-cultures in the septicæmic variety.

Prognosis.—This is good *quoad vitam* in typical uncomplicated cases, and bad in the varieties mentioned above.

Treatment.—It is important that the patient should remain in bed and be carefully nursed.

Liquor ammoniæ acetatis in ½ drachm doses in a mixture combined with 3 to 5 grains of sodium salicylate, alternated with 1 drachm doses of the ammoniated tincture of quinine, well diluted, should be given every two hours until the symptoms are relieved.

Pyramidon may be administered with benefit, if desired.

The diet should be light and nutritious, and the heart and respiratory organs should be carefully watched.

Prophylaxis.—The patient should be isolated as far as possible, and on recovery his room, bedding, clothing, etc., should be disinfected. Vaccines have not been very successful.

CHAPTER LIX

WAR ZONE FEVERS

General remarks—Trench fever—Icterus castrensis gravis—Icterus castrensis levis—References.

GENERAL REMARKS.

It may be thought that it is unnecessary to introduce the subject of the diseases of the different zones of the war into a work on tropical diseases, but many of the maladies which have affected the troops during the war in the Salonica area, in Egypt and Palestine, in Mesopotamia and East Africa, are essentially tropical diseases, as were those of Gallipoli. Most of the fevers from which the troops suffered have been described in the preceding chapters, and many of the other diseases, such as the dysenteries and skin diseases, will be dealt with in the chapters which follow; but, excluding these, there are three conditions which merit a little consideration—viz., trench fever and the severe and mild forms of infective jaundice, often called icterus castrensis gravis (or Weil's disease), and camp jaundice—because, in making a diagnosis of a fever, these conditions must be considered, and we are now preparing the way for the chapter on diagnosis.

We therefore consider that a very brief account of these three conditions is necessary for our present purpose.

TRENCH FEVER.

Synonyms.—Periodic one day fever, Salonica fever, Pyrexia of unknown origin, Five days' fever, Volhynia fever, Russian remittent fever, Meuse fever, Trench skin, Gaiter fever, Shin fever, Trench shin, Shank fever, Polish fever, Quintan fever. *French*, La Fièvre des tranchées. *German*, His-Wernersche Krankheit, Fünftagefieber, Periodische Fieber; *Latin*, Febris quintana, Febris volhynica.

Definition.—A relapsing fever of as yet unknown origin, and spread by *Pediculus corporis* de Geer, 1778, commonly by the infected faeces being rubbed into the excoriated skin. It is characterized by a sudden onset of fever associated with pains in muscles and bones, particularly in the legs, with especial tenderness of the shins, and lasting twenty-four to forty-eight hours or longer, followed by other attacks of fever of less and less severity, separated by apyrexial intervals of five days' duration (more or less), and ending in complete recovery.

History.—As Strong has pointed out, there is insufficient data to permit any of the diseases described by the ancients, or in mediæval or modern times, being connected with the disease; while McNee believes that it is unlike any disease reported in other wars, and that it may have been introduced into the British Army by Colonials. Early in 1915 Graham drew attention to the disease as seen in the British Army, in which thousands of cases occurred between April and October. In January, 1916, it was observed in Salonica by McGavin, Wylie, and Acland, of No. 1 New Zealand Stationary Hospital. In May, 1916, it was observed in Mesopotamia, and in the same month was reported by Beauchant and Boidin as being present in the French Army in France, and about this time Werner in Warsaw drew attention to its existence in the German armies, and Hurst gave a good general account of the disease. In the same year McNee, Renshaw, and Brunt showed that the disease could be transmitted to healthy men by intramuscular and intravenous injections of the blood of patients, and the Germans also were similarly successful. In the same year it was observed at Salonica that the clothes or body louse, *Pediculus corporis*, was the only possible source of infection in a certain hospital orderly who had never been in contact with patients, and in whom the incubation was eighteen days from the first time he became infected with lice from some clothing. In 1918, Strong, Swift, Opie, McNeal, Baelzer, Pappenheimer, and Peacock, in France, showed that the virus was present in the blood plasma and would not pass through a filter. They also proved that the louse was the infective agent, and that the virus was naturally conveyed by its bite. This virus is present in the plasma, sometimes in the urine, and occasionally in the sputum. Artificially the disease may be transmitted by rubbing lice fæces, human infected urine or sputum, into excoriated skin, but the incubation resembles that of the inoculation of infected plasma.

A little later, in the same year, the British Committee in London showed that lice bites did not produce the disease, which, however, could be produced in healthy men by rubbing infected louse fæces into excoriated cutaneous areas. Further, they demonstrated that the incubation period was six to eight days, and that blood taken from the infected men and injected into healthy men could reproduce the disease after an incubation of five days. Also, in 1918, Couvy and Dujarric de la Rivière claimed that a spirochæte, *S. gallica* Couvy and de la Rivière, 1918, could be found in the blood of man and infected guinea-pigs, and in the liver and kidneys of these guinea-pigs. The infected guinea-pigs were shown to suffer from a fever resembling that in man. They, however, did not retransfer the disease from the guinea-pig to man, and the general opinion at present is that the organism is not the cause of the disease. Other organisms such as a piroplasma and a hæmogregarina have been described as causal.

In 1916 Toepfer found ***Rickettsia*** bodies similar to those described in 1909 by Ricketts in Rocky Mountain spotted fever, and by

Ricketts and Wilder, in 1910, in typhus. In 1917 Da Rocha Lima called the bodies found in trench fever *Rickettsia quintana*, to distinguish them from those found in typhus (*R. prowazecki*) and those occasionally seen in normal lice (*R. pediculi*). These findings were supported in 1918 by Arkwright, Bacot, and Duncan.

In 1919 Bradford, Bashford, and Wilson described minute bodies which they had succeeded in cultivating from the blood of patients, using Noguchi's method of anaerobic cultures. These bodies are morphologically identical with Rickettsia bodies, but they are Gram-positive.

Climatology.—The disease is known to exist in England, Flanders, France, Salonica, Greece, Macedonia, Tyrol, Galicia, Poland, Russia, and Mesopotamia.

Ætiology.—The ætiology has not been completely elucidated. Toepfer first found minute bodies in the intestinal contents of lice fed on trench fever patients, which he considered to be Rickettsia bodies: these bodies were somewhat similar to those found in Rocky Mountain fever and typhus. Toepfer's work was confirmed and enlarged by Da Rocha Lima, who called the parasite *Rickettsia quintana*, and more recently by Arkwright, Bacot, and Duncan. These latter authors describe the bodies as being minute Gram-negative organisms, round, oval, or lancet-shaped diplococci, 0·3 microns in their shorter diameter by 0·3 to 0·4 in length; the first appearance in the excreta of lice being as a rule eight to ten days after the first infecting feed. They seem to be slightly smaller and less frequently lancet-shaped than those found in typhus. The size of these bodies is such that they should not pass as a rule a bacterial filter, but may occasionally pass a filter which retains such bacteria as *B. typhosus*.

Bradford, Bashford, and Wilson report that they have cultivated from the blood of patients, by using Noguchi's method, minute bodies which seem to be very similar to Rickettsia bodies, but are Gram-positive.

The trench fever virus is considered to be a resistant filterative virus by the American Commission. This Commission (composed of Strong, Swift, Opie, Macneal, Baetjer, Pappenheimer, Peacock, and Rapport) carried out a very thorough investigation in 1918, and came to the conclusion that the virus was carried from the sick to the healthy by the agency of the clothes louse, *Pediculus corporis* de Geer, 1778, and that it was usually conveyed by the bites.

The War Office Commission (composed of Byam, Carroll, Churchill, Dimond, Lloyd, Sorapure, and Wilson) came to the conclusion, after a series of important experiments, that the infection was contaminative by means of the louse fæces infecting scratches on the skin.

Pathology and Morbid Anatomy.—Unknown.

Symptomatology—*Incubation.*—Clinically the incubation period is believed to vary from fourteen to thirty days, because this is the time required to induce the disease experimentally by infected lice when permitted to bite healthy persons. Experimentally it is six to eight days from the time that infected lice fæces are rubbed into scratches, and five days after the inoculation of infected blood. During this stage there may be slight prodromata in the form of headache and pains in the limbs, but these may be absent.

Attack.—The *onset* is sudden, the patient feeling giddy, weak, and shivering. He feels so ill that he has at once to stop his work, and complains of shortness of breath, pain in the left side, in the back, legs, and behind the eyeballs, as well as of headache. The temperature quickly rises to 101° to 104° F. The conjunctivæ are injected, and nystagmus may be present if the eyes are turned completely sideways.

There are two curious types of this stage of the illness—viz., the *appendicular* and the *cerebro-spinal*. In the former, the patient suffers from abdominal pain, constipation, slight abdominal distension, tenderness, and vomiting, and in Allied and German armies the diagnosis of appendicitis has been made. At other times there may be pains and stiffness of the neck, and the case may be mistaken for cerebro-spinal meningitis.

The *Course* of the disease is that the next morning the temperature has fallen to normal or nearly normal, but it may remain high, the appetite is lost, the tongue is furred, and there may be pharyngitis and constipation. Now the patient complains of pains in the muscles and bones of the legs, and has tenderness in the shins, over which there is cutaneous hyperæsthesia, and there may be pain and tenderness in the fibula, humerus, ulna, or along the vertebral column.

Herpes labialis may appear, and fairly often a discrete roseolar rash, and very rarely a scarlatiniform or small papular rash, may be seen on the chest, back, or abdomen. The spleen and more rarely the liver may now enlarge. The blood shows a leucocytosis, with a relative mononuclear increase. The red corpuscles are not reduced in amount, but the hæmoglobin is usually reduced, and there is polychromatophilia.

First Intermission.—After twenty-four to forty-eight hours, or longer, the temperature falls to normal, the symptoms disappear, and the patient feels well, though sometimes he feels slight discomfort in the muscles and bones.

Second Attack.—Some two to ten, but more usually five, days after the cessation of the first attack the patient begins to feel ill, with headache, pains in the legs, and fever, the temperature rising to about 101° F. Next day the temperature is normal, and this attack may cease, or the fever may recur in the evening, but usually ceases next day.

Intermissions and Attacks. These now succeed one another at regular intervals of about five days' duration, but the attacks of fever become shorter and shorter and the temperature lower and lower, so that unless care is taken to register the temperature every two hours about the time of an expected attack, the fever may be missed by the day and night temperature chart. Although the patient does not feel or look ill, the pains and tenderness in the shins may become worse during each attack and may keep him from sleeping. The number of relapses is variable, and may reach six or seven.

Rash.—In a fairly large number of patients a delicate macular rash appears with each recurrence of the fever. It is generally seen on the chest and abdomen, and consists of small red macules which disappear on pressure.

Termination.—After lasting a variable time (five to six weeks), the disease gradually dies out and the recovery is complete.

Complications and Sequelæ.– Tachycardia and so-called soldier's heart may occur.

Varieties.—English observers recognize a short and a long type. In the former the fever lasts for three to four days, falls to normal, and after a few hours rises again for two to five days, when it falls to normal and the fever stops. This variety resembles dengue fever. The long type is the typical fever.

The Germans also recognized a simple paroxysmal form, but they also mention a typhoidal and a rudimentary form.

Diagnosis.—This has to be made from influenza, dengue, pappataci fever, relapsing fever, malaria, smallpox, typhus, and enteroidea.

From *influenza* it may be distinguished by the absence of catarrhal symptoms and the mononucleosis.

From *dengue* and *pappataci* by the absence of leucopenia.

From *relapsing fever* by the absence of marked enlargement of the spleen and of the spirochætes in abundance in the blood.

From *smallpox* and *typhus* by the absence of the severe constitutional symptoms.

From *malaria* by the absence of the leucopenia and of the typical parasites from the blood.

From *enteroidea* by the sudden onset and the pains in the muscles and bones, and by negative hæmoculture and serological reactions.

Prognosis.– This is good, as the mortality is nil and the recovery complete.

Treatment.—Pyramidon is strongly recommended, but constipation must be relieved, and the patient should be disinfected at once. His clothing and bedding should be disinfected in moist heat at 70° C. for half an hour.

Prophylaxis.—This is mainly louse destruction (*vide* the chapter on Typhus, p. 1338), but the urine and sputum of patients should also be disinfected. Cups should be provided for the sputum.

ICTERUS CASTRENSIS GRAVIS.

Synonyms.—Weil's disease, Epidemic jaundice, Infective jaundice, Spirochætal jaundice, Spirochætosis icterhæmorrhagica, Larrey-Weil disease. *French*, Maladie de Weil, Typhus hépatique; *German*, Infektiöser Fieberhafter Ikterus, Infektionikterus, Weilschen Krankheit; *Japanese*, Odan-eki; *Latin*, Icterus febrilis seu infectiosus, Typhus biliosus nostras, Morbus weili.

Definition.—An acute specific fever caused by *Spiroschaudinnia icterohæmorrhagiæ* (Inada, Ido, Hoki, and Keneko, 1915), and characterized by jaundice, albuminuria, enlargement of the spleen, pains in the muscles, with sometimes hæmorrhages and a high mortality.

History.—The disease was first mentioned in Minorca in 1745, and then along the coast of Italy. Larrey, in 1800, seems to have described this disease as seen in Napoleon's army in Egypt. It was also noted by Carville in 1859, and by Worms in 1865, while a number of cases occurred during the American Civil War. As the mortality from jaundice was low in the South African War, it is probable that it was absent. In the present war it has occurred in the British, French, Italian, Serbian, and German armies, though it has been confused with the milder type. In 1886 Hirsch popularized the complaint and Weil again drew attention to the disease, and in 1911 Hecker and Otto wrote a monograph on it. As regards the tropics, it was noted in India in 1849, and in subtropical countries it was seen in Smyrna and Egypt. In this history authors noted two types, a mild, resembling simple catarrhal jaundice, and a severe, which some of them called a type of bilious remittent fever, and said that some of the cases had hæmorrhages and nervous symptoms. During the last few years it has received much attention, because cases of jaundice have been frequently noted in the armies In 1915 the Japanese investigators mentioned above discovered the causal agent, and this has been confirmed by French, English, Italian, and German workers. Noguchi has found that strains of *S. icterohæmorrhagiæ* isolated from patients in Japan and Belgium, and from rats in America, are identical morphologically and serologically. He has created for the organism a new genus, *Leptospira*, which will probably be generally accepted in the near future.

Ætiology.—The causal agent is *Spiroschaudinnia icterohæmorrhagiæ* (p. 447), which is considered to be the same as the spirochæte found in the kidneys and urine of wild rats, in which it lives. It is believed that the organism escaping in the rats' urine, and to a less extent in human urine, is the source of infection, which takes place through the skin when walking barefoot on sodden ground or by entering the alimentary canal in water.

Pathology.—The jaundice is probably caused by obstruction to the smallest bile ducts, brought about by a polymorphonuclear exudate into the tissues surrounding them.

Symptomatology.—The *incubation period* varies from five to seven days, the average being six days, which agrees with an accidental infection.

The *onset* is usually abrupt, with occasional shivering and high fever, faintness, giddiness, and prostration. The patient is flushed and looks and feels very ill. The spleen and liver enlarge, and the superficial lymph glands may become palpable.

Course.—Jaundice appears two or three days after the onset. The tongue is coated with a brown fur, and sordes form on the lips and teeth. Vomiting may be present from the first, and hiccough may also be troublesome. There may be pain and tenderness in almost every part of the body. The neck may be stiff, and in these cases the cerebro-spinal fluid may be under pressure and contain an excess of polymorphonuclear cells and lymphocytes, as well as albumen and bile.

The conjunctivæ may be injected, and herpes may be present on the lips.

Jaundice usually appears two or three days after the onset of the symptoms, but may be later, though it is almost always present before the temperature drops. Pruritus is slight or absent.

The blood shows a diminution of red corpuscles and hæmoglobin, and an increase of leucocytes, while a very few spirochætes are present between the fourth and ninth day. The pulse is slow in proportion to the temperature. The urine usually contains bile, albumen, granular and hyaline casts, and sometimes a few red corpuscles, and the spirochæte can be found after the first week.

Hæmorrhages from the lungs, the stomach, or more rarely the bowels, may occur, while epistaxis and purpura may be seen in severe cases.

Termination.—The temperature drops by crisis or rapid lysis from the eighth to tenth day.

Relapse.—There is often a return of the fever some few days after it falls to normal, and the relapse may last from a few days to ten or even fifteen days, but there is no increase in the symptoms.

Convalescence.—This is often prolonged.

Diagnosis.—The cardinal diagnostic points are:—

1. The presence of the spirochæte in the blood between the fourth and ninth day (it is difficult to see), and in the urine. Blood may be inoculated into the peritoneal cavity of guinea-pigs, in which illness supervenes after inoculation of not less than six days.

In order to discover the spirochæte in the urine, it is necessary to adopt Castellani's method of centrifuging 20 c.c. and pouring off the supernatant fluid, then adding another 20 c.c. and again centrifuging, and so on until about 200 c.c. of urine has been centrifuged, after which the deposit may be examined.

2. The severity of the symptoms and the sudden onset, the severe pains, the jaundice, the enlargement of the liver and spleen, the albumen in the urine, with casts and a few red blood corpuscles.

3. The pulse is slow in proportion to the temperature.

The differential diagnosis has to be made from camp jaundice, enteric jaundice, septic jaundice, malarial jaundice, acute yellow atrophy of the liver, typhus, blackwater fever, pneumonia with jaundice, yellow fever, and relapsing fever.

From *camp jaundice* (*icterus castrensis levis*) it can be diagnosed by the sudden onset, the severity of the symptoms, and the shortness of the illness.

From *enteric jaundice*, which is rare, it may be recognized by the presence of the polymorphonuclear leucocytosis and the absence of leucopenia, and the usual signs of enteric fever, while blood cultures fail to demonstrate the typhoid bacillus and its allies.

From *septic jaundice* it can be separated because the jaundice appears at an early and not at a late stage in the disease, and by the absence of septic infections clinically and by hæmoculture.

From *malarial jaundice*, and especially the Weil's disease-like type, by the absence of the malarial parasites in numbers and by the presence of the slight leucocytosis.

From *acute yellow atrophy* by the absence of the diminution of urea and uric acid, by the absence of leucine and tyrosin in the urine, and by the increase in size of the liver.

From *typhus* by the absence of the peculiar facies, of the subcuticular mottling and the typical rash, and by the presence of jaundice, which is only occasionally seen in that disease.

From *blackwater fever* by the absence of hæmoglobin from the urine.

From *pneumonia with jaundice* by the absence of right-sided lobar pneumonia.

From *yellow fever* by the pulse being rapid from the first and falling as the temperature falls.

From *relapsing fever* by the absence of abundant ordinary spirochætes from the blood, and by the peculiar characters of the typical spirochætes of Weil's disease when present in blood, in which it is found only in small numbers.

Prognosis.—This is serious, the death-rate being some 30 per cent., and convalescence being prolonged.

Treatment.—The repeated subcutaneous or intravenous injection of 20 to 60 c.c. of the serum prepared by Inada, Ido, Hoki, Ito and Wani or of Martin and Pettit's immunized horse serum is recommended. Salvarsan and its allies are useless. Symptomatic treatment for constipation by salines and aperients is also to be remembered.

Prophylaxis.—Disinfect the urine of patients for some nine weeks from the onset of the attack. Catch and kill rats. Disinfect the ground of the endemic area or remove the persons from this area.

ICTERUS CASTRENSIS LEVIS.

Synonym.—Camp jaundice.

Definition.—A slightly febrile disorder, characterized by mild febrile symptoms, followed by a mild attack of jaundice lasting some two to eight weeks, after which there is a very prolonged convalescence.

Remarks.—We have already noticed that older writers have divided Weil's disease into two types, one mild and the other severe. Camp jaundice represents the mild form, and clinically is practically indistinguishable from catarrhal jaundice. It was very common in Eastern war zones, and its symptomatology may be divided into the pre-jaundice period and the jaundice period.

Climatology.—It was common in Gallipoli, the Balkans, Italy, and France.

Ætiology.—This is at present unknown. Certain authors consider it to be of paratyphoid origin, but this is not so. Spirochætes have been described in the urine by several observers, including one of us. These organisms are often not pathogenic to guinea-pigs, and have not yet been demonstrated to be the cause of the disease.

Pathology.—It would appear as though the jaundice was due to obstruction to the common bile duct, either by swelling of the duodenal mucosa or to mucus in the duct.

Symptomatology.—The *onset* is gradual. The patient feels tired, complains of aches in various joints and muscles for weeks, the skin may appear to be normal, and the temperature is either normal or not very high (99° to 100° F.). The patient has often the sensation of suffering from very high fever, while on taking his temperature he may find it normal or subnormal. During this stage very often the urine is darker than usual and contains biliary pigments. We have come across patients feeling fairly well, but complaining of what they called rheumatism for months before the jaundice appeared: others had remarked the staining of their shirts by the urine. This stage may last for several weeks; in one of our cases it lasted three months before the jaundice appeared.

The Jaundice Stage.—First the sclerotics, then the skin, slowly become icteric. The degree of jaundice is seldom so marked as in cases of true obstructive jaundice. The patient generally feels absolutely done up, often with pains and aches all over the body; as a rule there is very little or no pruritus, in contrast to so many other types of jaundice. He has no appetite, and may feel inclined to vomit. The temperature is normal or subnormal, pulse usually slow, but may be of normal frequency; the spleen generally is not palpable, nor is the liver in most cases, there may be pain on pressure in the region of the gall-bladder, but this is not a constant symptom. There is often constipation, and the stools may be whitish or of the usual brownish colour; at times there are periods of diarrhœa, alternating with periods of constipation. The urine is scarce and very dark-coloured; it may contain a trace of albumen and casts. The *jaundice stage lasts between two and eight weeks.* Recovery is slow, and for weeks and months after the jaundice is over the patient may feel very weak.

Diagnosis.—The characteristic features of the disease are:—(1) Its epidemicity; (2) its slow onset; (3) its long course divided into a pre-icteric and an icteric period.

With regard to the *differential diagnosis*, it can be separated from *catarrhal jaundice* only by its epidemicity.

From *icterus castrensis gravis* (Weil's disease) it can be differentiated by the mildness of the symptoms, by the slowness of the onset, and by the slightness or absence of the febrile symptoms and the absence of hæmorrhages.

From *enteric jaundice* it can be separated by the absence of enteric organisms, as shown by hæmocultures, and by the absence of the enteric serum reactions in the later stages.

From *malarial jaundice* it can be diagnosed by the absence of malarial parasites in the blood and also by the absence of serious symptoms.

Prognosis.—This is favourable *quoad vitam*, but the course of the disease may be prolonged, and for weeks and months the patient may be very depressed and weak.

Treatment.—There is no specific therapy, and hence treatment must be symptomatic, with rest in bed, milk diet, and urotropin in 10-grain doses three times a day.

Prophylaxis.—The urine and fæces should be disinfected.

Nanukayami.

A seven-day fever resembling a typical Weil's disease has been reported from several Japanese observers from the province of Fukuoka. Ido, Ito and Wani have found that the causative agent is a spirochæte—*S. hebdomadis*—which is serologically distinct from *S. icterohæmorrhagiæ*. The normal host of the spirochæte seems to be the field-mouse, *Microtus montebelli*.

REFERENCES.

The *Tropical Diseases Bulletin* is most useful for the diseases of the war zones, as it contains not merely epitomes of English, French, Italian, and Greek papers, but also those written by Germans.

CHAPTER LX

THE DIAGNOSIS OF A TROPICAL FEVER

Preliminary—Thermometric pseudo-fever—Acute fevers—Fevers of less than eight days' duration—Fevers of more than eight days' duration—Chronic fevers—Summary.

PRELIMINARY.

THE method of diagnosis contained in the present chapter is not intended to be comprehensive, and the reader who expects to find every possible situation dealt with will be disappointed, because this is not our intent, and, indeed, would be a practical impossibility.

We are endeavouring to place before him such information as we have found necessary to use in some twenty-odd years of tropical life, and we may perhaps be pardoned if we mention some plain facts before starting on our subject.

Firstly, we trust that our reader will realize that it is one thing to draw up a nice-looking scheme of diagnosis upon paper, and it is quite a different thing to give a system which will be applicable at the bedside; but no one knows better than we do how difficult it is to write a system so applicable.

Secondly, we trust that our reader has not forgotten that there is such a thing as clinical medicine—that is to say, a system of diagnosis based upon the bedside examination of the patient. In our opinion, every patient should be most carefully examined, from the crown of his head to the soles of his feet, by ordinary clinical methods before any attempt is made to utilize the resources of the laboratory.

A systematic clinical examination of every patient is most essential. It is the sum total of the various symptoms, none alone pathognomonic, which establishes the diagnosis in conjunction with which the results from the laboratory must be considered. A practitioner who is unable to come to some sort of a diagnosis without the aid of a laboratory should, in our opinion, utilize his earliest spare moments in a course of post-graduate instruction with regard to clinical methods.

Thirdly, we are of the opinion that the laboratory work should never be omitted as a check to confirm or to adjust this clinical diagnosis. Specimens sent for diagnosis to a laboratory should always be carefully collected. This collection should at least be supervised by the practitioner, and not left to subordinates entirely.

otherwise mistakes will be possible. The specimens should always be collected and forwarded in the most aseptic method possible, and should be accompanied by a statement recording the nature of the specimen, the date and time of its collection, the nature of the examination desired (which should not be vague—*e.g.*, not 'urine for examination,' but clearly stated, 'urine to be examined *quantitatively* for sugar'), and a brief statement of the salient features of the case and the suspected clinical diagnosis, because it is the duty of the practitioner to help the laboratory in its work.

Finally, we desire most earnestly to impress upon the reader that the essential feature in the diagnosis of a tropical fever is a combination of clinical examination with laboratory work.

THERMOMETRICAL PSEUDO-FEVER.

The practitioner working in high air temperatures should remember that the clinical thermometer, being of the maximum type, will rise quickly to some temperature corresponding to that of the air, and will remain thereat. Mistakes have been made, such as recording a number of cases of fever in an institution. In high air temperatures the thermometer should be taken out of cool water, placed in the patient's mouth, left there long enough to record the actual temperature, and then quickly replaced into cool water, in which it is examined.

The practitioner knows well the precautions *re* hot liquids or solids having been placed in the mouth before the thermometer, thus giving high readings, and the effect of draughts falling on the cheeks preventing the rise of the mercury: or, in other words, of the possible thermometrical fallacies of which these are examples.

ACUTE FEVERS.

The acute fevers may, for purposes of diagnosis, be divided into those which have lasted less than eight days, and those which have been in progress eight or more days when seen by the practitioner.

FEVERS OF LESS THAN EIGHT DAYS' DURATION.

These fevers may be divided into:—

I. Those exhibiting some striking physical sign.
II. Those not exhibiting any striking physical sign.

I. WITH SOME STRIKING PHYSICAL SIGN.

The physical signs to which we refer may be classified into:—

A. Traumatisms.
B. Skin eruptions.
C. Derangement of some bodily system.
D. Localized derangement of some organ.

A. TRAUMATISM.

The presence of a traumatism suggests that an acute fever may be *septic* in nature, but in the tropics no one should forget the possibility of the fever being caused by the reawakening of *old malarial infections*, or even being associated with a new malarial infection, acquired, perhaps, at the same time as the traumatism.

If the fever is intermittent, recurring every third or fourth day, it is malaria. If it is quotidian, pay attention to the following points: If the spleen is hard it is probably malaria—make a blood film; if Laveran's parasites are present or marked mononucleosis, it is probably malaria: if polymorphonuclear leucocytosis is present, it is probably septic fever.

If the evidence is in favour of sepsis, or if malaria has been excluded, bacteriological examination of the blood and of the local discharge should be made, and should include search for aerobic and, if necessary, anaerobic organisms.

B. SKIN ERUPTIONS.

These may be considered under the following headings:—

1. Erythematous eruptions.
2. Papular eruptions
3. Urticarial eruptions.
4. Purpuric eruptions.
5. Vesicular eruptions.
6. Bullous eruptions.
7. Pustular eruptions.
8. Pigmentation.

1. ERYTHEMATOUS ERUPTIONS.

(A) ERYTHEMATOUS RASH GENERALIZED.

I. *The rash is more or less typical of scarlet fever* :—

- (*a*) Onset of eruption less than forty-eight hours after the appearance of the sore throat —*Scarlet fever.*
- (*b*) Onset of eruption more than forty-eight hours after the appearance of the sore throat—*Erythema or dermatitis scarlatiniformis.*
- (*c*) Throat symptoms mild or absent :—
  - (A) Examine blood for malarial parasites:—
    1. If present —*Malaria.*
    2. If absent inquire into drugs, especially quinine—*Anaphylactic drug eruptions.*

II. *The rash has some maculo-papular elements* :—

- (*a*) Coryza and Koplik's spots have been or are still present—*Measles.*
- (*b*) Coryza and Koplik's spots absent :—
  With enlargement of the occipital, cervical, and other lymphatic glands—*German measles.*

III. *The rash has the characters of a blush, with or without œdema :—*

(*a*) The rash, though general, is more marked in one area:—

1. Evidence of a bite or sting—*Bite or sting of a venomous animal.*
2. No such evidence, special region pits on pressure:— Examine night and day blood for microfilariæ—*Filariasis.*
3. Macules on wrist and ankles only becoming general on third day; severe symptoms; yellow tinge in conjunctivæ. Occurs in Rocky Mountains—*Spotted fever of the Rocky Mountains.*

(*b*) The rash is not specially marked in one area:— Examine blood for eosinophilia and the fæces, after a purge, for the eggs of intestinal worms—*Helminth infections.*

IV. *Erythema fugitive, faint, annular, most marked on trunk :—* History of residence in Tropical Africa. Glands in posterior triangle of neck enlarged. Examine gland juice and blood for trypanosomes—*Sleeping sickness.*

V. *Erythema with marked cerebral symptoms, vomiting, retraction of head—Kernig's sign.*

1. Examine the blood for malarial parasites, if present—*Malaria.*
2. If absent, perform lumbar puncture and examine for meningococci *Epidemic cerebro-spinal meningitis.*

VI. *Erythema mild, amounting to very severe blushing, and most marked on the face :—* Eyes injected, severe pain at back of eyes, high fever. Occurs in locality where phlebotomus is endemic—*Pappataci fever.*

VII. *Erythema with little or no fever, but with marked gastro-intestinal symptoms :—* With or without signs of collapse—*Ptomaine poisoning.*

(B) ERYTHEMATOUS RASH LOCALIZED.

I. *Rash distributed on parts exposed to light :—* On face, neck, and hands, often feet; associated with gastro-intestinal and nervous symptoms. Fever is not a marked feature of simple pellagra, and when this occurs it is due to a complication, generally with one of the enterica group of fevers—*So-called typho-pellagra.*

II. *Rash not specially confined to parts normally exposed to light :—*

(*a*) Associated with œdema in some part:—

1. Œdematous and erythematous areas coincide. (*a*) Area defined by sharp edges. Sometimes vesicles present and leucocytosis—*Erysipelas.* (*b*) Lymphatics inflamed, microfilariæ in blood. —*Filarial lymphangitis.*

2. Œdema of face and eyelids and gastro-intestinal disturbance, eosinophilia, and leucocytosis—*Trichinosis.*
3. No œdema of the face and eyelids. Very rare—*Polymyositis.*
4. Swollen area affected with leprotic eruption. Signs of leprosy in various parts of the body—*Leprotic fever.*

(*b*) Not associated with œdema:—

1. Severe constitutional symptoms and marked backache; signs of vaccination absent, poor, or old. Case of smallpox known to exist in neighbourhood—*Suspect smallpox.*
2. There is a recent wound due to a rat-bite, or a history of a rat-bite seven to twenty-one days previously, of which the wound may have healed. Site of bite red and swollen, becomes ulcerated. Enlarged lymphatic glands. Erythematous eruption with purple spots—*Rat-bite fever.*
3. History of a cat-bite some ten to twenty-one days before illness; maculæ around site of bite and then on limbs; infiltration of skin, enlarged lymphatic glands. Pains in muscles and joints. Splenic enlargement. Fever relapsing in type—*Cat-bite fever.*
4. Pains and aches all over the body, but constitutional symptoms not very severe. Rash appears with the fall of the temperature on the third day. No malarial parasites in the blood. Stegomyia (or Culex) mosquitoes abundant. Endemicity of dengue-like fevers known—*Dengue.*

2. PAPULAR ERUPTIONS.

These eruptions often form part of the evanescent early symptoms of some fever, and are therefore difficult to arrange in a satisfactory manner. The practitioner will remember that drugs like iodides and the bromides may give rise to papular eruptions.

I. *Catarrhal symptoms present*:—

Maculo-papular eruption tending to form blotches. Koplik's spots present—*Measles.*

II. *Catarrhal symptoms slight or absent*:—

(*a*) *Constitutional symptoms severe*:—

1. Markedly severe headache and backache. Papules bright red and shotty, appearing between the third and fourth day, first on the forehead—*Smallpox.*
2. In a child which has been ill for three days with pain all over the body and often delirium or convulsions. Papules about the size of a pin's head on chest, back, and abdomen—*Dengue* (Van der Scheer's fever).

3. Pale dusky red papules or macules, fading into the normal skin, but slightly elevated, disappearing on pressure, at the margins of the axillæ, wrists, flanks, chest, back, shoulders, arms, and legs, with subcuticular mottling. Exclude malaria by blood examination—*Typhus fever.*
4. Large red papules on face on the fifth to seventh day of illness, spreading over body as macules, after a visit to Akitaken and Nugataken, of the Island of Nippon, Japan. Enlarged lymphatic glands in some area of the body, and a few vesicles on area drained by lymphatics going to these glands, are indicative of bites by *Microtrombidium akamushi—Tsutsugamushi fever.*

(*b*) *Constitutional symptoms not severe and not following recent vaccination*:—

1. Rash of maculo-papules, circular, discrete; not as bright or as elevated as measles. No Koplik spots. Occipital and other lymphatic glands enlarged. Pink eye present—*German measles.*
2. Fever slight or, at times of epidemic, absent in some cases. Rash general, composed of bright pinhead papules or red macules (*i.e.*, morbilliform), associated with itching and with a few macules on the palms and soles—*Papular fever* (Castellani and Chalmers).

(*c*) *Constitutional symptoms not severe, following recent vaccination*:—

Rash composed of papules and papulo-vesicles, of large pinhead size, appearing some seven to nine days after vaccination—*Vaccine lichen.*

3. URTICARIAL ERUPTIONS.

(*a*) Fever slight, after ingestion of certain foods—*Febrile urticaria.*

(*b*) Worms present—*Helminthic febrile urticaria.*

4. PURPURIC ERUPTIONS.

Purpuric puncta may be caused by flea-bites and pediculi, and have nothing to do with the fever. Many drugs, ptomaine poisoning, and snake-bite produce purpuric spots or patches. Very rarely serum injections produce purpuric eruptions about seven to nine days after the injection. The leukæmias, chronic alcoholism, Bright's disease, and jaundice, may be associated with purpuric rashes. In fevers as a rule it points to septicæmia, and is more of a prognostic than of a diagnostic value, even in epidemic cerebrospinal meningitis, in which, in our tropical experience, it is rare. Peliosis rheumatica, with its associated tonsillitis and pains in the joints, is very rare. It will be remembered that in scurvy there is no fever. With these provisos we make the following suggestions:—

Clear signs of the disease causing the purpuric eruption:—

(*a*) Yellow tinge in skin or eyes:—

1. Urine black from hæmoglobin—*Blackwater fever.*
2. Urine without hæmoglobin:—
   - (A) *Bile in the urine:*—
     - (i.) Examine blood and urine for the peculiar spirochæte with its central minute waves—*Icterus castrensis gravis* (*Weil's disease*).
     - (ii.) Spirochætes of doubtful pathogenicity may be present or they may be absent: little or no fever—*Non-febrile jaundice* (*camp jaundice*).
   - (B) *Bile not in urine:*—
     Severe fever; examine blood for malarial parasites—*Malarial fever.*
   - (C) *Albumen in urine:*—
     Epigastric tenderness. Faget's sign—*Yellow fever.*

(*b*) Without yellow tinge in the skin or eyes:—

1. Retraction of head. Kernig's sign present. Lumbar puncture reveals meningococci—*Epidemic cerebro spinal meningitis.*
2. With developed disease—*e.g.*, typhoid, diphtheria, scarlet fever, smallpox, measles (hæmorrhagic conditions known in the tropics)—*Septicæmic condition.*
3. With buboes or marked pneumonic symptoms. Examine blood culturally, sputum and fluid from enlarged lymphatic glands microscopically, for plague bacilli—*Plague.*
4. Without marked signs of any disease. Blood culture—*Septicæmia.*

5. VESICULAR ERUPTIONS.

The practitioner will be on his guard to exclude vesicles which are the result of bites of insects, such as sand-flies and mosquitoes, as well as those due to the ingestion of drugs, such as bromides and iodides. Also the pyoses, which are without fever. Among these, pyosis corletti causes bullæ.

I. *Onset with severe constitutional disturbance:*—

Rash on third to fourth day; shotty papules becoming vesicles fifth to sixth day. Vesicles circular, tense, umbilicated, and multilocular—*Smallpox.*

II. ***Onset with mild constitutional symptoms, but with severe local pain, generally along a nerve, but in any case confined to one region:—***

Rash a couple of days or more after commencement of the pain. Usually confined at first to painful region, and then becomes general, but may be general from first. Vesicles dome-like or flattened, become umbilicated; no inflammatory areola; leave scars—*Vesicular fever* (Castellani and Chalmers).

III. *Onset mild and without severe local pain, without history of recent vaccination*:—

Rash on first to third day. Often first sign of illness. Appears on back, chest, and abdomen. First in form of pale red macules, often with raised centre, quickly developing into superficial unilocular vesicles, some of which may become umbilicated—*Chicken pox.*

IV. *Onset mild, history of vaccination twelve to twenty-two days or more before eruption*:—

Generalized vesicular eruption, not umbilicated at first, and preceded by a papular rash. Vesicles become umbilicated—*Generalized vaccinia.*

6. BULLOUS ERUPTIONS.

Bullous eruptions may be caused by plants and drugs. In newly-born children bullæ on the hands and feet suggest congenital syphilis.

I. There is a well-defined raised erythematous area upon which the bullæ are present. Bullæ to be examined for streptococci—*Erysipelas.*

II. No such area present, but wounds, enlarged lymphatic glands, with severe constitutional symptoms, common in the tropics. Examine blood and bullæ for organisms—*Septic pemphigus.*

III. In recently-born children examine bullæ for streptococci and other pyogenic organisms—*Pemphigus neonatorum.*

7. PUSTULAR ERUPTIONS.

It will be remembered that there are pustular syphilides unattended by fever, and pustular tuberculides of which fever is not a marked sign.

I. *Clear history of recent vaccination with Jennerian vaccine*:—

Small dark-coloured or black centre in the vaccine area, surrounded by dark reddish swollen area, on which are the vaccinial vesicles and pustules. Around this a bluish area, the whole surrounded by a wide erythematous blush—*Gangrenous vaccinia.*

II. *No history of recent vaccination:—*

(*a*) Localized red swelling, with several points of suppuration. Examine bacteriologically for cocci—*Carbuncle.*

Localized red solid swelling, with black centre, and round it pustules often mixed with vesicles and bullæ. Examine bacteriologically for *Bacillus anthracis*—*Malignant pustule.*

(*b*) Generalized pustular eruption in a patient who has been seriously ill for six days or more, with at times swelling of eyelids, lips, or eyes—*Smallpox.*

8. PIGMENTATION.

In acute fevers the important cutaneous pigmentation is the yellow tinge due to jaundice. This is rare in *malaria* and in the early stages of the *enteric fevers,* and hence need only be mentioned. For blood pigments in the skin see the *purpuric eruptions,* and for black pigmentation see the chronic fevers.

I. *Liver and spleen one or both enlarged:—*

(*a*) Abdominal tenderness. Typical spirochætes in blood—*Relapsing fevers.*

(*b*) Abdominal tenderness not marked:—

1. Peculiar spirochætes in blood and urine—*Weil's disease.*
2. No spirochætes in the blood:—
   - (A) Hæmoglobinuria—*Blackwater fever and its allies.*
   - (B) No hæmoglobinuria, severe symptoms, albuminuria, black vomit, etc.—*Yellow fever.*

II. *Liver and spleen not enlarged:—*

(*a*) Symptoms mild. Fever slight or absent. No signs or symptoms of pneumonia—*Icterus castrensis levis* (*camp jaundice*).

(*b*) Physical signs and symptoms of pneumonia. Pneumococcus in sputum—*Pneumonia.*

C. BODY SYSTEMS.

Fevers associated with some marked sign or symptom directing attention to a given system of the body may be arranged according to the system deranged as follows:—

A. Derangements of the Alimentary Canal.
B. Derangements of the Respiratory System.
C. Derangements of the Circulatory System.
D. Derangements of the Urinary System.
E. Derangements of the Generative System.
F. Derangements of the Lymphatic System.
G. Derangements of the Muscular System.
H. Derangements of the Osseous System.
I. Derangements of the Connective Tissue.
J. Derangements of the Nervous System.

A. *Symptoms pointing to the alimentary canal:—*

I. *Mouth and Throat:—*

(*a*) Pyorrhœa, marked gingivitis, or even the presence of bridges, crowned or stopped teeth, with pain, shrinking of the gums, etc.—*Septic fever.*

(*b*) Angina with whitish or greyish membrane on the fauces or tonsils:—

Examine bacteriologically:—

1. Streptococci present—*Streptococcal angina.*
2. Klebs-Loeffler bacilli present—*Diphtheria.*
3. Fusiform bacilli present—*Vincent's angina.*

II. *Stomach:—*

(*a*) Black vomit:—

Associated with jaundice, Faget's sign, and severe constitutional disturbance—*Yellow fever.*

(*b*) Vomiting, pain and tenderness in diaphragmatic region. Severe constitutional symptoms, with or without hiccough; passage of blood *per anum*—*Poisoning with viperine venom or phlegmonous inflammation of the stomach.*

III. *Intestines:—*

(*a*) Choleraic diarrhœa, or profuse diarrhœa, or dysenteric diarrhœa with fever.

Examine blood:—

1. Malarial parasites—*Pernicious malaria.*
2. Marked mononucleosis with enlargement of the spleen.—

   Splenic or hepatic puncture:—

   (A) Malarial parasites—*Pernicious malaria.*
   (B) Kala-azar bodies—*Kala-azar.*
3. Eosinophilia without enlargement of the spleen. Blood cultures—*Intestinal septicæmias or toxæmias due to worms.*

(*b*) Vague bowel symptoms or signs of intestinal schistosomiasis. Examine fæces for eggs and blood for eosinophilia—*Fevers due to intestinal worms.*

(*c*) Pain in the appendicular region—*Appendicitis.*

(*d*) Slight diarrhœa or constipation. General disturbance of health slight or moderately severe.

Examine motions for:—

1. Amœbæ—*Amœbiasis.*
2. Enteric bacilli. Confirm by blood cultures—*Enteroidea.*

B. *Symptoms pointing to the respiratory system :—*

I. Nose:—

(*a*) *Acute rhino-pharyngitis :—*

Examine secretion microscopically and culturally:—

1. Spirochætes—*Spirochætal rhino-pharyngitis.*
2. *Micrococcus catarrhalis* and similar organisms —*Common cold.*
3. Influenza bacillus or filterable virus present—*Influenza.*
4. Influenza baccillus, or filterable virus with Streptococci—*Streptococcal complications of influenza.*

(*b*) *Nose partially blocked :—*

Examine swabs microscopically and culturally for the Klebs-Loeffler bacillus —*Diphtheria.*

(*c*) *Larynx :—*

More or less stridor. Examine swabs of throat for Klebs-Loeffler bacillus—*Diphtheria.*

(*d*) *Bronchi :—*

Signs of bronchitis, with or without blood in the sputum. Examine fresh sputum microscopically, and if necessary by the dark ground illumination:—

1. Eggs—*Paragonimiasis.*
2. Spirochætes—*Bronchospirochætosis.*
3. Fungi—*Bronchomycosis.*
4. Acid-fast organisms:—
   (A) Tubercle bacilli—*Tuberculosis.*
   (B) Nocardia—*Pulmonary Nocardiasis.*

(*e*) *Lungs and pleura :—*

Physical signs of inflammation of the lungs or pleura, or both:—

1. Expectoration chocolate-coloured —*Liver abscess.*
2. Expectoration bloody or rusty. Examine microscopically for the same points as under bronchi and for the pneumococcus —*Pneumonia.*
3. Expectoration not chocolate-coloured nor bloody—*Diseases of lungs and pleura other than above.*

C. *Symptoms pointing to the circulatory system :—*

1. Marked collapse after exposure to great heat (especially associated with high atmospheric humidity) or to the sun's rays. There may or may not have been initial fever—*Heat syncope.*
2. Disturbed action of the heart, with severe constitutional symptoms and petechial eruption—*Infective endocarditis.*

D. *Symptoms pointing to the urinary system:—*

- (*a*) Urine black, due to hæmoglobin:—
    1. Following on a dose of quinine—*Quinine hæmoglobinuria.*
    2. With malarial parasites in numbers in blood—*Malarial hæmoglobinuria.*
    3. Not associated with quinine or malarial parasites in numbers in the blood—*Blackwater fever.*
    4. Associated with the administration of some drug such as chlorate of potash for a sore throat—*Toxic hæmoglobinuria.*
- (*b*) Suppression or marked diminution of the urine:—
    Differentiate by the history of the case, the region of infection, the presence or absence of Faget's sign, black vomit, etc.—*Blackwater fever or Yellow fever.*
- (*c*) Passage of large quantities of urine:—
    Examine for malarial parasites or other signs of malaria—*e.g.*, enlarged and tender spleen—*Pernicious malaria.*
- (*d*) Bile in the urine:—
    1. Associated with hæmoglobin—*Blackwater fever.*
    2. Not associated with hæmoglobin:—
        - (A) In epidemic form:
            Examine blood and urine for spirochætes.
            - (i.) Mild cases—*Icterus castrensis levis.*
            - (ii.) Severe case with hæmorrhages—*Icterus castrensis gravis* (*Weil's disease*).
        - (B) Not in epidemic form:—
            No spirochætes. During or after an attack of typhoid or paratyphoid fever—*Bacillary jaundice* (*Enteric jaundice*).

E. *Symptoms pointing to the reproductive system:—*

- (*a*) Chill, sudden pain and swelling along the spermatic cord, with often severe fever, but no erysipelatous appearance of the skin—*Endemic funiculitis.*
- (*b*) Fever after childbirth. Examine the aseptically collected uterine discharge for streptococci and other organisms—*Puerperal fever.*

F. *Symptoms pointing to the lymphatic system:—*

- (*a*) Cervical glands enlarged:—
    1. Most marked on the left side, associated with obstinate constipation and mild symptoms. Puncture of glands reveals no organisms—*Pfeiffer's glandular fever.*

2. Most marked in the posterior triangles of both sides of the neck. History of residence in sleeping sickness areas. Glandular fluid obtained by puncture shows trypanosomes—*Trypanosomiasis.*
3. Enlarged glands in neck and other parts. Œdema of face with characteristic crepitation. Fugitive œdemas in various parts. Enlarged and tender spleen. Enlarged liver. Increase in size of the thyroid gland. Residence in Tropical South America—*Chagas' disease.*

(*b*) *Lymph glands anywhere enlarged :—*

4. Pain in some lymph glands: tender, enlarged, freely movable under skin. Search area drained by lymphatics going to gland for circular vesicle or small black or brownish necrotic area indicative of a bite. Puncture of glands shows no bipolar plague bacilli. History of residence in the Akitaken and Nugataken of the Island of Nippon, Japan—*Tsutsugamushi disease.*

(*c*) *Inguinal or axillary glands enlarged :—*

5. Acute onset, high fever, great prostration. Puncture of glands reveals plague bacilli—*Plague.*
6. Gradual onset, slight fever. Very mild symptoms, malaise, pain on walking. Inguinal or crural glands enlarged, hard, very painful on pressure. Puncture shows sterile fluid—*Climatic bubo.*
7. Glands enlarged, inflamed, or suppurating, with chancre on penis, septic wound, or ulcer or *gonorrhœal* infection—*Septic infections.*
8. Occurring in the course of one of the enteroidea fevers—*Intestinal infections.*
9. High fever, lymphangitis, associated with an erysipelatous condition of the skin. Blood examination during night (or during the day in certain cases) reveals microfilaria—*Filarial lymphadenitis.*

G. *Symptoms pointing to the muscular system :—*

(*a*) Remittent or intermittent fever, with rheumatoid pains and abscesses in various parts of the body—*Myositis purulenta tropica.*

(*b*) Remittent fever, with rheumatoid pains, but no abscess formation. Œdematous patches often present, marked eosinophilia—*Trichinosis.*

H. *Symptoms pointing to the osseous system :—*

(*a*) Pain and tenderness, especially near a joint—*Osteomyelitis.*

(*b*) Sudden attack of fever, with great tenderness over, and pain in, the os calcis or other tarsal bone, which begins to increase in size—*Endemic enlargement of the os calcis.*

I. *Symptoms pointing to the connective tissue:—*

Rigors with fever and aching or dragging sensation, and outline of a worm under the skin of affected area—*Dracontiasis.*

J. *Symptoms pointing to the nervous system:—*

(*a*) Almost any acute sign or symptom pointing to the nervous system, including signs of mania, melancholia, or dementia, and associated with fever, with or without enlargement of the spleen. Examine blood for malarial parasites or mononucleosis—*Malaria.*

(*b*) Signs of meningitis present—*e.g.*, Kernig's sign, retraction of the head, etc. Examine cerebro-spinal fluid:—

1. Polymorphonuclear leucocytes and cocci present—*Epidemic cerebro-spinal meningitis.*
2. Trypanosomes present; also in juice from enlarged neck glands. Residence in Tropical Africa—*Sleeping sickness.*

(*c*) Signs of acute alcoholism:—

If picked up by the police, even if there is a smell of alcohol, examine spleen and take blood films if necessary. Drunk or dying in the tropics is often a question of alcoholism or malaria. Fever may be absent in both instances—*Acute alcoholism or malaria.*

D. DERANGEMENT OF SOME ORGAN.

The signs and symptoms associated with some organ of the body may be considered under the following headings:—

1. The Spleen.
2. The Liver.
3. The Pancreas.
4. The Suprarenal Capsules.
5. The Parotid.

A. *The spleen:—*

I. *Enlargement slight:—*

Rose-coloured spots on the abdomen. Symptoms of typhoid fever. Make blood cultures and fæcal cultures —*Enteroidea fevers.*

II. ***Enlarged and tender :—***

(*a*) Examine blood films for malarial parasites and for spirochætes—***Malaria*** or ***Relapsing fevers.***

(*b*) With œdema of the face and enlargement of the thyroid and lymphatic glands and liver. Residence in South America—***Chagas' American trypanosomiasis.***

III. ***Enlargement considerable :—***

(*a*) Generally a history of illness lasting some time, of which present fever is only a recurrence. Firm enlargement. Malarial parasites in blood—***Exacerbation of chronic malaria.***

(*b*) No malarial parasites in the blood:—

Great increase in white blood cells with myelocytes—*Leukæmia.*

(*c*) No malarial parasites and no great increase of leucocytes in the blood:—

1. Splenic or hepatic puncture shows Leishman-Donovan bodies *Kala-azar.*
2. Shows no Leishman-Donovan bodies — *Febrile splenomegaly.*
3. Toxoplasma bodies present *Toxoplasmosis.*

B. ***The liver :—***

Enlarged and tender:

1. Pain in the right shoulder, rigidity of right rectus, diminution of movement of right side of the diaphragm. Examine motions for amœbic cysts and the blood for mononucleosis (present) and malarial parasites (absent) –***Amœbic liver abscess.***
2. Signs of severe septic infection, jaundice, etc. If origin of sepsis not evident, examine fæces for intestinal worms and for enteroidea micro-organisms—***Multiple septic liver abscesses.***
3. Slight yellowish tinge in the sclerotic, seldom signs of general jaundice. Patient not seriously ill. No amœbiasis—*Tropical liver.*

C. ***The pancreas :—***

I. With intense pain in the upper and left part of the abdomen, which is distended with gas; vomiting and constipation—***Acute pancreatitis.***

II. Signs and symptoms of diabetes: threatened Kussmaul's coma. Recurrent attacks of fever every other day. Examine for malarial parasites: if absent and if only polymorphonucleosis give a few doses of quinine and note action on fever—***Malaria and diabetes.***

D. *Suprarenal capsules :—*

Signs suggestive of acute peritonitis— *i.e.*, high fever, distended tympanitic abdomen, quick pulse. No effusion into abdominal cavity. Examine blood for malarial parasites and for mononucleosis. If absent, give quinine and again test blood —*Acute malaria attacking suprarenals.*

E. *Parotid glands :—*

Painful tender swelling of parotid, especially if bilateral— *Mumps.*

II. ACUTE FEVERS WITHOUT STRIKING PHYSICAL SIGN.

A *Patient is carrying on his ordinary work :—*

I. Fever is intermittent, every third or fourth day. Examine spleen for enlargement and tenderness, and examine blood for malarial parasites and mononucleosis, which may be absent. Clinical symptoms alone may be positive— *Malarial fevers.*

II. Fever is quotidian. Examine spleen for tenderness and enlargement. Examine blood for malarial parasites and mononucleosis. If none, give quinine and note action on fever – *Malaria.*

III. No malarial parasites, and quinine therapy without effect :—

(*a*) Pulse dicrotic: slow in proportion to the temperature. History of several days' indisposition. Tongue furred, constipation, or diarrhœa. Gurgling on pressure in right iliac region. Make blood and fæcal cultures, and examine for enteroidea organisms —*Enteroidea group of fevers.*

(*b*) Pulse not dicrotic; slow in proportion to the temperature. Attack sudden, with at first pain and tenderness, which later disappear in the region of the appendix. No malarial parasites in blood— *Gangrenous appendicitis.*

(*c*) Abrupt onset, catarrhal symptoms, with sensation of considerable illness and with generalized pains, often in epidemic form —*Influenza.*

(*d*) With or without signs of bronchitis, enlargement of liver and spleen, or with signs of broncho-pneumonia. Examine sputum for tubercle bacilli, or if lung symptoms absent test cuti-reaction— *Acute phthisis or tuberculosis.*

(*e*) Gradual onset, temperature increasing every night. Headache and rheumatoid pains in body and limbs. Tongue furred. Blood cultures for *M. melitensis* and *M. paramelitensis*—*Undulant fever.*

B. *Patient unable to carry on his usual duties :—*

(*a*) Liver and lymphatic glands enlarged. Spleen not enlarged. Examine blood. Signs of great destruction of red blood-corpuscles (presence of *Bartonella bacilliformis*). Residence in Peru—*Oroya fever.*

(*b*) Sudden onset, with injected conjunctivæ (pink eye), high fever, comparatively slow pulse. Severe rheumatoid pains. Liver and spleen normal. Patient irritable, with pain in head and eyes, and may be delirious. Endemic area for *Phlebotomus* flies—*Pappataci fever.*

(*c*) Sudden onset, with severe pain in some part of the body or all over the body. With or without enlargement of the lymph glands, with generally a maculo-papular eruption on the third or fourth day. Conjunctivæ injected. Fauces congested. Pulse increases proportionately with the fever. Endemic area for stegomyia (perhaps also for *Culex fatigans*)—*Dengue fever.*

(*d*) Sudden onset. Hyperæsthesia over shins. Pains in the legs. Often slight splenic enlargement. Mononucleosis in blood. May or may not be history of association with lice. Blood examination excludes malaria, relapsing fever, etc.—*Trench fever.*

(*e*) Sudden onset, with or without rigors and pains. Examine blood for malarial parasites—*Malaria.*

(*f*) Gradual onset. Signs of enteric fever. Make blood and fæcal cultures—*Enteroidea group of fevers.*

(*g*) Blood examination reveals marked polymorphonuclear increase. Examine gums, teeth, ear, nose, throat, fingers, toes, bones, and every orifice of the body, for possible source of infection; make blood cultures—*Septicæmia.*

(*h*) Blood examination. Examine night and day blood for microfilariæ—*Filariasis.*

(*i*) Examine fæces for intestinal eggs, especially after a purgative—*Toxæmias due to intestinal worms.*

(*j*) Gradual onset, with marked pains in the joints, profuse sweating, high fever, and relatively slow pulse. Furred tongue—*Undulant fever.*

(*k*) Sudden onset, with hyperpyrexia, delirium, or coma associated with high atmospheric temperatures—*Thermic fever* (*heat-stroke*).

(*l*) Sudden onset, with or without history of fever. Syncope associated with high atmospheric temperatures—*Heat syncope.*

FEVERS OF MORE THAN EIGHT DAYS' DURATION.

Fevers of more than *eight days'* and less than *six weeks'* duration may be classified as follows:—

A. *Fever of intermittent type* :—

With malarial parasites or pigment in blood or with enlarged spleen:—

I. Fever every day—*Quotidian malaria.*

II. Intermittent fever every third day—*Tertian malaria.*

III. Intermittent fever every fourth day—*Quartan malaria.*

B. *Fever of the relapsing type* :—

I. Without malarial parasites or pigment, and not reacting to quinine therapy. Intervals between attacks several days. During attack spirochætes in blood—*Relapsing fevers.*

II. With malarial parasites and no signs of spirochætes, and reacting to quinine therapy—*Malaria.*

III. Without parasites, and only one or two relapses; not reacting to quinine therapy. After a long fever presumed or proved to be enteroidea in type. Examine fæces and urine for enteroidea organisms—*Enteroidea type of fever.*

C. *Fever remittent or continuous* :—

I. Reacting to quinine therapy—*Malaria.*

II. Not reacting to quinine therapy.

A. WITH MARKED PHYSICAL SIGNS.

1. *Well-defined local pain and tenderness* :—

Examine blood films. Leucocytosis, blood cultures, urine cultures. Lastly, examine cerebro-spinal fluid (earlier if head or spine symptoms)—*Septicæmias or toxæmias due to foci of deep suppuration.*

2. *Signs of lung disease* :—

Examine sputum:—

(*a*) Tubercle bacilli—*Tuberculosis.*

(*b*) Other organisms and signs of pneumonia—*Broncho-pneumonia.*

3. *Organic cardiac murmurs* :—

With or without petechial eruptions. Signs of gonorrhœa or rheumatism—*Infective endocarditis.*

4. *Nervous symptoms* :—

Pain in the head, retraction of the head. Kernig's sign. Examine cerebro-spinal fluid—*Meningitis.*

5. *Skin eruptions* :—
   - (*a*) Rose-red spots—***Enteric fevers.***
   - (*b*) Flushing of the face, with subcuticular mottling and severe symptoms. Typical eruption on fourth day—***Typhus fever.***
   - (*c*) Purulent discharge from nose. Bullæ, nodules, and ulcers in skin, with papulo-pustular eruption. Work with horses—***Glanders.***
   - (*d*) Pustular eruption—***Glanders.***
   - (*e*) Dark or black pigmentation—***Addison's disease.***
6. Enlarged lymphatic glands—***Hodgkin's disease.***
7. Tenderness in a bone, especially near a joint. Blood cultures—***Osteomyelitis.***
8. Nodules and tenderness in muscles. Puncture the nodules and examine:—
   - (*a*) Pus—***Purulent myositis.***
   - (*b*) Filaria—***Filariasis.***
9. *Splenic enlargement* :—

   Examine blood:—
   - (*a*) Marked increase of lymphocytes or leucocytes with myelocytes—***Leukæmia.***
   - (*b*) Malarial parasites or pigment in leucocytes—***Malaria.***

   Splenic or hepatic puncture :—
   - (*a*) Malarial parasites or pigment—***Malaria.***
   - (*b*) Leishmania parasites—***Kala-azar.***
   - (*c*) Absence of Leishmania parasites—***Splenomegaly, febrile form.***
   - (*d*) Toxoplasma bodies present—***Toxoplasmosis.***

B. WITHOUT MARKED PHYSICAL SIGNS.

A. *Intermittent fevers* :—
- I. Fever every third or fourth day—***Malaria.***
- II. Fever every day. Examine blood:—
  - 1. Malarial parasites or distinct mononucleosis—***Malaria.***
  - 2. Malarial parasites absent; distinct polymorpholeucocytosis—***Septic fevers.***

B. ***Relapsing fevers*** :—

Fever for several days after period of apyrexia—***Relapsing fevers.***

C. ***Remittent and continuous fevers*** :—
- I. Benefited by quinine, with or without parasites in blood—***Malaria.***

II. Not benefited by quinine:—

(*a*) Test the serum reactions for typhoid and the paratyphoids, and the other common enteroide organisms of the period and locality. Confirm by blood cultures—large quantities, 10 c.c., of blood taken at night—or by fæcal cultures—*Enteroidea group.*

(*b*) Test for Mediterranean fever by serum reactions and blood cultures—*Undulant fever.*

(*c*) Culture of aseptically collected urine—*Pyelitis.*

(*d*) Examine motions for eggs of intestinal worms—*Intestinal toxæmias due to worms.*

(*e*) Wassermann reaction—*Syphilis.*

(*f*) Cuti reaction for tuberculosis—*Tuberculosis.*

(*g*) Other causes having been excluded. Bodily temperature 99°-101° F.: shows only slight rise once a day. Patient indisposed during the attack—*Low intermittent fever.*

(*h*) Patient residing in locality with high atmospheric temperatures. Patient not indisposed during the attack—*Low heat fever.*

(*i*) Same as in (*g*), but in children with higher temperatures, 103°-104° F., or more—*High intermittent fevers.*

CHRONIC FEVERS.

By the term 'chronic fevers' we mean those which continue longer than six weeks.

A. *Intermittent in type :*

I. Occurring every third day, with enlargement of the spleen and malarial parasites, or yielding to quinine therapy—*Tertian malaria.*

II. Occurring every fourth day, with enlargement of the spleen, and malarial parasites or pigment in the blood, or yielding to quinine therapy—*Quartan malaria.*

III. Occurring every day, with enlargement of the spleen and malarial parasites, yielding to quinine therapy—*Quotidian malaria.*

B. *Relapsing in type :—*

Attacks of fever lasting a few days, separated by intervals of several days, with severe symptoms. Examine blood for spirochætes. If necessary, inject monkeys and examine blood during an attack of fever for spirochætes—*Relapsing fevers.*

- C. *Remittent or continuous in type :—*
  - I. Benefited by quinine therapy—*Malaria.*
  - II. Apparently not benefited by quinine therapy:—
    - (*a*) Ulcers or tumours present in some part of the body. Examine thoroughly, including nose, naso-pharynx, and all apertures of body. Especially examine the teeth, particularly crowned teeth or bridges. Examine fingers and toes carefully—*Septic infection or absorption.*
    - (*b*) *Cutaneous dark pigmentation a marked feature :—*
      - 1. Examine spleen for enlargement and blood for malarial parasites or mononucleosis. Insufficient quinine administered—*Malaria.*
      - 2. Fever generally absent. No signs of malaria. Vomiting at times. Weakness, etc.—*Addison's disease.*
    - (*c*) *Splenic enlargement a marked feature :-*
      - I. Examine blood films:—
        No malarial parasites seen.
        - (A) Marked increase in white cells, lymphocytes, or with myelocytes *Leukæmia.*
        - (B) Having excluded leukæmia, *but not before*, examine blood obtained by splenic puncture:—
          - 1. Malarial pigment or parasites present—*Malaria.*
          - 2. Leishman-Donovan bodies present—*Kala-azar.*
          - 3. Leishman-Donovan bodies absent—*Febrile splenomegaly.*
          - 4. Toxoplasma-like bodies present—*Toxoplasmatic febrile splenomegaly.*
          - 5. All parasites absent—*Pseudo-kala-azar.*
    - (*d*) *Œdema a marked feature :-*
      - I. Examine blood for malarial pigment, parasites, or mononucleosis, and the spleen for enlargement—*Chronic malaria.*
      - II. No signs of malaria:—
        - (A) Examine motions for eggs of intestinal worms, especially ancylostoma ova—*Ankylostomiasis.*
        - (B) No eggs or signs of worms. In South America. Examine blood during an attack of fever for trypanosomes—*Chagas' disease.*

(*e*) *Intestinal indigestion a marked feature* :—

I. Examine motions after test-meal for muscle fibres, fat globules; extract fat. Examine urine for Cammidge's reaction. Fever not a marked symptom—*Chronic pancreatitis.*

II. Attacks of fever a marked symptom. No muscle fibres, etc., in motions. No Cammidge's urinary reaction. Examine fæces after a purge for eggs of intestinal worms, and if absent, for micro-organisms of proteus and allied groups—*Intestinal infections and toxæmias in helminthiasis.*

(*f*) *Enlarged lymphatic glands a marked feature* :—

I. Fever not a marked feature; glands very much enlarged in many parts of the body. No very great increase in the number of leucocytes—*Hodgkin's disease.*

II. Attacks of fever a marked feature. Glands only moderately enlarged, especially in the posterior triangles of the neck. Residence in Tropical Africa. Examine gland juice for trypanosomes —*Sleeping sickness.*

Summary.

This small sketch of the diagnosis of certain tropical fevers may be found useful when read in conjunction with the preceding chapters. We would, however, again emphasize the point that the only method of diagnosing fevers is by long bedside experience, associated with careful laboratory work.

SECTION B

GENERAL DISEASES

DIVISION. I: CAUSATION, ANIMAL PARASITES.

SUBDIVISION A: DUE TO PARASITIC PROTOZOA.

Framboesia Tropica.
Verruga Peruviana.
Rhinosporidiosis and Sarcosporidiosis.

SUBDIVISION B: DUE TO PARASITIC WORMS.

Paragonimiasis.
Katayama Disease.
Filariasis.

SUBDIVISION C: DUE TO PARASITIC ARTHROPODS.

Myiasis.
Porocephalosis.

DIVISION II.: CAUSATION, VEGETAL PARASITES.

Leprosy.
Histoplasmosis.

DIVISION III.: CAUSATION, CHEMICAL.

SUBDIVISION A: DUE TO CHEMICAL DEFICIENCY.

Beri-Beri and Epidemic Dropsy.

SUBDIVISION B: DUE TO POISONS.

Tropical Poisonings.

DIVISION IV.: CAUSATION, UNKNOWN.

Pellagra.

CHAPTER LXI

FRAMBŒSIA TROPICA

Synonyms—Definition—History—Geographical distribution—Ætiology—Histopathology—Symptomatology—Diagnosis—Prognosis—Treatment—Prophylaxis—References.

Synonyms.—In the British Colonies the disease is usually called 'yaws': in the French colonies 'pian.' In Venezuela and other South American countries the name 'bubas' is much used. German and Italian authors generally use the term 'Frambœsia,' which was first used by Sauvage in 1750 on account of the raspberry-like appearance of the eruptive elements. Charlouis in 1882 suggested the term 'Polypapilloma tropicum': Noc, Stevenel, and Iman introduced the term 'Castellani's spirochætosis,' Da Matta 'Castellani's treponemosis,' and Violle the term 'cutaneous spirochætosis.' Other local names are 'gattoo' (West Coast of Africa), 'dubi' (Gold Coast), 'tramosi' (Calabar), 'ab oukine' (Gaboon), 'nkoulou,' 'tetia' (Congo Coast), 'momba' (Angola), 'parangi' (Ceylon), 'buena' (Burma), 'puru' (Borneo, Federated Malay States), 'patek' (Dutch Indies), 'tonga' (New Caledonia and Loyalty Islands), 'coco' (Fiji), 'tona' (Tonga Island), 'lupani tono' (Samoa), 'galis pateros' (some parts of the Philippine Islands), 'ki-mo' (French Indo-China).

Definition.—A tropical specific infectious and contagious disease caused by *Treponema pertenue* Castellani, and characterized by a frambœsiform granulomatous eruption.

History.—It has been suggested by Hume, Adams, and others that frambœsia was the disease which afflicted the Israelites during their emigration from Egypt, and that therefore the term 'saraat' in the thirteenth chapter of Leviticus does not mean leprosy, as usually translated. Ali Abbas and Avicenna, who wrote at the end of the tenth century, mention a disease called 'safat,' or 'sahafati,' with symptoms not unlike those of frambœsia; but most authors are of the opinion that the disease referred to by the two Arabian physicians was syphilis. The study of the disease first began to engage the attention of European physicians after the discovery of America. Oviedo y Valdez (1478-1557) describes it in his work, 'Historia General e Natural de las Indias.' Piso (1648) refers to the malady in his work, 'De Medicina Brasiliensis.' Rochefort (1656), Raymond Breton (1665), and Labat (1694), report it from the West Indies, stating that it occurs frequently among the natives (Caribs), who called it 'pyans,' or 'yaya.' Bontius, in 1718, reported that frambœsia was endemic not only in the West Indies, but also in Java, Sumatra, and other Dutch colonies of the East, where it was known by the name of 'anboyna pox,' or 'pimple.' In the days of the slave-trade, outbreaks of frambœsia frequently occurred in the crowded ships carrying African slaves to America. Special hospitals for the isolation and treatment of slaves suffering from the disease were built on all the important estates in the West Indies. Occasionally in the countries in which it is endemic the disease may increase to such an extent as to cause veritable epidemics. An example of such an epidemic occurred in Dominica in 1871, when two special segregation hospitals had to be built for frambœsia patients.

In 1769 an outbreak of a peculiar disease occurred in Scotland. It was called 'sibbens,' or 'sivvens' (*sivvi*, Celtic for raspberry), and was apparently imported by sailors belonging to a vessel coming from the West Indies, which was wrecked off Wigton in Cumberland.

The so-called 'button scurvy' of Ireland, endemic there in the eighteenth and the beginning of the nineteenth centuries; the 'radesyge,' which broke out in Sweden and Norway in 1710; and the 'mal de chicot' in Canada, have likewise been considered by some writers to be forms of frambœsia.

Several authors have endeavoured to distinguish between 'yaws,' 'pian,' 'boubas,' and 'parangi'; but those who have had the opportunity to study the disease in different countries have all come to the conclusion that 'yaws,' 'pian,' 'boubas,' and 'parangi,' are simply different names for the same disease, though of course each of these terms is often used by natives to cover several closely allied conditions. The term 'boubas,' for instance, is used by the inhabitants of Brazil for various ulcerative conditions, such as frambœsia, leishmaniasis, and blastomycosis, but most of the medical South American authorities use it as a synonym for frambœsia. Unfortunately, Breda used it to denote a form of leishmaniasis, and caused much confusion. The experimental researches of one of us in cases of frambœsia contracted in different parts of the world (tropical America, East and West Africa, etc.) show that 'yaws,' 'pian,' 'boubas,' and 'parangi,' are merely synonyms, but it is possible that there may be several varieties of the spirochæte which is the cause of the disease.

Since the time of Labat several authors have upheld the syphilitic nature of frambœsia. This theory was supported at one time by Sir J. Hutchinson. In recent times the disease has been investigated, both clinically and experimentally, by a large number of observers.

In 1882 Charlouis proved by actual experiment that syphilis and frambœsia are two different maladies. The clinical investigation of the disease by Numa Rat was also of great value. His report, published in 1891, has become classical.

Among the more recent observers who have investigated the disease in various parts of the tropics are Neisser, Daniels, Wellman, Jeanselme, Powell, Braush, Martin, Halberstadter, von Prowazek, Ashburn, J. Craig, Nichols, Strong, Flu, Noc, Stevenel, Iman, Da Matta, Spronk, Sheman, Schüffner, Maul, and many others.

Geographical Distribution.—Framboesia is essentially a tropical disease, as few, if any, genuine cases have been reported from places outside the tropical and subtropical zone, and in the tropics it is never found on the mountains and cold districts, as we remarked in the previous editions of this manual. Bahr states that cases who have contracted the disease at a higher elevation than 800 feet are very rare. At the present time a skin disease not unlike framboesia has been reported from Greece by several writers.

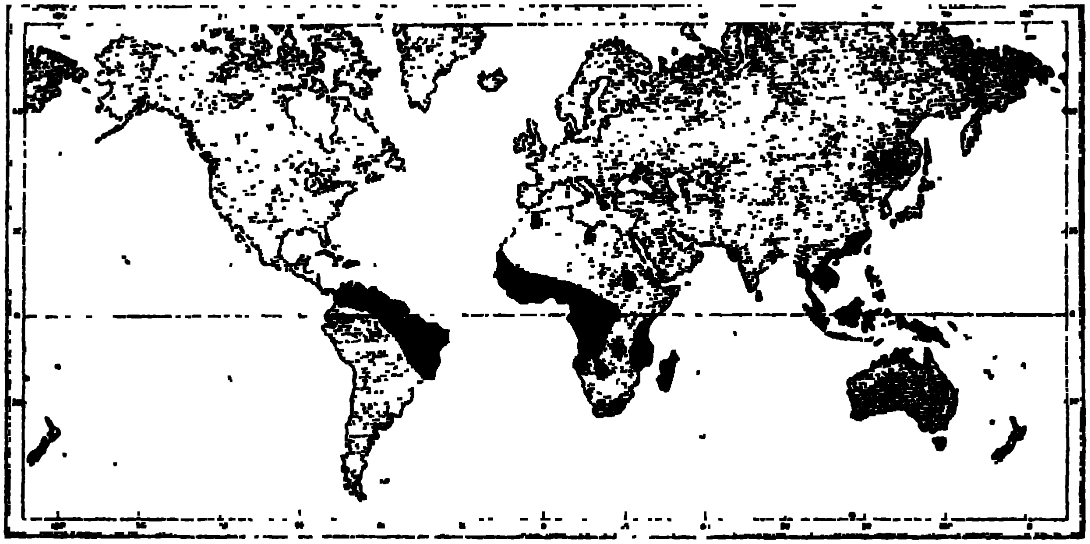

FIG. 685.—DISTRIBUTION OF FRAMBŒSIA TROPICA

Africa.—The disease till recently was said to be very rare in the northern regions of the continent, though some cases were reported from Algeria; the researches of Gabbi and Sabella have demonstrated, however, that it is common in Tripoli. It is apparently rare in Egypt, though, according to some writers, it is observed fairly frequently in the Sudan. It is very common on the West Coast, especially on the Gaboon River, in the Congo Free State, and in Angola. The disease is quite common in Nigeria. It is also found in Mozambique, in Madagascar, and the Comoro Islands. In Uganda and the region of the Great Lakes it is occasionally met with. It has been noted among the Kaffirs in South Africa, near Kimberley, by Griffith, and by many other observers in several other districts of South Africa, Rhodesia, and Nyasaland.

Asia.—The disease is very common in the Malay Peninsula, Assam, Upper Burma, Siam, Java, Batavia, and is extremely frequent in Ceylon, where the number of cases treated in the Government Hospitals during the last ten years has been on the average 3,500 per year, and it must be noted that the patients treated in hospitals represent only a small portion of all the cases.

In India it is very rare, though small outbreaks of the disease have been described by various observers. It occurs in certain parts of China, but is unknown in Japan and the central and western regions of the Asiatic continent. It is present in the Philippine Islands.

America.—It is very common in the West Indies, and occurs in British Guiana, Venezuela, Colombia, and Brazil. Cases have been reported from the southern United States, but never from the northern States nor from Canada. Recently Wood has recorded a case in a white child in North Carolina.

Australasia.—The disease is present in Northern Australia, and occurs frequently in many of the Pacific Ocean islands—Samoa, New Hebrides, New Caledonia, and Fiji. It is absent in New Zealand and Tasmania.

Ætiology.—Different kinds of bacteria have been described as causative agents of framboesia. Eijkman found some peculiar bacilli; Pariez observed numerous micrococci; Powell, in 1896, cultivated from two cases a yeast; Nicholls and Watts, in 1899, isolated a coccus which, inoculated into animals, failed to reproduce the disease. In February, 1905, Castellani observed a *Treponema*, or spirillum, as he thought it at the time. This organism, which he called *T. pertenue*, is now generally admitted to be the cause of the disease. For the description of the organism, see p. 457.

Incidence of the T. pertenue in Framboesia Lesions.—The presence of the *Treponema* is constant in the primary lesion and in the unbroken papules of the general eruption. It may be found in the spleen, lymphatic glands, and bone-marrow. In the blood it has not yet been demonstrated microscopically, though there is no doubt that the blood of the general circulation is infectious, inasmuch as monkeys inoculated with it develop typical yaws lesions in which the *Treponema* is abundantly present. The *Treponema* is absent in the cerebro-spinal fluid, and generally in the tertiary lesions.

Bacteriological Flora found in Open Sores of Framboesia.—While *T. pertenue* is the only germ found in the non-ulcerated lesions, the ulcerated lesions of framboesia are soon invaded by all kinds of germs. Apart from innumerable bacteria, various kinds of spirochætes are present. One form is rather thick, and takes up the stain easily. It is morphologically very similar to the *Spirochæta refringens* of Schaudinn. Another form is thin, delicate, with coils varying in size and number, and with blunt extremities—*S. obtusa* Castellani. A third form is likewise thin and delicate, but tapers at both ends —*S. acuminata* Castellani: *T. pertenue* is also present in many cases.

Inoculation Experiments of Framboesia in Man.—Paulet, in 1848, inoculated fourteen negroes with the secretion taken from frambœtic granulomata. All of them developed framboesia, the inoculation period varying from twelve to twenty days, when at the seat of inoculation in ten cases the first nodule appeared, soon followed by a typical general eruption. In two cases apparently the eruption did not start from the seat of inoculation.

Charlouis, in 1881, inoculated thirty-two Chinese prisoners, who had never suffered from the disease, with crusts and scrapings from a case of yaws. The disease developed in twenty-eight of them, beginning invariably at the seat of inoculation. Moreover, he inoculated a native suffering from typical yaws with syphilis. The inoculation was quite successful, a primary syphilitic sore developing, followed by all the usual types of secondary eruption. That yaws patients are not immune against syphilis is proved also by Powell and Nichols and others, who have described several cases of syphilis supervening on yaws. Syphilitic patients may contract frambœsia naturally and experimentally.

Inoculation Experiments in Monkeys and Other Animals.—Neisser, Prowazek, Halberstadter in Java, and shortly afterwards Castellani in Ceylon, have shown that monkeys are susceptible to frambœsia. According to their experiments, the inoculation period varies from a minimum of sixteen days to a maximum of ninety-two. The appearance of the lesions developing at the seat of inoculation is practically the same in all cases—viz., an infiltrated spot slowly increasing in size, and soon becoming moist, the secretion drying into a thick crust. Removal of the crust exposes a raw, granulating, red surface.

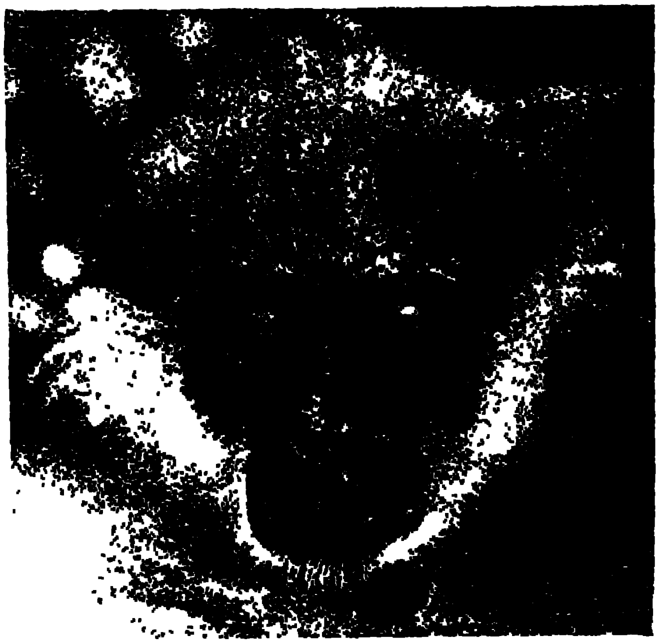

FIG. 680.—MONKEY INOCULATED WITH FRAMBŒSIA.

In the monkeys of a low class (genus *Macacus*, genus *Semnopithecus*) the eruption is, as a rule, localized to the seat of inoculation. The infection, however, is general, as is proved by the presence of *T. pertenue* in the spleen and lymphatic glands besides the local lesions. Halberstadter has obtained a general eruption in ourang-outangs. According to Castellani's experiments, splenic blood, obtained by puncturing the spleen of a patient affected with frambœsia, can reproduce the disease in monkeys. The inoculation of the blood of the general circulation also may occasionally produce the disease. The inoculation of cerebro-spinal fluid into normal monkeys has always proved negative.

Neisser, Halberstadter, von Prowazek in Java, and later Castellani in Ceylon, have proved that monkeys successfully inoculated with framboesia do not thereby become immune to syphilis, and, *vice versa*, monkeys successfully inoculated with syphilis do not thereby become immune to framboesia. According to Levaditi, monkeys immunized for yaws do not acquire any immunity for syphilis, but monkeys immunized for syphilis may acquire a partial immunity for framboesia. According to Ashburn and Craig, monkeys of the species *Cynomolgus philippinensis* are susceptible to framboesia, but not to syphilis.

The following facts are in favour of the *T. pertenue* being the specific cause of framboesia:—

1. In the non-ulcerated papules, in the spleen, in the lymphatic glands of framboesia patients, as well as in inoculated monkeys, the *T. pertenue* is the only organism present. No other germ can be demonstrated either microscopically or by cultural methods.

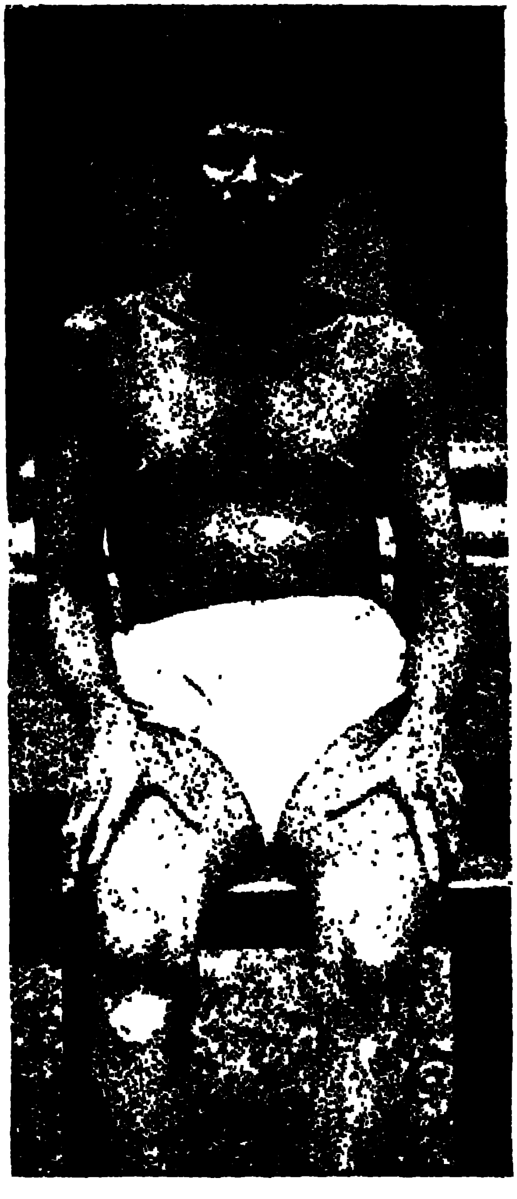
2. The extract of framboesia material containing the *T. pertenue*, but, so far as our present methods of investigation permit us to say, no other germs, is effective when inoculated into monkeys.

3. The extract of framboesia material from which the *T. pertenue*, has been removed by filtration becomes inert, and monkeys inoculated with it do not contract the disease.

PREDISPOSING CAUSES.—As is the case in other infectious diseases, dirt and other insanitary conditions favour to a certain extent the development and dissemination of the disease. The malady is rare among Europeans, and also among the better-class natives, who live amidst good sanitary surroundings, while it is very common among the villagers and low-caste natives, who live in uncleanly overcrowded huts. Sex does not exercise any influence, nor does age to any great extent, though the disease is more frequently met with in children and young people. The native practitioners of Ceylon are inclined to ascribe an important predisposing influence to certain foods. Some incriminate a kind of fish called 'balla mai,' others a cereal known as 'kurrakan.' Duprey inculpates in the West Indies the abuse of mango fruit.

Histopathology.—The histopathology of framboesia has been investigated by Unna, Macleod, Jeanselme, Plehn, and more recently by Schuffner, Marshall, Shennan, Siebert, Ashburn, Craig, and Löhe. In the frambœtic papules the surface epithelium is greatly increased in thickness, and numerous elongated down-growths are seen. The epithelial layers show many patches, in which the epithelial cells are swollen, vacuolated, and degenerating. Small, sharply circumscribed areas are also seen containing polymorphonuclear leucocytes and detritus. The layers near the corium and its processes are, however, almost normal in appearance. The connective-tissue corium forms a thin layer, from which narrow, elongated, papillary processes pass into the epithelium, some of them nearly reaching the surface. The corium is the seat of marked œdema. There is a diffuse cellular infiltration made up of polymorphonuclear leucocytes, large and small mononuclear leucocytes, eosinophiles, plasma cells, mast cells, connective-tissue cells, and some extravasated erythrocytes. In the older nodules the plasma cells are present in such enormous numbers as to dominate all the others. Macleod has shown that there is no perivascular mononuclear infiltration so characteristic of syphilis, nor any endothelial proliferation in the vessel walls. The frambœtic lesion also differs from that of syphilis in affecting the epithelium rather than the cutis, in the more considerable œdema, and in the absence, as a rule, of the giant cells.

When the frambœtic granulomata have reached a certain stage, a very well-marked hyperkeratosis is noticeable. One of us has called attention to the appearance of the films taken in the usual way from the granulomata, and stained according to Leishman's method. In such films it is interesting to note the presence of a large number of polychromatic red blood cells of very different sizes, some much larger than the normal erythrocytes, some much smaller. They are stained deep or light blue instead of pink, and sometimes have a granular appearance. The leucocytes present in the films frequently contain in their protoplasm, and sometimes in their nuclei, roundish or oval, more or less deeply blue stained bodies, which are probably polychromatic micro-erythrocytes engulfed by phagocytes. Some of these bodies present peculiar chromatin dots. In such films the Treponemata are almost constantly found. The Treponemata may be put in evidence also in sections by using the Volpino-Bertarelli or Levaditi's silver staining, as used by Spronk, Shennan, and Schüffner. The examination of sections so stained shows that the parasite is mostly found in the epithelial layers.



ig —Frambœsia: Primary Stage, showing the Primary Lesion or Frambœsoma below the Right Knee.

Symptomatology.—The course of frambœsia may be divided into three periods—a primary stage, comprising the development of the primary lesion or frambœsoma: a secondary or granulomatous stage, during which the characteristic frambœtic granulomatous eruption appears: a tertiary or late stage, in which the late manifestations of the disease develop—deep ulcerations and gummatous-like nodules. A fourth period may perhaps be added (paraframbœsial affections). This division into three or four periods is, of course, somewhat arbitrary, as symptoms considered to be characteristic of one period may make their appearance in another: tertiary symptoms, for instance, may appear during the secondary stage.

It has been stated again and again that the whole course of the disease lasts from three to six months in children, and six to twelve in adults, but according to our experience it has a much longer duration, and unless it becomes extinct after the secondary stage it may extend to many years. Indeed, we believe that in a certain number of cases, although there are periods during which the patient is apparently free from symptoms, the infection is merely latent, and sooner or later gives rise to renewed manifestations.

The Primary Stage: Frambœsoma.—After a period of incubation, varying in time between two to four weeks, characterized often by signs of malaise, rheumatoid pains, headache, irregular rise of temperature, the primary lesion or frambœsoma appears at the seat of inoculation, which is always extragenital. The primary lesion is a papule, which after about a week becomes moist, developing a yellowish secretion, which dries into a crust. Often at the place of inoculation several papules appear, become moist, and coalesce into a single element, covered by a thick crust. If after some days the crust is removed, the primary sore will appear as an ulcer, not rarely of large dimensions, with clean-cut edges and a granulating fundus. This ulcer may heal, leaving a whitish scar, which may later become pigmented; or in other cases it may develop into a granulomatous mass, not dissimilar to the granulomata of the secondary eruption, which appear later on, but frequently much larger. This large single projecting nodule is called 'mother yaw,' or 'maman pian' in French patois, 'buba madre' in Columbia of South America. Occasionally round it, before the general eruption begins, several smaller granulomata develop like satellites. The primary sore never feels indurated, and is often painful during the first stage of development. Later it may be quite painless. Occasionally there may be pruritus. The proximal lymphatic glands may become hard and enlarged, but they do not suppurate.

The seat of the primary sore is usually extragenital. The lesion may develop on an old ulceration, an itch pustule, an insect bite, a wound, or a vaccination mark. The smallest abrasion is sufficient for the entrance of the virus. Most of our female patients presented the primary sore on one of the mammæ, developing on some crack or abrasion of the nipple and areola. In several other women the primary lesion was found on the skin of the trunk, just above the hip, this being due to the custom of the Ceylon woman carrying her child astride of the hip. Any frambœtic element present on the scrotum or nates of the child, being continually rubbed against the skin of the mother, is likely to cause infection in the latter through any slight abrasion already present, or brought about by the friction. In men and children the primary lesion is frequently found on the hands, arms, and legs, but it may develop on any part of the body.

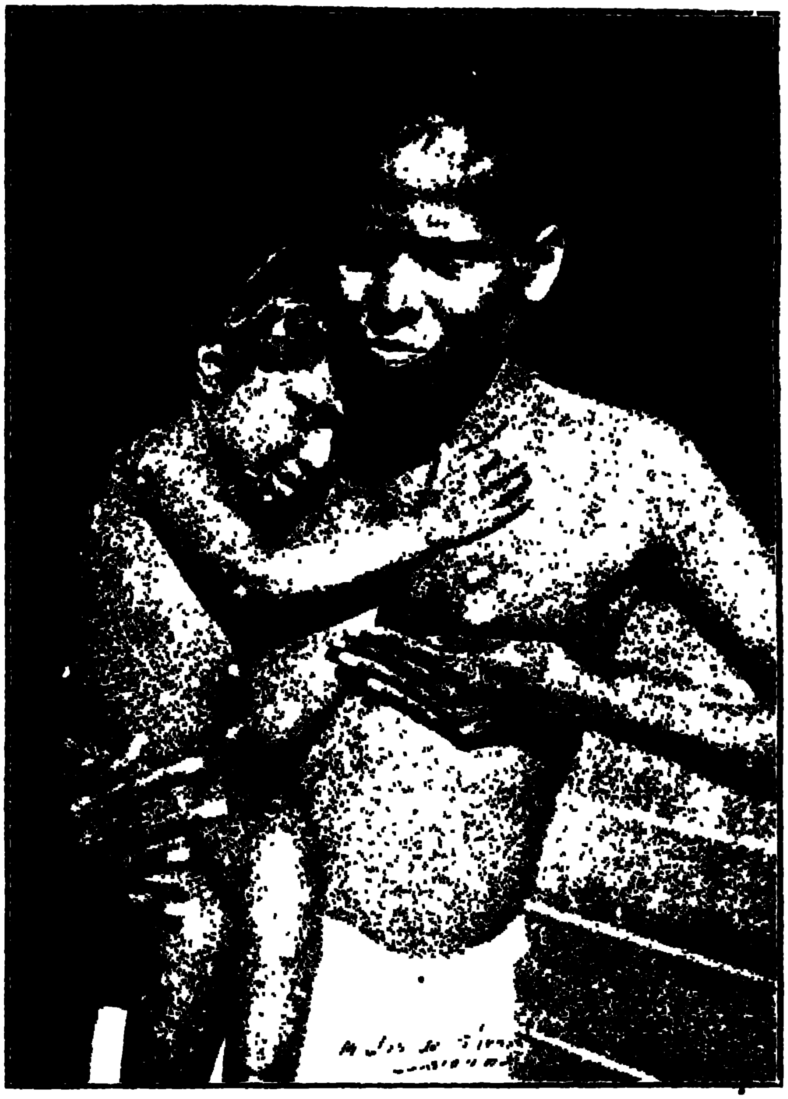


Fig. 688.—Child with General Granulomatous Eruptions, and Mother with the Primary Lesion (Frambœsoma) on the Left Mamma.

The primary lesion or frambœsoma may heal before the general eruption begins, but, as a rule, is still present when the secondary eruption appears. We observed a case in which the primary lesion was still present six months after its first appearance, and when the secondary granulomatous eruption had nearly undergone complete involution. The duration of the primary lesion, therefore, may vary between a few weeks and several months. The primary lesion leaves a whitish scar, which later on may become pigmented.

In some cases the scar is small and smooth, in others it is large and very thick. It is to be noted, however, that in Ceylon the disfiguring scar so frequently seen is partly due to the custom the natives have of cauterizing the sore deeply by very primitive methods. In other cases the large disfiguring cicatrix is due to the frambœsoma having developed on an old ulcer, which on healing leaves a coarse scar.

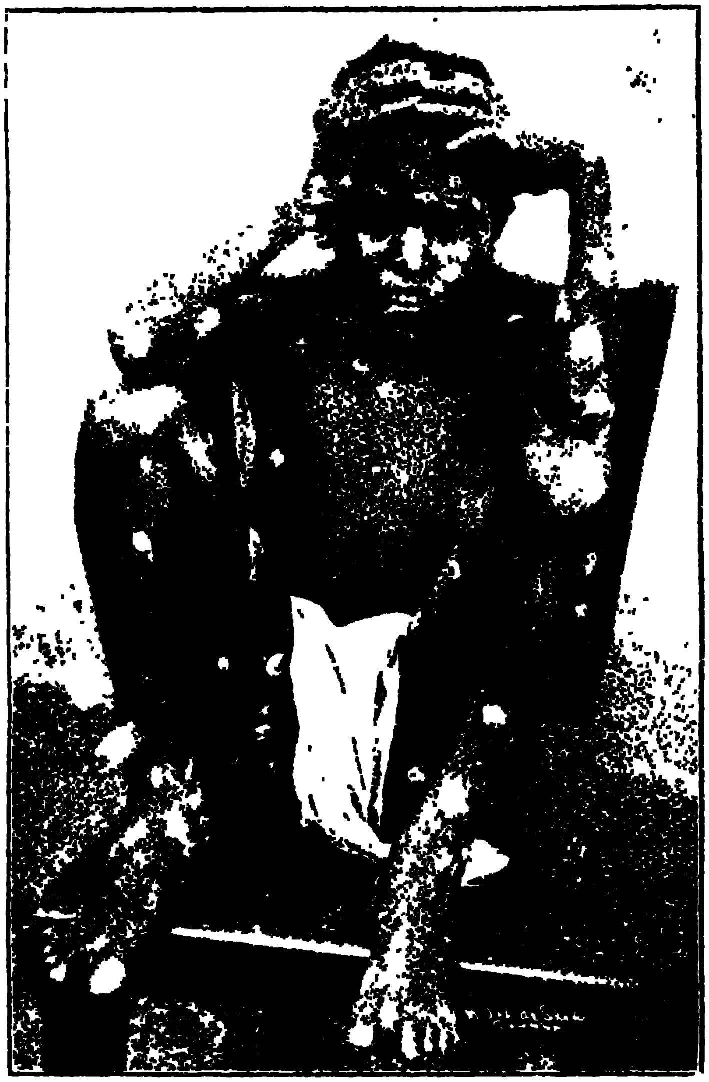

FIG. 689.—FRAMBŒSIA: GENERAL GRANULOMATOUS ERUPTION

The Secondary or Granulomatous Stage.—The general eruption usually begins between one and three months after the first appearance of the primary lesion. It is preceded by malaise, headache, severe pains in the muscles, joints, and bones. In some cases there may be fever of an intermittent type. The patient, however, is ordinarily able to attend to his work. The general eruption develops as follows: minute roundish papules, the size of pin-heads, appear on various parts of the body; some papules soon show a yellow point or minute yellow crust at their apex. Most of the papules

remain of practically the same size for many weeks, and disappear, leaving occasionally some furfuraceous patches: others become larger, several often coalescing, and frequently acquiring a dark areola in natives, a reddish one in Europeans. Some of the larger papules increase in size, and develop into the characteristic large granulomatous nodules covered with a crust, honey-yellow or brownish, formed of desiccated secretion. If the crust covering the granulomata be removed, there will be seen a raw surface throwing up red or yellowish fungoid granulations secreting a thin, slightly purulent secretion, which soon dries into a crust. These frambœtic granulomata are of various size, from a large pea to a nut, and may be found on practically any part of the body. They are extremely common on the upper and lower limbs, and on the face. On the scalp they are very rare. They may form rings round the mouth and anus, and may enclose sound skin (so-called *yaws ringworm*). They may remain of the same size and appearance for months. Often, after a few weeks, the secretion diminishes, and a process of hyperkeratosis sets in. They then become of much harder consistency, and some of them, especially those on the dorsum of the feet and toes, may be covered with numerous small,

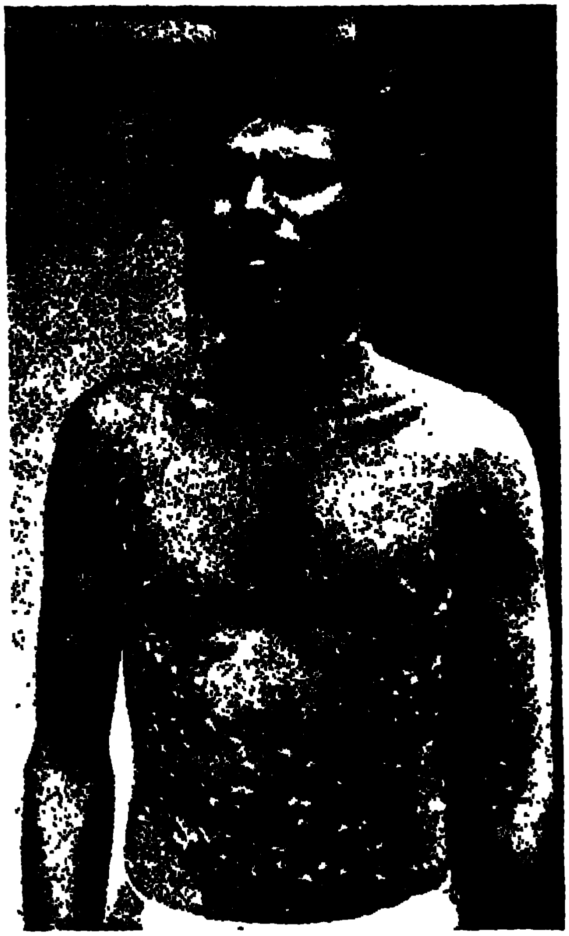

FIG. 690. FRAMBŒSIA (SECONDARY STAGE): GENERAL ERUPTION

hard, verrucose-like protuberances. In the majority of cases—within three to six months in children, and six to twelve months in adults—the granulomata dry up, shrink, and disappear, leaving dark hyperpigmented spots, or occasionally apigmented areas, on their site, which are most persistent. In some cases the granulomatous eruption may continue for several years, new crops of nodules appearing from time to time in succession. Each frambœtic granuloma generally undergoes involution within two to four months, leaving behind, as a rule, a dark area or, more rarely, a depigmented spot. Occasionally, however, the granuloma does not regress so soon. In one of our patients a single granuloma persisted for two years after all the others had disappeared.

FIG 691.—FRAMBŒSIA: GENERAL ERUPTION OF THE SECONDARY STAGE

The granulomata are seldom painful, unless they develop between the toes, on the soles of the feet, or round the nails. They very often cause itching. The patient often exhales a peculiar offensive odour, which has been variously described as sour or musty. This is probably due to the growth of various bacteria, representing secondary infections beneath the crusts of the granulomata. This offensive odour is especially noticeable when the secondary infection is due to bacilli of Vincent's fusiform type and coarse spirochætes. In such cases, if the sores are well washed with perchloride solution for two or three days, these organisms disappear, and the smell is no longer noticeable, though the granulomata do not undergo any change. Though the frambœtic granuloma is the charac-

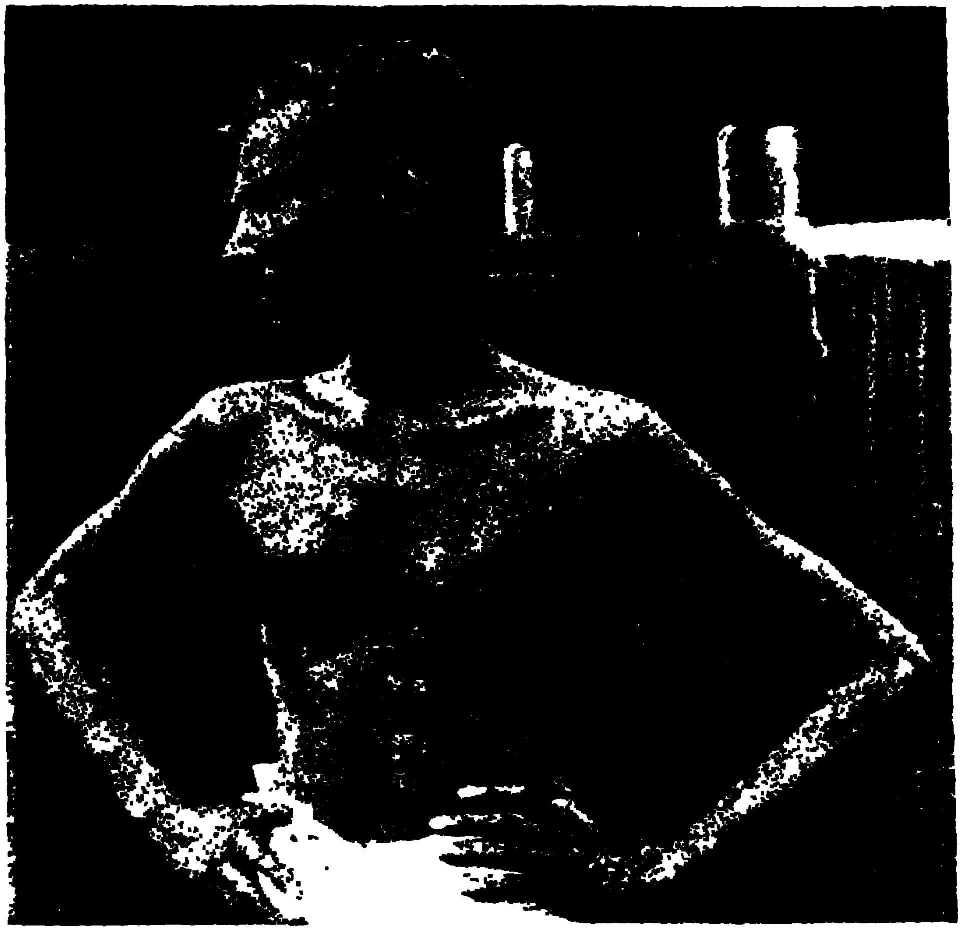

FIG. 692.—FRAMBŒSIA (SECONDARY STAGE): GENERAL ERUPTION.

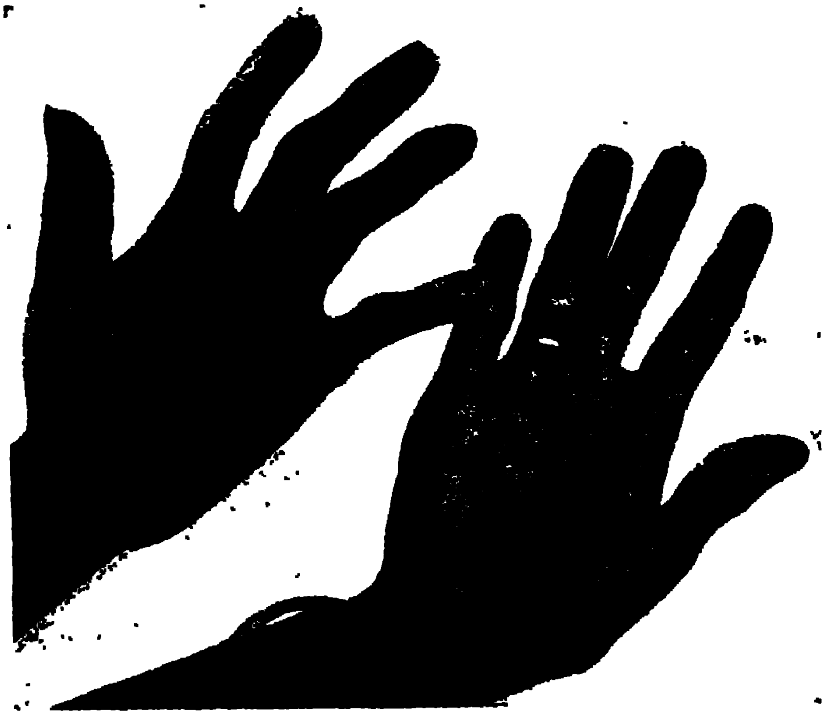

FIG. 693.—FRAMBŒSIA: ERUPTION ON THE HANDS.

teristic eruption of the secondary stage, there are during this stage other types of eruption or *frambœsides*—papular, scaly, and occasionally ulcerative. An average ordinary case will present at the

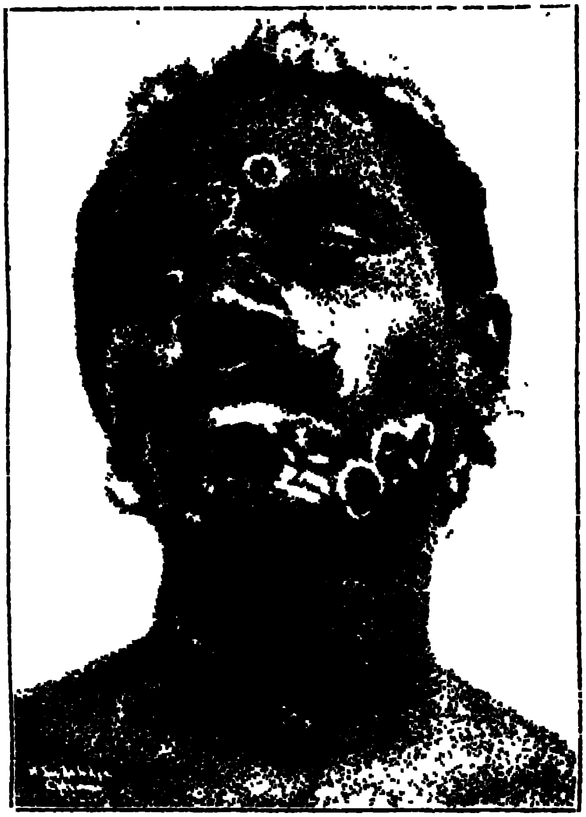

Fig. 694.—Frambœsia: Circinate Eruption

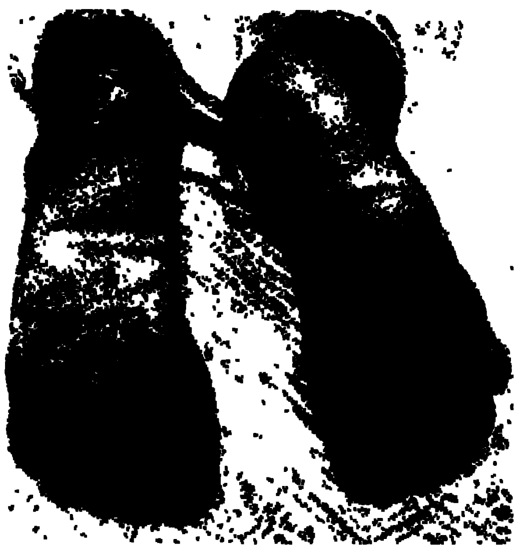

Fig. 695.—Frambœsia: Granulomata on the Heels of the Feet.

same time several typical frambœsiform granulomata, numerous small reddish papules with the epidermis intact, other papules which have become moist and are covered by a tiny yellow crust, several furfuraceous patches here and there, and spots of increased pigmentation at the place of previous granulomata. Occasionally

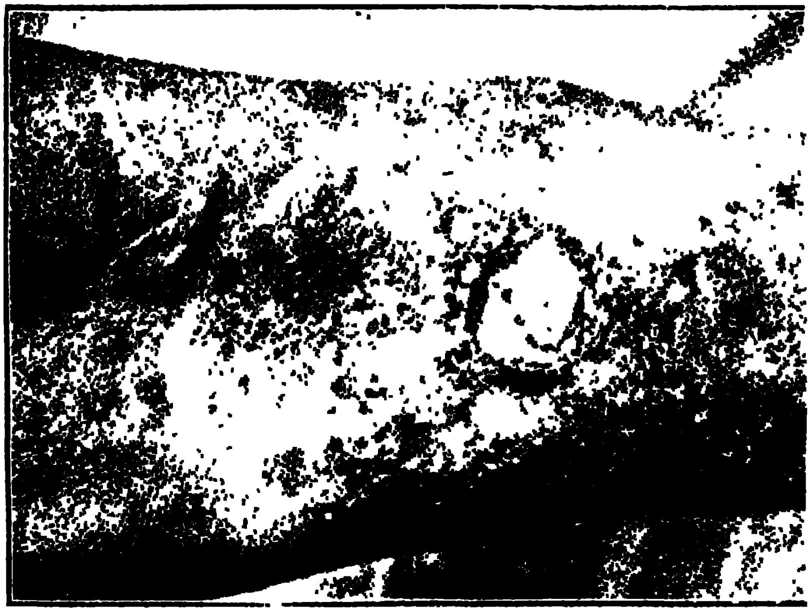

FIG. 696.—FRAMBŒSIA: LESIONS ON SOLE OF FOOT.

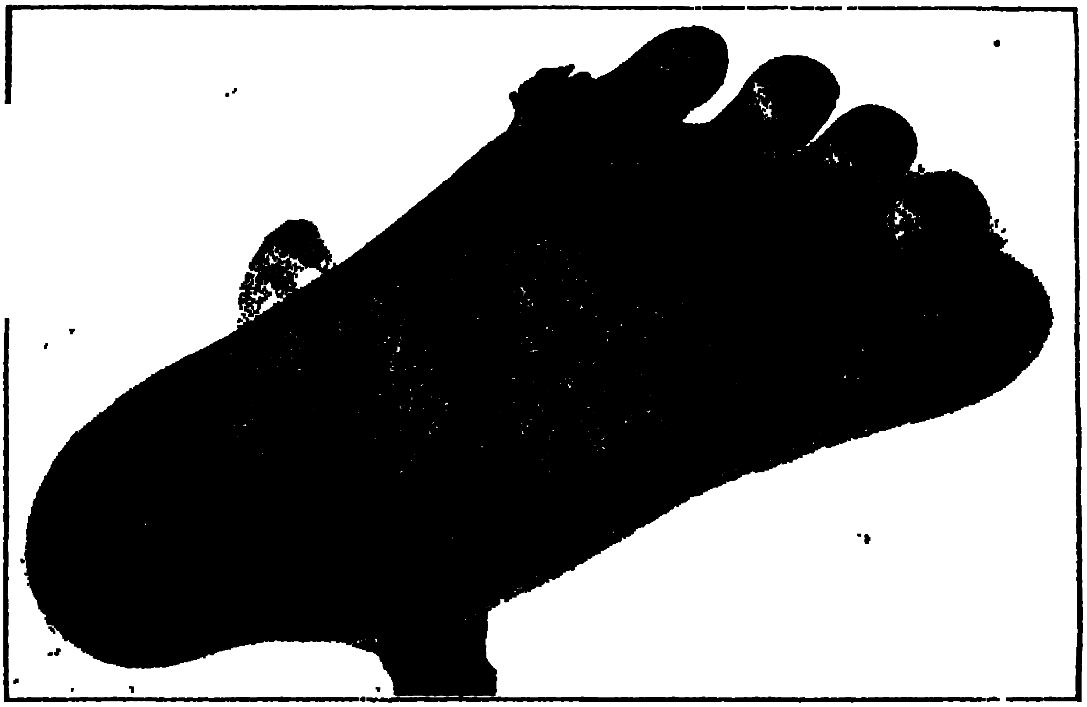

FIG. 697.—FRAMBŒSIA: LESIONS ON SOLE OF FOOT.

some granulomata break down, and large irregular ulcers form, presenting in their centre reddish papillomatous masses, which in our experience do not usually heal spontaneously. At times in the latter period of the secondary stage peculiar roundish or irregularly outlined whitish patches are present, especially on the back and arms, with a nutmeg-grater-like surface. On closer observation these patches are seen to consist of numerous hard, conical papules, containing in their centre an epidermic plug, which is easily removed, leaving a depression in the papules. Sometimes the plugs are spiny, and in this case the eruption closely resembles lichen spinulosus.

ERUPTIONS ON THE PALMS AND SOLES.—The granulomatous eruption very frequently attacks the soles of the feet. At first dark brownish or intensely livid spots appear; the thick epidermis is gradually pierced by frambœsial nodules similar to those found in other regions of the body. This affection of the soles is very painful; the natives of Ceylon call it 'dumas.' Similar lesions may occur on the hands. The granulomatous infiltration may attack the matrix and margins of the nails (frambœtic onychia and paronychia). The nails become thickened, dry, brittle, and may be cast off entirely, though later they grow again.

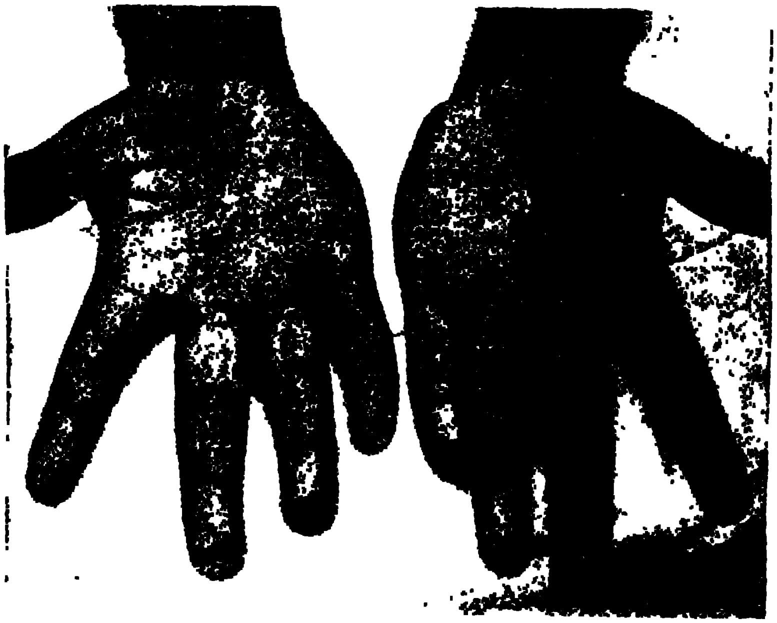

FIG. 698.—FRAMBŒSIA: PITTED APPEARANCE OF THE HANDS.

After the granulomata have disappeared, occasionally at the same time peeling, whitish patches may be seen on the palms of the hands and soles of the feet closely resembling the syphilitic *psoriasis palmaris and plantaris.*

PECULIAR PITTED FRAMBŒSIDE OF THE PALMS OF THE HANDS.—In several cases in the latter part of the secondary stage hard, round, flattened papules or small nodules, having a thick, hard, epidermic plug in their centre, may be observed on the palms and wrists. This plug falls off spontaneously or is easily pulled out, when a deep depression remains. The papules gradually disappear, but the depressions remain, and the palms acquire a peculiar pitted appearance. This condition of the palms may remain unchanged for several years after all symptoms of framboesia have disappeared. A somewhat similar appearance of the soles of the feet is occasionally met with.

Lesions of the Hair and Nails.—We have never noticed any change in the appearance of the hair, or alopecia. A few hair-follicles may be destroyed when the granulomata develop on the scalp, which, however, seldom occurs.

Lesions of Mucosæ.—These are not very common. During the secondary stage small granulomatous nodules may develop at the base of the tongue, also whitish patches closely resembling syphilitic leukoplakia. Small granulomata may develop on the nasal mucosa.

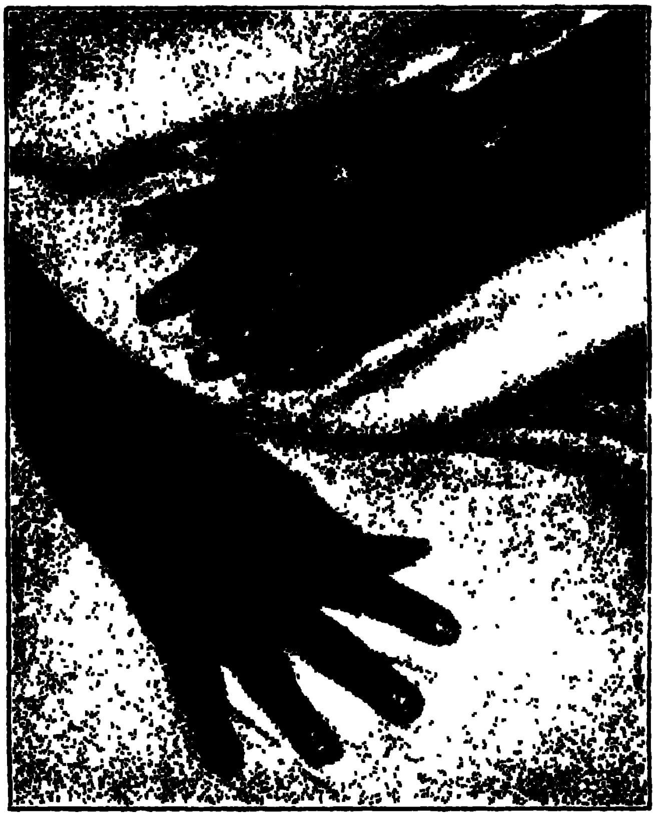

FIG. 699.—FRAMBŒSIA: DACTYLITIS.

Constitutional Symptoms—*Fever.*—As already stated, fever is frequently present, of intermittent or remittent type, before the general secondary eruption begins. During the secondary stage it is usually absent, unless complications supervene.

Lymphatic Glands.—In a number of cases in our experience various groups of lymphatic glands are found to be enlarged. The enlarged glands are roundish or spindle-shaped, hard, painless, and never come to suppuration, unless a secondary pyogenic infection is present. The cervical and inguinal glands are most frequently enlarged.

ALIMENTARY SYSTEM.—As a rule the digestive functions are not disturbed. In children slight diarrhœa may be occasionally noticed preceding the general eruption. The spleen and liver are frequently found enlarged in children, but this is probably due to preceding or concomitant malaria infection. The microscopical examination of the fæces of framboesia patients will frequently reveal ova of various worms—*Ascaris lumbricoides, Trichuris trichiura,* and occasionally *Ancylostoma duodenale*—but this is of frequent occurrence also in normal natives.

RESPIRATORY SYSTEM.—As a rule the respiratory, as well as the circulatory, system is not affected. Occasionally small granulomatous ulcers are to be found in the nasal mucosa and more rarely in the larynx.

LOCOMOTORY SYSTEM.—*Joints.*—In some patients several of the large articulations may become swollen and very painful. The condition is often of an acute character, and may be accompanied by fever, so that an attack of articular rheumatism complicating the frambœtic infection might be suspected. Sodium salicylate, however, is not beneficial, while the administration of large doses of potassium iodide speedily reduces the temperature to normal and cause the swelling of the articulation to subside. At other times one articulation only is involved, and the symptoms may become so serious as to suggest purulent arthritis. In many cases the smaller articulations become involved. The symptoms in such cases are not acute, and there is usually no fever.

Bones.—Inflammation of the periosteum of various bones is of common occurrence. Very frequent is a form of multiple periostitis of the digital phalanges, the cause of the multiple dactylitis so often seen in framboesia patients.

Maul has investigated the bone and joint lesions of Framboesia, and has noted that, in the Philippine Islands, 20 per cent. of the cases are suffering from such lesions, which may simulate tubercular or central septic abscesses, gummata, hydatid cyst, benign cyst, fibrous osteitis, enchondroma, endothelioma, secondary carcinoma, myeloma, and sarcoma. The same author has made a careful roentgenological survey, and has found that in the majority of cases the bone lesions appear as rarefied areas, irregularly oval, with the long axis parallel to that of the bone, from a few millimetres to 2 or 3 centimetres in length. Most of the lesions seem to originate in the interior of the bone, but some appear as small excavations on its outer surface.

Muscles.—Contractures of various groups of muscles may be observed. Fairly common is a contracture of the flexor muscles of the forearms. This contracture is often permanent, and in our opinion is probably due to pathological alteration of the peripheral nerves, rather than being of direct muscular origin.

NERVOUS SYSTEM—*Neuritis.*—Neuralgic pains are often observed, but also a true form of neuritis must be admitted. We have seen in several cases clear symptoms of neuritis of the sciatic nerve, with severe pain along the course of the nerve, and signs of motor and trophic disturbances.

Hyperidrosis.—In several of our patients we have noticed hyperidrosis. The phenomenon was limited to the face in some cases, to the hands and soles of the feet in others. It never extended to the whole body, and generally affected symmetrical regions. Hyperidrosis is more frequently observed in children than in adults. In a case at the Colombo Clinic a boy of fourteen, presenting a general eruption of framboesia, the hyperidrosis of the face was so marked that large drops of perspiration were constantly dropping down. He was treated with potassium iodide. After a month the granulomata had disappeared, and the hyperidrosis was no longer noticeable. In some cases the hyperidrosis ceases suddenly without any treatment. The condition, however, may last for some weeks or months.

The Eyes.—Granulomatous and papular eruptions may develop on the eyelids. A slight periostitis of the orbital margin is not rare, the margin becoming thickened and very painful on pressure. The occurrence of iritis is denied by most authors. In the Colombo Clinic two typical cases were observed during the general granulomatous eruption. In both cases the affection was of moderate severity. There was photophobia, ciliary congestion, discoloration of the iris. Pupillary reaction was almost absent. Both cases recovered on large doses of iodides without any local treatment.

The Genito-urinary System.—The primary lesion is rarely, if ever, found on the genital organs. In fact, in all the cases we have seen the primary lesion was always extragenital. Eruptions of the secondary stage, papular and granulomatous, frequently involve the skin of the penis and of the labia. Granulomatous ulceration may be found on the vaginal mucosa. The urine, as a rule, does not contain anything abnormal; only when there is fever—as, for instance, when the articulations are acutely involved—then a slight amount of albumen may be present.

The Blood.—There is often a certain degree of anæmia, never very severe. The number of red blood-corpuscles varied in our cases from 3,000,000 to 4,000,000, the hæmoglobin index (Fleischl) from 50 to 75. The red blood-corpuscles did not show anything abnormal in their shape. On several occasions a comparatively large number of polychromatic erythrocytes were noticed, staining blue instead of pink with Leishman's method. Many of these basophile red cells are micro-erythrocytes. The leucocytes varied from 7,000 to 11,000 per cubic millimetre. In the majority of cases an increase was noticeable in the number of the large mononuclears, even when there was no sign and no history of malaria. The number of lymphocytes is generally normal. Clapier and Violle have recently emphasized this, and note that it is in contrast to what one sees in syphilis, in which the lymphocytes are increased in number, while the large mononuclears are in normal amount. In many cases the eosinophiles are increased, this being probably due—in part, at least—to the presence of intestinal worms, as revealed by the microscopic examination of the stools, which shows frequently ova of *Ascaris lumbricoides*, *Trichuris trichiura*, and in a few instances of *Ancylostoma duodenale*. Density and viscosity of blood seem to be normal according to Violle, and the coagulability is not impaired. Auto-agglutination is generally absent, but has been recorded in certain cases.

Complement-Fixation Reactions.—Wassermann reaction is positive in the great majority of recent cases, but is fairly often negative in old cases. According to Schüffner and Violle, in frambœsia there is often fixation if an alcoholic extract of syphilitic liver is used as antigen, while there is no fixation if an aqueous extract is used. In syphilis there is generally complete fixation.

Cuti-Reactions.—The cuti-reaction with 'frambœsin,' prepared with cultures of *T. pertenue* according to the technique used by Noguchi in the preparation of luetin, is often positive. Luetin also may at times give a positive reaction, though less marked

FRAMBŒSI MYC

CEREBRO-SPINAL FLUID.—The liquid is in all cases perfectly clear, like distilled water. No cellular sediment on centrifugalization is found in most cases. In a few some rare mononuclear cells are found. The pressure is not increased. The physical and chemical characters do not show much variation from what is found in normal conditions. The density varied in our cases between 1003 to 1005. A certain amount of globulin was present, and a substance (dextrose?) reducing Fehling's solution. This reducing substance was in several cases distinctly in excess of what is observed in the normal fluid. No cholin is found. The reaction of the fluid is alkaline. The liquid is sterile; no treponemata can be detected.

Tertiary or Late Stage.—The disease often terminates with the secondary stage. In some cases, however, the infection does not become extinct, and tertiary lesions appear. These have been denied by many observers, but having been able to watch cases for several years through the whole course of the disease, we have no doubt as to their existence. Sometimes the secondary and tertiary stages merge into each other, but frequently the tertiary symptoms appear after the lesions of the secondary stage have undergone complete involution. The interval of time varies considerably in length, and may extend to many years. The characteristic lesions of the tertiary period are gummatous-like nodules and deep ulcerative processes. These gummatous nodules may develop in any tissues. When developed in the skin and subcutaneous tissues, they are indolent, and by their softening and breaking down ulcers are produced which may occasionally present clear-cut margins and a granulating fundus, and when several contiguous nodules break down, serpiginous ulcers are left. In other cases deep, irregularly shaped ulcerations with very thick and undermined edges are seen; in others —and these are the more numerous —large fungating ulcers are present. On healing, these various ulcers leave whitish scars, which are often thick and disfiguring. Frequently the scar-tissue undergoes retraction, and thereby causes permanent contractures and disfigurement. Lesions of the osseous type are very frequent, painful nodes developing under the periosteum of several bones, ribs, sternum, etc., and we are inclined to believe that *Gangosa* (p. 1876), an ulcerative condition of the palate, nose, and pharynx, is in reality a tertiary manifestation of yaws. In other cases a diffuse chronic periostitis is present, altering the normal shape of the bones. Contractures of various groups of muscles are frequently seen. Tertiary affections of the internal organs and of the central nervous system seem to be rare. Cases of aneurysm considered to be of frambœsial origin have been

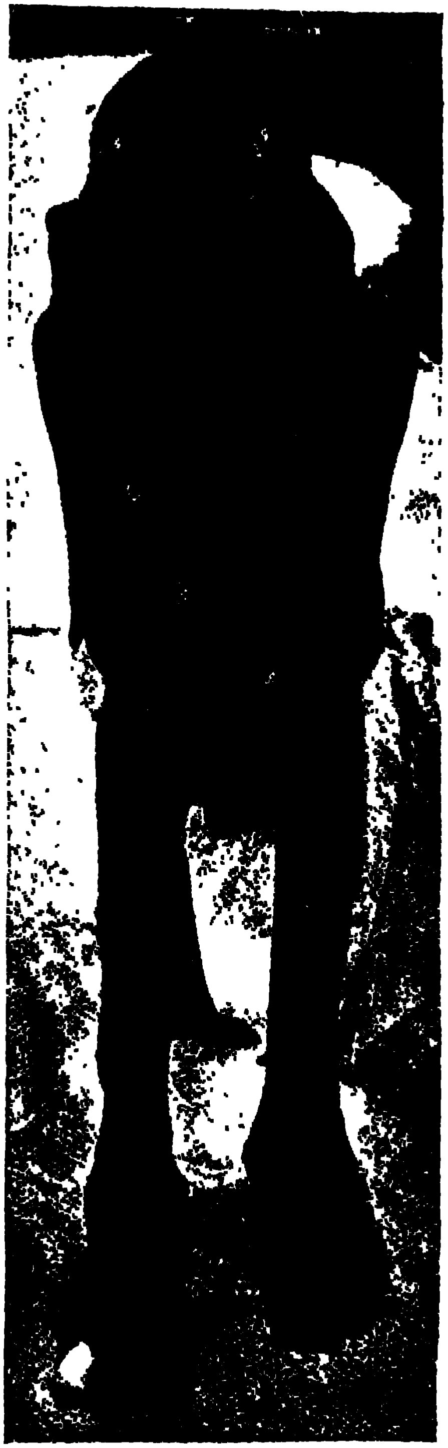

FIG. 701.—FRAMBŒSIA: TERTIARY STAGE.

observed. The malady does not appear to be hereditary; in fact, it is worth noting that, in contrast to syphilis, parents generally contract the malady from their children.

Fourth Stage: Paraframbœsial Affections.—Cases of tabetic symptoms and symptoms pointing to paralysis progressiva believed to be due to an old frambœsial infection have been placed on record by Harper and others.

Communicability.—Frambœsia is usually conveyed by direct contact from person to person. It appears, however, that the germ is unable to enter through the normal skin, and that there must be some pre-existing abraded surface, small wound, or ulceration. Women are frequently infected by their children, the primary lesion appearing often on the mammæ. In the native women of Ceylon the primary lesion frequently develops on the skin of the trunk just above the hip, slight abrasions caused by friction being usually present on this part, owing to the habit they have of carrying their children astride of the hip. Among certain Congo tribes it is a common dictum that a woman affected with the Nkoulou (yaws) should not sleep with her child, or he will certainly contract the malady. The natives, however, believe that the infection may be contracted also by partaking of contaminated food. In our opinion there can be little doubt that in certain cases insects may carry the disease. It is very noticeable that flies eagerly crowd on the open sores of frambœsia patients. In the hospitals, as soon as the dressings are removed, the frambœtic ulcerations become covered with flies, sucking with avidity the secretion, which they may afterwards deposit in the same way on ordinary ulcers of other patients. Ants also are occasionally seen to go on to the frambœtic

FIG. 702.—FRAMBŒSIA: TERTIARY STAGE.

ulcerations, as well as on to ordinary ulcers. In Nuttall's classical work on the rôle of insects as carriers of parasitic diseases several authors are quoted (Alibert, Hoish, Cadet, Wilson) who believe that the infection may be conveyed from one individual to another by flies. Wilson states that this belief prevails among the natives of the West Indies.

One of us made some experiments to prove that flies are instrumental in the dissemination of the disease. A number of flies were fed on scrapings from slightly ulcerated frambœtic papules. The flies (*Musca domestica* and allied species), before feeding on the frambœtic material, were examined. The examination showed that they did not harbour any treponemata, either on their mouth organs or on their legs. On examination after feeding, the majority presented coarse spirochætes, and a few of them also *T. pertenue.* In another experiment flies fed on yaws material were placed on scarified spots over the eyebrows of several monkeys, and kept there for two hours by means of strips of gauze smeared with collodion at their margins. One of the monkeys became infected. Sambon considers that a fly of the genus *Hippelates* plays a very important rôle in the dissemination of the disease in the West Indies.

Modder some years ago suggested that *Ixodes bovis*—*i.e.*, *Margaropus annulatus* var. *australis*—or some of the Argasidæ might be the transmitting agent. Bahr has suggested that the causative treponema may be transmitted by some blood-sucking insect whose range is definitely limited by the character of the vegetation or by climatic factors. According to certain authorities yaws may be communicated by means of food. R. P. Greggio states that natives of some Congo tribes suffering from yaws place inside the manioc they are selling portions of crusts removed from their own yaws lesions, in the belief that in this way the disease will leave them, will 'emigrate' to the buyers, who will become infected by eating the manioc.

Diagnosis.—In countries where the disease is endemic the diagnosis is generally easy, the large frambœsiform nodules, capped with thick yellow crusts, being typical. By some observers the disease has been confused with *verruga peruviana* and with *syphilis.*

Verruga Peruviana.—This disease is strictly limited to certain valleys of the Andes at an elevation of from 3,000 to 10,000 feet. Its eruptive elements, unlike those of frambœsia, frequently attack the various mucosæ, and bleed with great facility., The microscopical examination for spirochætes is negative.

Syphilis.—By some authors frambœsia has been looked upon as a form of syphilis. The results of experimental investigations of yaws and syphilis prove conclusively that the two diseases are distinct, inasmuch as (1) patients suffering from syphilis may contract yaws, and patients suffering from yaws may contract syphilis; (2) monkeys successfully inoculated with yaws do not acquire any immunity against syphilis; (3) mercury has practically no action on frambœsia.

Syphilis has a world-wide distribution; frambœsia, on the other hand, is restricted to certain parts of the tropics. Frambœsia is extremely common in Ceylon, extremely rare in India. Syphilis is common to both countries. In Samoa, according to Turner, syphilis was unknown up to at least 1880, while frambœsia has been endemic there ever since the group was discovered. In Fiji, too, up to a few years ago syphilis was not present, while frambœsia was almost universal. Daniels has made the interesting observation that in British Guiana frambœsia of late has disappeared, while syphilis is still rampant. As regards clinical features, frambœsia differs from syphilis by the following characters: the primary lesion is, as a rule, extragenital; the principal type of eruption is a papule, which proliferates into a characteristic frambœsiform granulomatous growth; there is an extremely well marked pruritus. The disease is apparently not hereditary; in fact, in contrast to syphilis, parents generally contract the malady from their children. The histopathology differs also in the two diseases. In frambœsia the proliferative changes of the epidermis are much more marked, the granulomata present a more diffuse plasma cell infiltration, and their bloodvessels have no tendency to the thickening of their walls, which is so characteristic of syphilis. Giant cells are generally absent. Naturally these differential histological details must be considered collectively, as there is no individual histological character which exceptionally might not be present in both syphilis and frambœsia.

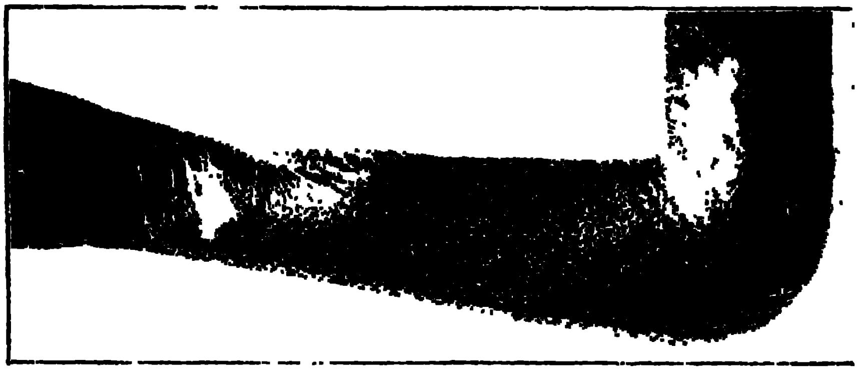

Fig. FRAMBŒSIA: TERTIARY STAGE.

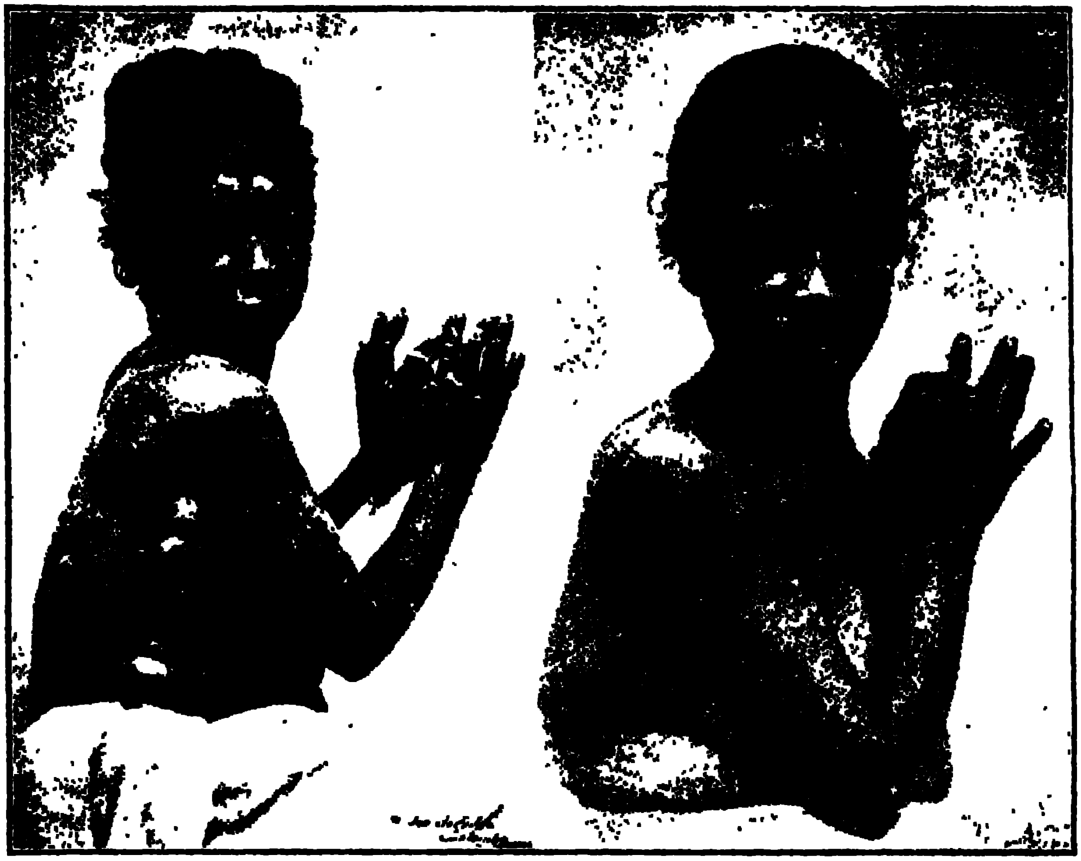
Boubas and Pian.- Some of the older authors believed that under the names of yaws, boubas, and pian three different diseases were indicated. All those, however, who have had opportunity to investigate frambœsia in different parts of the tropics have come to the conclusion that these various denominations are simply local synonyms indicating the same pathological entity, though, of course, each of these terms is sometimes used by natives to indicate, besides frambœsia, other clinically similar conditions. Comparative experimental investigations made by one of us have led to the same result, inasmuch as he has been able to demonstrate that monkeys successfully inoculated with Ceylon frambœsia become immune to boubas and pian, and *vice versa.*

Breda and De Amicis, in Italy, have not found *T. pertenue* in

Italian emigrants returning from Brazil, and suffering from what they considered to be boubas; but Splendore has shown their cases to have been cases of leishmaniasis and blastomycosis. The fact is, that in South America the term boubas is used by the natives to cover several clinically similar diseases, while most medical writers use the term as a synonym for framboesia. Rivas, Linderman, and Robledo have found the *T. pertenue* in their cases of boubas in Venezuela, Brazil, and Colombia. It is not to be excluded, however—in fact, it is probable—that future investigation will show that there are several varieties of *T. pertenue*.



FIGS. 704 AND 705.—FRAMBOESIA BEFORE AND AFTER TEN DAYS' TREATMENT WITH CASTELLANI'S MIXTURE.

Cutaneous Leishmaniasis.—A type of cutaneous leishmaniasis (Bush-Yaws), fairly common in the West Indies, may simulate yaws, but the presence of leishmania bodies and absence of the *Treponema pertenue* will clear the diagnosis.

Prognosis.—The prognosis is not serious so far as life is concerned. In 1908, in the Ceylon hospitals, 3,246 cases were treated, with twenty-three deaths; in 1904, out of 3,591 cases, sixteen died; in 1903, out of 3,254 cases, ten only died. The prognosis is far more serious in children than in adults. When the disease ends fatally the termination is gradually due to secondary infection, the frambœtic ulcerated lesions becoming phagedenic, and giving opportunity to septicæmia and pyogenic processes to develop. Though framboesia rarely terminates in death, its long duration and great contagiousness render it a serious malady. The patients suffering from it are unable to attend to their work. Epidemics of framboesia, therefore, are of the greatest consequence on tea, sugar, and other plantations, as they reduce the supply of labour.

Treatment.—The most efficacious and quickest treatment is by Ehrlich-Hata salvarsan or neo-salvarsan, while potassium iodide and tartar emetic are fairly efficacious, and mercury practically useless. Salvarsan and neo-salvarsan and their substitutes seem to act in framboesia more quickly and more powerfully than in any other spirochætal and treponemal condition; in fact, in framboesia the *therapia sterilans magna* in Ehrlich's meaning, by a single dose, can at times be obtained. Salvarsan was first tried with good results in experimental yaws by Nichols, and in patients suffering from the disease by Strong in the Philippine Islands, and Castellani in Ceylon, while Alston in the West Indies made the interesting observation that the serum of patients treated with salvarsan showed remarkable curative powers when injected in framboesia patients. Recently the salvarsan treatment of framboesia has become general, having been used with very good results by De Gorge and Mouzels, Sabella, Born, and many others. The salvarsan treatment is especially efficacious in recent cases. Relapses, however, occasionally occur. In very old cases with tertiary lesions the treatment may fail. At the present time neo-salvarsan, instead of salvarsan, is generally used.

MODE OF ADMINISTRATION AND DOSAGE.—Neo-salvarsan and its substitutes novarsenobenzol, neokharsivan, novoarsenobillon, and to a certain extent galyl, are much more soluble than salvarsan and its substitutes arsenobenzol, kharsivan, etc., and are therefore used in practice in preference to salvarsan. Moreover, Castelli has shown that the *dosis tolerata* of neo-salvarsan in infected rabbits is nearly three times larger than for salvarsan, and that the *dosis sterilans* is one-tenth of the *dosis tolerata*.

The dosage of neo-salvarsan and most of its substitutes is, in adults, 0·4 to 0·6 gramme, though larger doses up to 1 gramme have been given with impunity. The dosage is therefore approximately 0·01 gramme per kilogramme of weight; in children half or one-third doses should be given. The best method of administration is by intravenous injection, and we have found Ravaut's method of concentrated solutions very convenient, although we do not use such highly concentrated solutions as does Ravaut, who recommends dissolving neo-salvarsan in only 1 or 2 c.c. of water. We generally dissolve 0·3 or 0·4 gramme of neo-salvarsan in 10 c.c. of sterile distilled water or sterile physiological salt solution, and make the intravenous injection, using a 10 c.c. syringe.

The patient is made to lie down quietly on a couch or in bed. The skin is painted with tr. iodi and the veins of the bend of the elbow made turgid by applying an elastic band round the arm. The needle, already attached to the syringe containing the solution, is inserted in one of the veins; if blood appears in the liquid, it means that the needle is in the vein, and the piston of the syringe is then very slowly and gradually pressed down until all the liquid has been injected.

Three to six injections of neo-salvarsan at three to six days' interval are generally sufficient to obtain a cure, though in a number of cases one injection is sufficient to make all the symptoms disappear. If one injection only is given, 0·4 to 0·6 gramme should be injected; when a course of three or more injections is carried out we often give 0·3 gramme the first time, 0·4 gramme the second time, and 0·6 gramme the third time and afterwards.

The patient should keep, if possible, at complete rest in bed for several hours after the injection, and in individuals with weak heart the injection of neo-salvarsan may be preceded by a hypodermic injection of caffein. The patient may complain at times of headache, and there may be a rise of temperature, but very seldom are serious symptoms caused by the drug, though cases of transient coma, delirium, epileptiform crisis, nephritis, and jaundice have been recorded.

Salvarsan.—Salvarsan may be given by intramuscular, subcutaneous, or intravenous injection; by the mouth in alkaline solution; and also by the rectum in the form of enemas or suppositories. We recommend the intramuscular and intravenous injections. The administration by the rectum in our experience does not give any good result, and of the oral administration we have no personal experience.

Intramuscular Injections.—The injection is generally given in the buttocks, with the usual precautions as regards the disinfection of the skin, and the use of a sterile all-glass syringe. The quickest method of disinfecting the skin is to paint it with tincture of iodine. The dose to be given in adult males is 0·40 to 0·50 gramme; in adult females and thin individuals 0·30 and 0·40 gramme. A dose exceeding 0·60 gramme should never be given either in males or females. In children the dose is 0·03 to 0·04 gramme for each year of age, or 0·008 gramme for each kilogramme of weight.

The injection of salvarsan in the same dose can be repeated after two or three weeks, if the first one has not been completely successful. The drug is not easily soluble, and various methods of preparing the liquid to be injected have been described. The simplest method is Ehrlich's. The salvarsan powder (0·30 to 0·60 gramme) is rubbed with a little methyl alcohol (pure) in a sterile vessel, and then mixed with 10 to 20 c.c. of normal salt solution.

An alkaline or neutral solution is preferable, and is prepared by rubbing the drug in a sterile mortar with 10 to 20 drops of a 15 per cent. solution of sodium hydrate, and adding 8 to 10 c.c. of sterile distilled water, stirring continuously. In order to prepare a clear solution, it generally requires 1 c.c. to 1·2 c.c. of the sodium hydrate solution for 0·6 gramme of salvarsan; a suspension of the drug in olive-oil or some other fatty material may also be used. A good preparation of this type, which we have often used, is by Pasini.

The suspensions in oil may often be given with advantage subcutaneously in the interscapular region. The intramuscular or subcutaneous injection of salvarsan, especially the acid solution, is generally painful, and is followed by a hard infiltration, which lasts for some weeks. Occasionally a slough forms, which has to be removed surgically.

Intravenous Injections.—The dose is smaller than for the intramuscular injection, 0·4 gramme for men and 0·3 gramme for women being sufficient.

The preparation of the solution to be injected is as follows. One of the glass phials in which salvarsan is put up in the dose of 0·6 gramme is broken, and the contents (0·6 gramme of salvarsan) is carefully added to 30 or 40 c.c. of physiological salt solution made with distilled water in a sterile stoppered vessel. It is dissolved by shaking thoroughly, and by adding 1·2 c.c. (about 23 drops) of 15 per cent. sodium hydrate solution. A precipitate is formed which redissolves. The solution should then be diluted to 300 c.c. with normal saline; 1 or 2 more drops of sodium hydrate may be required if the liquid is not clear. Each 50 c.c. of this solution contains 0·1 gramme of salvarsan. In man, 200 c.c. should be injected, in women 150, in children less, according to the rules given *supra*.

For the intravenous injections special apparatus have been devised, based on the principle of the Grantly douche. A convenient one, which may serve for all these forms of injection, has been placed on the market by W. H. Martindale.

Precautions to be Observed. - The solution should be prepared with sterile salt solution made with freshly prepared distilled water and chemically pure sodium chloride. It should be *perfectly clear*, it should be slowly infused into the vein (200 c.c. in about eight minutes); it should not be cold (about the temperature of the body if possible); the patient should be in bed, and should be kept there for a couple of days. If signs of collapse occur during the infusion, it should be stopped at once, and an injection of caffein given.

Tartar Emetic.—Broden, in 1910, and later on other observers, tried antimonial preparations by intravenous injection as in sleeping sickness. The results are much less satisfactory than with salvarsan or neo-salvarsan.

Intravenous Injections of Tartar Emetic associated with Other Drugs.- Potass. iodide and mercury were associated by one of us with tartar emetic, but the mercury did not seem to increase the action of tartar emetic. Herewith two formulæ:--

1.	Tartar emetic .	gr. iii.
	Potass. iodid. ..	gr. xxx.
	Aq. dest. ..	ad ℥i.
2.	Tartar emetic ..	gr. iii
	Potass. iodid. .	gr. xxx.
	Hydrarg. perchlor.	gr. ⅛
	Aq. dest.	ad ℥i.

One to 3 c.c. may be given diluted in 8 or 10 c.c. of sterile water by intravenous injection every other day.

Treatment by Oral Administration of Drugs.—When neo-salvarsan, salvarsan, or their substitutes, are unobtainable, or in districts where lack of medical men and skilled nurses makes any method of treatment by injections difficult or impossible, treatment by oral administration is very convenient, and the mixture known in the tropics as 'Castellani's yaws mixture' will be found effective in many cases.

This mixture contains tartar emetic, gr. i.; potass. iodid., ʒi.; sodium salicylate, gr. x.; bicarbonate of soda, gr. xv.; water or chloroform water, to 1 oz. One ounce is given three times daily diluted in three or four times the amount of water, to adults and youngsters of over fourteen years; half doses to children of eight to fourteen years of age, and one-third or less to younger children.

To Europeans it is advisable to give half doses, as they do not stand full doses so well as do natives.

The active drugs in the mixture are the potassium iodide and the tartar emetic; the salicylate of soda does not influence the yaws lesions, but seems to hasten the disappearance of the thick crusts, while the bicarbonate of soda, though rendering the mixture cloudy and inelegant, prevents to a great extent the symptoms of iodism and decreases the emetic properties of the mixture, in this way rendering possible the administration of massive doses of potassium iodide, and large doses of tartar emetic. In the few cases in which emesis is produced, the bicarbonate may be increased, or a small amount of liq. morphiæ or codein given before each dose; and in the comparatively rare cases in which severe iodism appears, epinephrine, as suggested by Milian, in grm. 0·002 doses, may be given by the mouth or by subcutaneous injection, twice daily.

The mixture as set down is cloudy, although it becomes clear when diluted with water at the time of administering it. At the suggestion of Dr. Dawson Williams some experiments were carried out to obtain a clear mixture, and it was found that the addition of sodium tartar. gr. x., or of glycerine ʒii. or of syrup ʒi. per dose, was sufficient to keep the mixture clear for weeks. The modified formula of the mixture is therefore as follows:- -Tartar emetic, gr. i.; potass. iodid., ʒi.; sodii salicyl., gr. x.; sodii bicarb., gr. xv.; sodii tartarat., gr. x., or glycerine, ʒii., or syrup, ʒi., Aq. ad ℥i. It is given in the same doses as the original mixture, and well diluted in water to prevent a severe sensation of burning in the stomach.

Either the original or the modified mixture is given in the doses mentioned for ten to fifteen days, then it is discontinued for about a week, and then given again for another ten to fifteen days. The results, as shown by Castellani, Spaar, Thomson, and more recently by Guerrero, Domingo, and Argüelles, who have carefully investigated this method of treatment in the Philippines, are usually very satisfactory in recent and fairly recent cases when they may be compared with those obtained by the salvarsan treatment. In chronic cases the results are not so striking, but as a rule much better than with any other known treatment, except salvarsan or neo-salvarsan.

The natives treat the disease in various ways. In Samoa the patient is rubbed down with sand and washed in the sea, after which the yaws are scraped with a shell. In the West Indies boiled and beaten-up leaves of the ' physic-nut ' are applied ,or powdered alum and sulphur used. In the Congo pieces of forge scoriæ are made incandescent and the yaws lesions touched with them. In Ceylon the *vedaralas* (native doctors) apply concoctions of various herbs, and give decoctions of sarsaparilla and other roots. They also use mercury disguised in various ways. The majority of European practitioners use potassium iodide. Others affirm this drug to be quite useless, and believe that cleanliness and good and abundant food are quite sufficient to bring about a cure.

In the Colombo Clinic for Tropical Diseases some experiments have been made on the various treatments, and the conclusion arrived at has been that the salvarsan and neo-salvarsan treatment is the most effective of all, while the mixture tartar emetic, potass. iodide, bicarb. of soda, and sod. salyc. is also very successful. Some cases may recover spontaneously, but this is certainly the exception, not the rule. Occasionally cases are met with refractory to any treatment, and tertiary lesions are often intractable. An important point often overlooked by the practitioner is that the oral treatment should be prolonged for a time after the complete disappearance of the eruption, inasmuch as clinical experience, as well as experiments on inoculated monkeys, prove that the specific treponemata may, and do, persist in the lymphatic glands and internal organs long after the cutaneous manifestations have disappeared. Atoxyl has been tried by Neisser in monkeys experimentally inoculated with the disease, and by one of us in human patients. The results are occasionally fairly good. Spittel has used, by intravenous injection, a solution of arsenious and mercuric iodide.

Local Treatment.—This consists chiefly in keeping the skin scrupulously clean, washing the eruption twice daily with a perchloride of mercury solution (1 to 1,000), which greatly allays the itching. The ulcerated lesions may be dusted with iodoform, europhen, xeroform, or boracic acid. Mercury ointments may be beneficial, but in our experience are not sufficient to hinder secondary pyogenic infections. Caustics are not called for unless the ulcers become phagedenic. In such cases pure carbolic acid is best. Though the external treatment may be useful, one must bear in mind that it is not, as a rule, sufficient alone to cure the disease.

Prophylaxis.—In countries where frambœsia is endemic the slightest abrasions of the skin should be taken care of and properly treated with antiseptics. Frambœsia patients should be prevented from mixing with the rest of the population, and should be isolated in special hospitals till the disease is cured. Their skin lesions should be properly dressed, and thus prevented from becoming a source of infection through the agency of flies and other insects. Their huts and belongings should be thoroughly disinfected.

CHAPTER LXII

VERRUGA PERUVIANA

Synonyms — Definition — History — Climatology — Ætiology — Pathology — Histopathology — Symptomatology — Diagnosis — Prognosis — Treatment — Prophylaxis — References.

Synonyms.—Peruvian wart, Verruga Blanda, Carrion's Fever, Verruga de Castilla, Verruga of the Andes, Verruga de Zapo ó de Quinua, Verruga Andicola, Verruga Mular, Verruga de Sangre, Fiebre de la Oroya, Verruga de Crapaud, Bouton des Andes. The word 'verruga' signifies in Spanish a wart.

Definition.—Verruga peruviana is a chronic endemic specific general disorder of unknown origin, not contagious, but apparently inoculable, and characterized by an irregular fever associated with rheumatoid pains and anæmia, followed by granulomatous swellings in the skin, mucous membranes, and organs of the body.

History.—It is probable that the disease existed in South America before the advent of the Spaniards, for the earliest references to it are found in Spanish works on Peru in the sixteenth century. The first record is by Agustin de Zárate, Treasurer of Lima, in his 'History of the Conquest of Peru,' written in 1543, in which he relates that warts or small tumours appeared on the face and other parts of the body, which were more deadly than smallpox, and almost as fatal as plague.

Garcilas de la Vega records that a quarter of the small army of François Pizarre perished from this cause, while Gomara, Garcilazo (1617), and other early writers, also drew attention to the disease. After this period writers on Peru either fail to mention the disease at all, or only write short paragraphs such as that in Cosme Bueno's geographical description of the province of Canta, published in 1764, in which it is mentioned under its ancient name of 'berrugas.'

The modern descriptions of the disease begin with the works of Tschudi in 1843, Malo in 1852, Smith in 1858, Salazar and Manuel Odriozola in 1858, Velez in 1861, and Dounon in 1871, the last named giving a very clear account of the complaint.

But little interest was, however, taken in it until 1870, when a severe outbreak of fever took place among the workpeople laying the railway-line between Lima and Oroya. This complaint for some reason was called 'Oroya fever,' although it did not affect Oroya. About the same time Dounon's excellent paper appears to have interested French naval surgeons, so that numerous investigations as to verruga and Oroya fever were made both by Peruvian doctors, such as Pancorvo and others in 1875, and French surgeons, such as Fournier in 1874, Bourse in 1876, and Tupper in 1877. During this period there was much disputation as to whether Oroya fever was related to verruga, or was a distinct clinical entity. In 1885 Daniel A. Carrion, a student of the Faculty of Medicine of Lima, who had for some time been studying the disease, attempted to settle this question by vaccinating both his arms with the blood from a verruga tumour on August 27, 1885, and on September 17 he began to suffer from the symptoms of Oroya fever, from which he died on October 5. In honour of his noble attempt to elucidate the ætiology of the fever, his compatriots have since referred to Oroya fever as Carrion's disease.

The unfortunate death of this brave young man stimulated inquiry, and a very large number of investigations were published, of which it is only possible to mention a few.

In 1885 Izquierdo announced the discovery of a bacillus in some specimens sent to him in spirit, which, of course, prevented anything of the nature of a thorough bacteriological investigation.

In 1887 Florez grew a coccus on agar-agar inoculated with the blood from persons suffering from verruga. In 1898 a most elaborate monograph by E. Odriozola appeared, which the reader interested in the subject is strongly advised to peruse.

In the same year Nicolle and Letulle independently described bacilli resembling those of tuberculosis in the skin lesions. Barton, in 1902, published the first careful bacteriological examinations of Carrion's fever, and from 1903 to the present time Biffi has written a series of able papers on the disease.

We are therefore confronted with two conditions described by authors—viz., a disease which may or may not begin with fever, and which ultimately ends with a most peculiar and typical eruption, verruga peruviana, and another disease characterized by an incubation period of twenty-one days, as proved by Carrion's inoculation, and of a severe type often ending in death, without the appearance of any eruption. Are these two conditions one and the same disease—that is to say, is Carrion's fever Peruvian wart without an eruption, or are the two separate pathological entities? Tasset, in 1872, held that they were separate entities, and that Carrion's fever was a typho-malarial fever, but since the inoculation of Carrion most authors have considered the two diseases to be one and the same, though every now and again some author has objected, and has held that Carrion's fever was typhoid. In 1901-02, Barton, as the result of careful bacteriological researches, concluded that in the blood and organs of persons dying from Carrion's fever a micro-organism could be found which, though similar to *Bacillus coli communis* in many respects, was easily separable therefrom. This organism was fatal to inoculated animals, causing a septicæmia and, it is said, a verruga-like eruption in the skin. Biffi has carefully investigated this bacillus, and finds that it is present constantly and in abundance in persons suffering from Carrion's fever, but is absent in patients suffering from verruga peruviana without fever. It is agglutinated by the serum of persons suffering from Carrion's fever, but not by that of patients suffering from verruga who have not had fever. The micro-organisms are, however, not always of the same strain. Thus, Biffi has separated two different strains, one of which resembles Schottmüller's *B. paratyphosus B*, and the other Gärtner's bacillus. Biffi and Carbajal were unable to confirm Barton's results as to the presence of a skin eruption in animals inoculated by these strains. They therefore conclude that Carrion's fever is a separate pathological entity distinct from verruga, and that it is a fever belonging to the paratyphoid group, but differs from the usual types by being due to a different organism, and by occurring in patients suffering from verruga. In this finding they are supported by the clinical observations of several observers, among whom may be mentioned Eder.

The next question which must be considered is the nature of verruga peruviana, for it has been suggested that it is frambœsia, and this has been specially emphasized, since it has been realized that it may run its course without any fever. Biffi, however, has clearly shown that they are separate, frambœsia being contagious, verruga not; frambœsia beginning with an initial lesion, verruga not; frambœsia being due to *Treponema pertenue* Castellani, verruga not. We may therefore conclude that verruga peruviana is a definite pathological entity. Further researches in the disease have been made by Bassett-Smith, Mayer, and others.

In 1915 Strong, Tyzzer, Brues, Sellards, and Gastiaburu published a valuable report, pointing out that Oroya fever was distinct from verruga peruviana.

The former, according to these investigators, is due to *Bartonella bacilliformis* (*vide* p 502), which in many ways resembles *Theileria parva*, while the latter is probably caused by a filterable virus, and can be inoculated into monkeys; it resembles closely Bassewitz's angiofibroma cutis contagiosum tropicum (p. 2253). Verruga may be spread by a blood-sucking arthropod. Townsend, in 1914 and 1915, declared his belief that this arthropod was *Phlebotomus verrucarum*.

Climatology.—Verruga peruviana is confined to South America, and to the western slopes of the Andes in Ecuador, Peru, Bolivia, and the northern parts of Chili, the most important endemic area being Peru, where it is almost limited to the departments of Ancachs and Lima, lying north and south of the tenth parallel, and on the western side of the Andes. The department of Ancachs comprises seven provinces, of which the provinces of Pallasca, Huaylas, Huaraz, and Cajatambo, which are on the western slopes of the Andes, are most affected, while that of Santa, which runs along the littoral, is almost free. The disease is, however, peculiarly limited to certain places in these provinces. The heights of these places vary from Cochas, in the province of Cajatambo, which is only at an elevation of 406 metres, to Cajatambo, in the same province, which is at an altitude of 3,350 metres, but according to Monge it is never naturally acquired at an elevation below 2,800 feet or above 9,000 feet, nor does it originate in the main valleys.

One striking peculiarity common to all the places is that they are in narrow valleys along tributaries of rivers. The principal infected areas are Tablachaca, Pallusca, Corongo, Pacatqui, and Ninabamba, in Pallusca; Huaylas and Caráz, in Huaylas; Yautan, Pariacoto, Rurasca, Nanca, Jangas, Pongor, Anta, and another district on a branch of the River Huarmey, in Huaraz; Cochas, Huaylillas, and Cajatambo, in Cajatambo.

In the department of Lima there are six provinces, of which Chancay, Canta, Huarochiri, and Yauyos possess endemic areas, which vary in height from 900 to 2,030 metres. In Chancay there is Huaycho; in Canta, Acos, Viscas, Yasu, Magdalena, and Yangas; in Huarochiri, Santa Eulalia, Palle, San Gerónimo, San Pedro de Casta, Surco, Cocachacra, Santa Ana, and Sisicaya; and in Yauyos, Omas.

The best-known area is that which lies along the railway from Lima to Oroya, which begins a little below the division of the River Rimac into the rivers Santa Eulalia and Cocachacra, along both of which the disease is endemic for some distance, including Santa Eulalia, San Gerónimo, Cupichu, San Pedro de Casta, San Pedro de Mama, Santa Ana, Corcona Cocachacra, San Bartolomé (where the stream which runs into the Cocachacra River is called the Aqua de Verrugas, because the people believed the disease came from drinking the water), Cuesta Blanca, and Surco.

Here again, as in the department of Ancachs, the disease is restricted to certain deep, narrow valleys, locally known as 'quebradas,' along which streams flow, and which are some 28 to 60 kilometres distant from the littoral, where the disease never occurs. A very important epidemiological point is that the disease only occurs in the summer when the rivers are in flood, and when all sorts of insects abound. Monge points out that earthquakes are correlated with small epidemics, probably because the disturbed population becomes more exposed to the infection, whatever that may be.

Ætiology. The causation of verruga peruviana is unknown. Popularly the disease is believed to be conveyed by the drinking-water, which, however, has long been discredited. In 1875 Pancorvo, taking into consideration the well-known fact that the persons who mostly suffer are people who work in the fields or disturb earth, suggested that it was an intoxication due to sulphuretted hydrogen liberated from the earth, a view which never received any marked support. Odriozola and Tamayo have failed to find any bacteria in people suffering from the eruption of Peruvian wart. It is said to occur in animals, especially quadrupeds, and not to be contagious. Chastang believes that some germ is inoculated by the thorns of *Cactus opuntia*. Long ago Raymondi suggested that verruga would, like rabies and syphilis, be found some day to be due to a definite virus. Translating Raymondi's views into modern thought, it would mean that the three diseases would be found to be due to a parasitic protozoon, and, indeed, there is no doubt about the truth of this with regard to syphilis and with regard to rabies, and it is quite possible that verruga peruviana will some day be found to be of protozoan origin, thus confirming Raymondi's striking conjecture.

The study of the distribution of the disease in the various provinces of Peru, as detailed above, with the aid of a large-scale map, will impress the reader with the similarity to the distribution of Rocky Mountain fever, and will lead him to the conclusion that the ætiological cause must in some way be associated with some blood-sucking animal, perhaps an arachnid: and, indeed, this is supported by a fact well known - that the persons most prone to the infection are those who work in the fields. Such ideas must, however, be taken as mere suggestions, as at present there is no direct evidence in favour of them. Very minute bacillary-like rods, thicker in the middle than at the ends and variable in number, have been described in the red cells by Barton, Gastiaburu, Rabagliati, and Biffi. They become scanty after the eruption, and disappear during convalescence. Similar bodies have been seen by De Vecchi, Bassett-Smith, and Martin Mayer. De Vecchi considers them to be products of degeneration.

Strong, Tyzzer, Brues, Sellards, and Gastiaburu's experiments would point to the virus being a filterable one, and inoculable in monkeys. Inoculated in the testes of the dog and rabbit it induces characteristic changes. As already stated, these authors believe that the disease is not connected with Oroya fever, which, according to them, is due to *Bartonella bacilliformis* (p. 502), and is not inoculable in monkeys.

Age, sex, and race appear to have no influence, though it has been asserted that the coloured races have a partial immunity, which is due to mild attacks at a very early age, as nearly every inhabitant in the towns of the endemic areas acquires verruga, and if reinfected has only a very mild attack, for, as a rule, an attack confers a lasting immunity. Strangers visiting an endemic area are attacked almost at once with the disease in its gravest form. The disease may be acquired by travelling through an endemic area, but there is much more risk of infection if a night is spent therein, and if the endemic zone is quitted before sunset the risk of infection is greatly diminished. Another important point is that newly-born infants may acquire the disease. Cole has made some inoculation experiments in monkeys with a certain degree of success.

Pathology.—As the causation is unknown, the account of the pathology must be limited to very few remarks. There has been great doubt as to whether verruga can be transmitted to animals by inoculation, though Odriozola related that he inoculated a bitch with the blood from verruga lesions obtained from a post-mortem, with the result that the animal developed a typical skin eruption, and eventually died. The disease is said to occur naturally among animals—*e.g.*, horses, mules, asses, dogs, and fowls—but especially among quadrupeds, although Monge states that no one has definitely proved that this is the verruga of man, and the ordinary laboratory animals cannot be infected with the disease. According to some observers, the infection in man begins with a general illness, which would appear from the fever, the anæmia, and the pains in different parts of the body, to be of the character of a septicæmia, after which the typical eruption appears on the skin, mucous membranes, and internal organs, when as a rule the general symptoms of fever, etc., abate, from which one would infer that the organism had left the blood stream, and become located in the skin and other organs. It is possible that it leaves the body by way of the skin. If, however, the local lesion develops in such places as the meninges, the choroid plexus, the choroid coat of the eye, the intestines, the œsophagus, or larynx, severe symptoms are apt to appear, and complicate the illness. If at the same time a paratyphoid-like infection takes place during the febrile stage, the true symptoms are masked, and a peculiar and very deadly type of fever, called 'Carrion's disease,' is produced.

The morbid anatomy is characterized by marked pallor of the body, œdema and dropsy, hypostasis of the lungs, enlargement of the liver and spleen, and hyperæmia of the bone-marrow; but apart from these general signs, the characteristic features are the appearance of the verrugas in the skin and subcutaneous tissues, in the ocular and palpebral conjunctivæ, the mucosa of the nose, the lips, gums, palate, tongue, pharynx, larynx, trachea, œsophagus, stomach, small and large intestine, in the substance of the liver, spleen, lungs, thymus, thyroid, testicles, kidneys, and lymphatic glands, and at times in the leptomeninges, the choroid plexuses, the choroid coat of the eye, in the substance of the muscles, on the periosteum of bones, on the peritoneal coverings of organs, and on the pleura and pericardium.

Histopathology. -The histopathology of the disease has been carefully studied by Letulle, Jamayo, Escomel, Jeanselme, Hercules, Biffi, De Vecchi, and very completely by Strong and his co-workers. The miliary and nodular forms take origin around the capillary bloodvessels in the form of a neoplasm which is the reaction of the areolar tissue to some perivascular irritant. The connective-tissue fibres become swollen, and between them lie embryonic connective-tissue cells, while the interareolar spaces contain polymorphonuclear cells and macrophages. Microscopically a non-ulcerated skin lesion shows the cells of the surface epithelium swollen and distended with glycogen. The papillary layer of the cutis has disappeared, and the dermis proper is infiltrated with round cells, which are mostly mononuclear or polymorphonuclear leucocytes, separated by a slight amount of fibrillar connective tissue, which may in places be entirely absent. There is some doubt as to whether the connective-tissue corpuscles contribute to the round-celled infiltration, as has been asserted by Izquierdo; in any case, the recognizable connective-tissue cells are always swollen, and their nuclei are altered in various ways. The cellular infiltration is very vascular, and in the case of the older tumours almost cavernous in structure; hence the liability to haemorrhage, which is such a marked feature of the disease.

The subcutaneous fatty tissue is always inflamed. In addition to these features, Letulle describes and figures some most peculiar structures seen, under a magnification of 400 diameters, between the cells of the epidermis, which he considers to be clasmatocytes.

The growths appear to be often invaded secondarily with micro-organisms, especially if ulcerated, while the eosinophiles disappear and the mononuclears diminish. Myelocytes may be present, and may number 0·5 per cent., and there may be some large mononuclear cells like macrophages. The nuclei of the polymorphonuclears are simply bilobed.

Symptomatology. The incubation period is not definitely known, and is stated to vary from eight to forty days, but to be most usually from twenty to thirty days, during which time prodromata, in the form of malaise, lassitude, and depression, may be experienced.

Febrile Stage (*Orova Fever*). The invasion is gradual, the prodromal symptoms increasing in virulence, while anaemia becomes apparent, and peculiar rheumatoid pains appear in different parts of the body. These pains are very striking and very misleading, for they may in some cases be limited to a single region, or even to a single joint or muscle: on the other hand, they may be more extensive, and lead to a diagnosis of some nerve disorder. As a rule, but not invariably, fever appears, and varies in intensity with the severity of the attack. There is usually insomnia and often delirium. Usually it is intermittent in character, the paroxysm beginning about noon with chills, severe pains, much thirst, and a rise of temperature to about 104° F., with a quick, soft, compressible pulse, and ending in about twelve hours by crisis, associated with sweating and an amelioration of the pains. The liver and lymphatic glands enlarge, but according to some authorities the spleen is not palpable. The patient rapidly becomes very anæmic and feeble, and usually constipated, but may at times suffer from severe diarrhœa. The destruction of red cells, according to Monge, is enormous, the number falling to 900,000 per cubic millimetre, with microcytes in large numbers, macrocytes, normoblasts (2,000 per cubic millimetre), megaloblasts (200 per cubic millimetre), polychromatophilia, and poikilocytosis, while the hæmoglobin value is always increased. There is the picture of the blood in a pernicious anæmia. There is always a marked leucocytosis, the count rising to 20,000 per cubic millimetre after the first few days, and increasing later The polymorphonuclear leucocytes number about 75 per cent. The condition of the bone-marrow has been studied by Corvallo, who finds excess of normoblasts and neutrophile myelocytes.

Eruptive Stage (*Verruga, sensu stricto*).- In many cases, after the febrile stage has lasted from twenty days to eight months, the skin begins to itch, and an eruption appears on the face, neck, the extensor surfaces of the arms and legs, and at times on the conjunctivæ, the lips, tongue, gums, palate, and pharynx. This eruption shows itself at first as small, pinkish-red, erythematous spots, sometimes associated with small vesicles, or more rarely with bullæ or pustules. The erythematous areas speedily become papules, and finally nodules, which may vary in size and in number. The usual size is about that of a pea.

When fully developed, they appear as elevated, cylindrical, fungiform, or irregular wart-like bodies, usually discrete, red in colour, generally firm to the touch (though they may be soft), and very liable to bleed. This type of eruption is the *forme miliare* (miliary type) of the Odriozolas and Salazar. In addition to these superficial tubercles there are deep subcutaneous nodules (nodular type), which lie under the unaltered skin, and from which at first they are quite free. These nodules may reach a large size, and become adherent to the skin, ulcerate, and reach the surface as large red fungating masses, which readily bleed. This is the *forme mulaire* of the above mentioned authors. Both types appear on the skin, but the miliary type may also appear on the mucous membranes and internal organs, while the nodular type is confined to the skin, especially at the flexures of the elbows and knees. The first crop usually appears on the face, and the extremities may be discrete or confluent: in the latter case no healthy area of skin may be visible. The miliary eruption may appear when the general symptoms have abated, but the nodular is accompanied by fever.

The area of the skin on which the spots appear is usually œdematous, a feature most commonly observed on the legs. With the appearance of the eruption the fever declines, the general symptoms abate, and the patient feels better, but the blood shows a marked diminution in the red cells, some of which are nucleated, and a corresponding reduction in the hæmoglobin, and this anæmia may be aggravated by hæmorrhages from the nodules, which may be so severe as to cause the death of the patient. This blood condition has been carefully investigated by Monge, who finds that at the commencement of the illness there is oligocythæmia, microcytes, macrocytes, normoblasts, and megaloblasts (under 1,000 per cubic millimetre), with poikilocytosis, polychromatophilia, and granular red cells. The hæmoglobin value is raised. The white cells are increased, and there is slight polymorphonucleosis. The mononuclears have well-marked basophilic protoplasm. At this stage the verrugas may develop in the internal organs, and cause serious symptoms; thus in the larynx they will cause dyspnœa: in the bronchi, bronchitis: in the lungs, pneumonia: in the pleura, pleurisy; in the nose, epistaxis and difficulty in nasal breathing; in the œsophagus, dysphagia; in the intestine, bloody diarrhœa; in the meninges, brain symptoms: in the eye, amblyopia; and in the uterus, metrorrhagia.

After lasting from four to six months, during which several crops appear and disappear, each preceded by an attack of fever, the eruption finally disappears, and the nodules, becoming pale and drying up, disappear without producing a scar, while the ulcerated nodules dry up and heal by cicatrization, and the patient is left

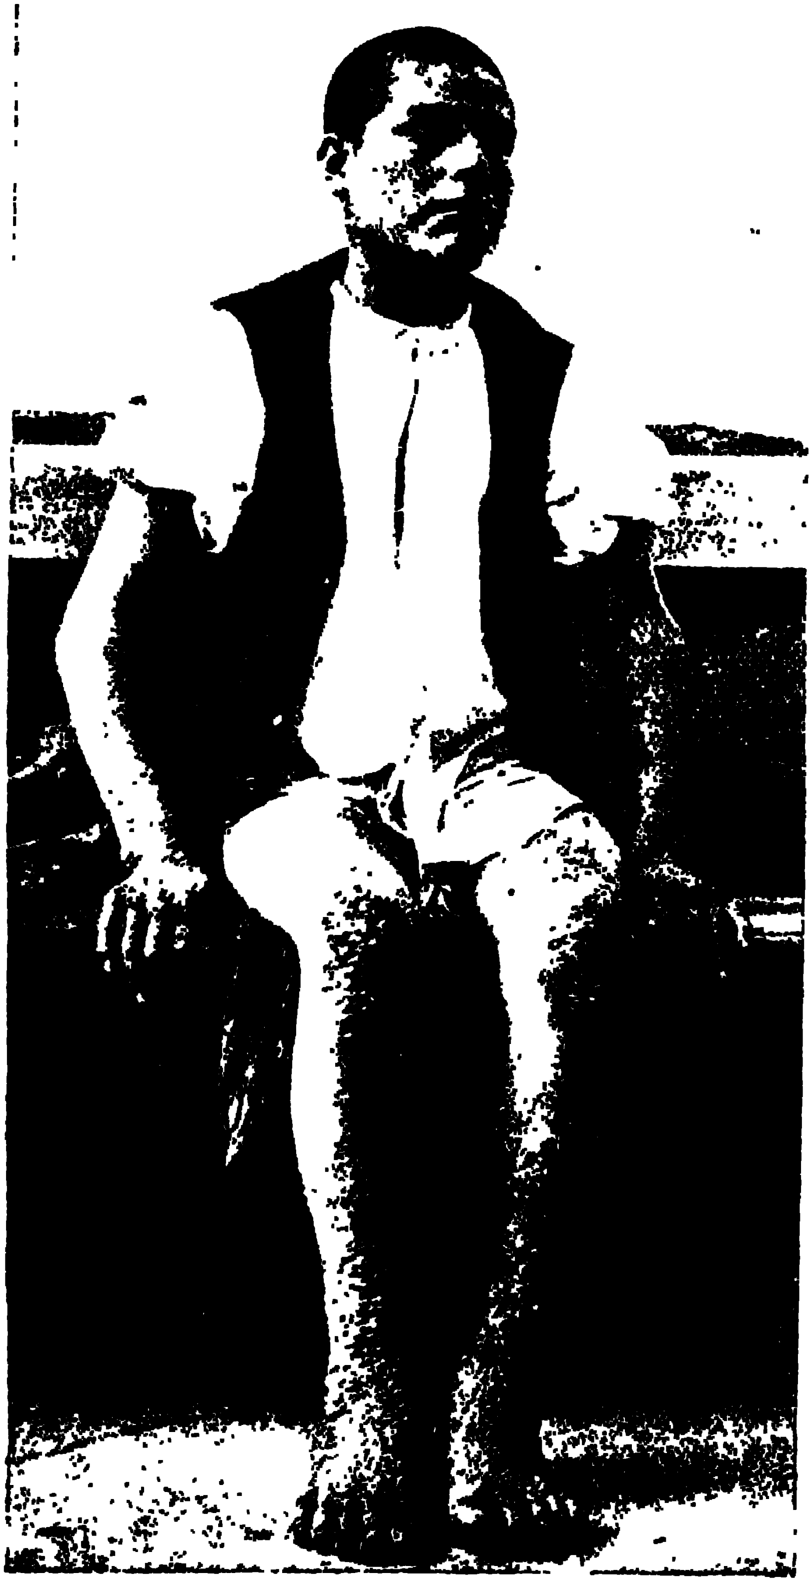

FIG. 706.—VERRUGA PERUVIANA: ERUPTION ON EXTREMITIES. (After Biffi, from the *Archiv fur Schiffs- u. Tropen-Hygiene.*)

convalescent, but anæmic and feeble. According to Monge, systematic examination of the blood reveals the fact that a time arrives, which he calls *the critical period*, when the leucocytes are reduced; the polymorphonuclear leucocytes also diminish in numbers, and the eosinophiles, which have been practically absent, reappear, and a definite mononuclear increase supervenes. This critical period lasts four to five days, and changes completely the blood picture.

During the decline of the disease there is slight oligocythæmia and granular red cells, while the mononuclear cells are increased to 50 to 60 per cent.; there is slight eosinophilia, and the hæmoglobin value is normal.

The course of the disease, however, is by no means as straightforward as depicted, for at times the eruption comes out poorly, and is limited in its distribution, or, having developed, may disappear, in which cases the general symptoms, which may have improved, are apt to return and cause a serious illness.

Acute or Severe Form. This form Carrion's disease, *sensu stricto* is considered by many authorities to be a condition separate from verruga, and when present in verruga to be merely a complication. It seems to be a fever of the enteroidea group. The temperature becomes almost continuous, the pains and the diarrhœa severe, the urine dark and scanty, acid in reaction, with high specific gravity, increased indican and urobilin, but rarely albumen, and never blood. It contains something which reduces Fehling's solution. According to some observers the anæmia becomes profound, the red cells being reduced to 500,000, according to Monge, nucleated red cells appearing, while death results in about two or three weeks.

Varieties. Slight cases may pass through the whole illness without fever, while more severe cases show intermittent or even remittent fever.

Complications. The complications are numerous, and include septic poisoning, malaria, tuberculosis, and syphilis.

The observers who consider Oroya fever a separate entity from verruga, admit that it is not rarely complicated with the latter.

Sequelæ.—The usual sequelæ are anæmia, dropsy, and affections of the nervous system.

Diagnosis. The most important feature in the diagnosis is residence in one of the endemic areas, when a person complaining of vague pains and illness, with distinct anæmia, with or without febrile symptoms, should be regarded as most likely to be suffering from the febrile or anæmic stage of verruga. The rapidity with which the anæmia is developed is an important point in the diagnosis, for in the severe forms of the disease the number of the red cells will fall in three to four days to less than 1,000,000 per cubic millimetre, and even in slight cases there will be a marked diminution. Concurrently in the severe forms all the signs of the blood picture of pernicious anæmia will develop This anæmia imprints a typical facies upon the patient. The febrile stage must be differentiated from malaria by the absence of the parasites in the blood, from typhoid by the serum reactions, from tuberculosis by skin and ophthalmic reaction, from rheumatism by the absence of the swelling of the joints, and from histoplasmosis by the absence of the parasite. The stage of eruption must be distinguished from framboesia by the absence of the eruption on the trunk, by the tendency to hæmorrhage, and the absence of *Treponema pertenue*.

It should be remembered [illegible] ding to Strong, Tyzzer, Brues, Sellards, and Gastiaburu's valuable [illegible] s, Oroya fever and verruga are two separate diseases. Oroya fev[illegible] haracterized by the profound anæmia, the fever, the presence of *B* [illegible] *acilliformis* in the blood, its non-inoculability in monkeys, while uncomplicated verruga is clinically identical with angiofibroma contagiosum; there is no fever, no severe anæmia, there is absence of *B. bacilliformis* and the condition is inoculable in monkeys and human being.

Fig. [illegible] GA PERUVIANA ERUPTION ON THE FACE, LIPS, AND TONGUE.
(After Bahr from the *Archiv für Schiffs- u. Tropen-Hygiene*.)

Prognosis.—With the possibility of such a serious complication as Carrion's fever arising, or in later stages of internal verrugas forming, the prognosis must be very guarded. A good sign is an early appearance of a widely-spread eruption, while a poorly-developed eruption associated with anæmia and marked weakness is of grave import. Monge states that the difference between two consecutive blood counts is of importance in deciding the prognosis, as an increase in the mononuclears and of the erythrocytes and the appearance of eosinophile cells marks an improvement.

The appearance of the eruption *per se* should not be considered a good sign if there is still marked oligocythæmia and polymorphonucleosis.

Especially serious is the disappearance of a poorly-marked eruption, and the reappearance of fever pains, etc. Cold weather and high altitudes are unfavourable, and complications increase the gravity of the case considerably, the former because it delays the development of the eruption and may cause it to abort, and the latter because it increases the tendency to hæmorrhage. The mortality varies from 10 to 40 per cent.

Treatment.—No specific treatment is known, but Odriozola recommends hypodermic injections of arsenic, and removal from the endemic region to the warm countries along the littoral will also be of benefit. Atoxyl, salvarsan, and neo-salvarsan may be tried. Chills and cold baths must be specially avoided as being apt to stop the development of the eruption, and hence to endanger the life of the patient. Drugs appear to be useless in the febrile stage, and though decoctions of maize, of *Buttneria cordata* (Buttneriaceæ), *Buddleia incana* (Scrofulariaceæ), or *Schinus molle* (Terebinthinaceæ), have been popular, they are now believed to be useless.

Tonics of iron and arsenic are useful during convalescence, but the iron is best administered by hypodermic injections. Carrion's fever must be treated in the same manner as typhoid fever.

Prophylaxis. In the present state of our knowledge the only possible prophylaxis is to avoid the endemic regions, and to protect the body against biting arthropods, especially at night.

REFERENCES.

There are numerous references in the 'Cronica Medica' published in Lima, but the most important monograph is that by E. Odriozola, which is excellently illustrated with maps and coloured plates, and in which the subject is treated in the fullest manner. CHAPTER LXIII

RHINOSPORIDIOSIS AND SARCO-SPORIDIOSIS

Rhinosporidiosis—The Sarcosporidioses—Sergentelliasis—References.

RHINOSPORIDIOSIS.

Definition. Rhinosporidiosis is a chronic infection caused by *Rhinosporidium seeberi* Wernicke, 1900, and characterized by the production of polypi on mucous membranes and papillomata on cutaneous surfaces.

History. The disease was first recognized by Malbran in South America in 1892, then by Seeber in 1896 in Buenos Aires, in a nasal polypus occurring in a young man aged nineteen years. In 1900 he gave a description of the parasite and its development, which we have been unable to obtain, but which is said to be a most excellent account. Later he found two other cases in the same town, and in 1900 the parasite was named *Coccidium seeberi* by Wernicke.

In 1903 Kinealy reported to the Laryngological Society a peculiar case of a polypus which he had found in 1894 growing from the septum of the nose of an Indian in Calcutta in the form of a pedunculated, raspberry-like body, with whitish spots on the generally red surface. On section this tumour was found to have peculiar bodies embedded in it. It was then carefully examined and described by Minchin and Fantham, who came to the conclusion that the peculiar bodies were Haplosporidians, and named them *Rhinosporidium kinealyi*. In 1905, Nair of Madras found similar nasal polypi in several people, who all came from the small native State of Cochin, on the west coast of India. These polypi were carefully described by Beattie in 1906.

In 1910 we observed the same parasite in a nasal polypus in Ceylon, and in the same year Ingram published an account of its occurrence in a conjunctival polypus and in a papilloma on the penis.

In 1914 Tirumurti gave a most excellent account of the disease.

In 1918 Chelliah, in Ceylon, not merely confirmed our original discovery of the disease in that island, but reported several more cases in Singhalese and moormen.

Climatology.—Rhinosporidiosis occurs in South America, in India, and in Ceylon, and quite possibly in other regions.

Ætiology.—The cause of the disease is *Rhinosporidium seeberi* Wernicke, 1900 (p. 533), which is present in the growths in the form of clear hyaline roundish cysts of varying diameter.

The life-history in man appears to be as follows:—

The free spores, which are small spherical ovoid bodies with single chromatinic masses, grow into sporocysts which have a few chromatinic granules. These sporocysts grow into larger bodies containing a few centrally placed pansporoblasts. When these cysts are mature they are filled with pansporoblasts which have formed spore morulæ containing some fourteen to sixteen clear shining spores.

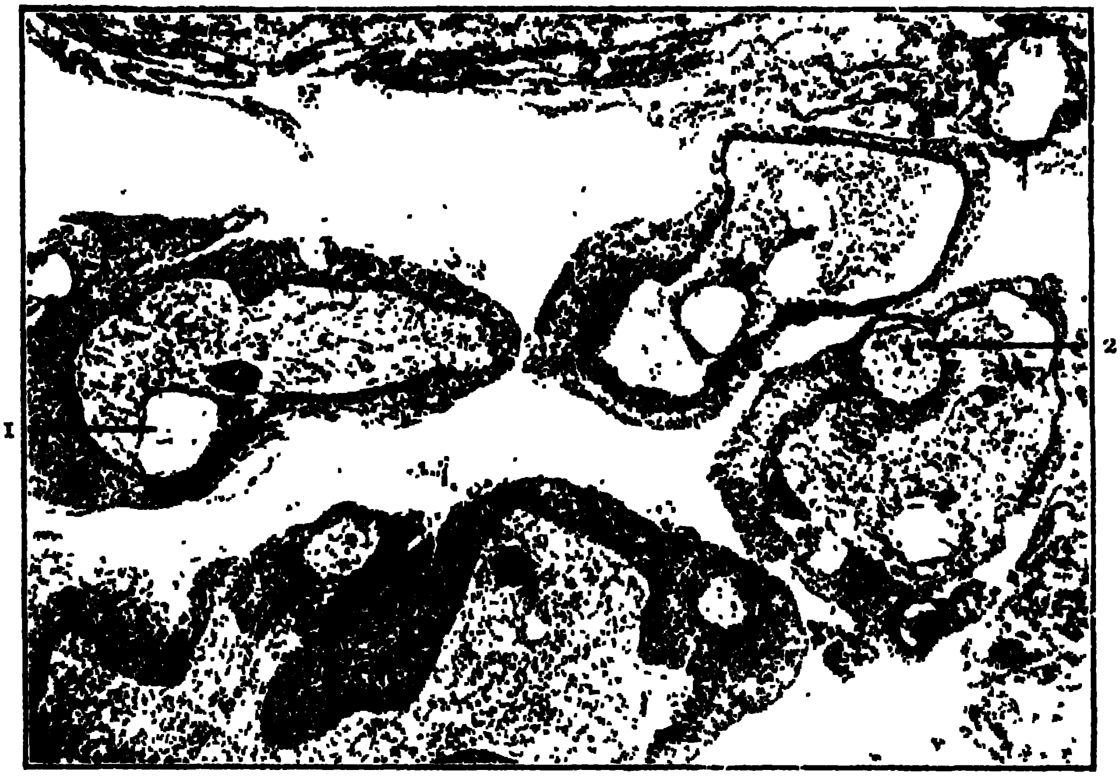

FIG. 708 SECTION OF NASAL POLYPUS SHOWING *Rhinosporidium seeberi* AT 1 AND 2. (× 30) CEYLON CASE. (PHOTOMICROGRAPH.)

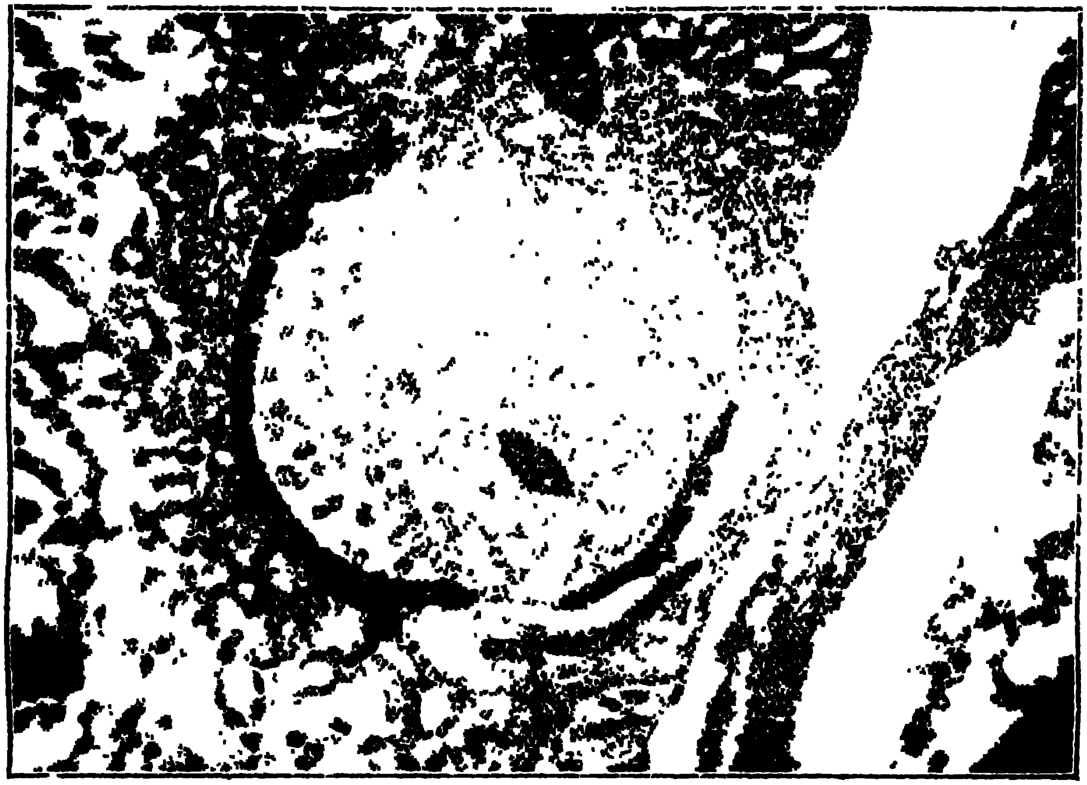
1 is reproduced much more highly magnified in Fig 709.

The cyst ruptures, the pansporoblasts escape and rupture, and so allow the spores to be liberated. Spores probably escape from the nose and other parts, and possibly infect man in this way, because there is some slight evidence of transference direct from man to man, though we were unable to trace any such cause in our Ceylon case. Probably the reservoir for the parasite is in some unknown animal. Spores which do not escape from the body propagate the parasite in the patient.

Morbid Anatomy.—When a polypus is teased out in the normal saline it will be observed that it is stalked, and that from this central peduncle strands of fibrous tissue branch out into processes. The tissue is studded with pin-head sized white dots which represent the cysts.

As can be judged from Fig. 708, the mucous membrane is thrown into folds which form papillomatous-like processes, in which, here and there, the epithelium is thin or wanting. The subepithelial tissue is very vascular, and is infiltrated with polymorphonuclear leucocytes, and shows small hæmorrhages at times, and in the nose may also be myxomatous in places. The cysts may be seen lying in this tissue or bulging through the epithelium (*vide* 2 in Fig. 708 and also in Fig. 709, which shows a cyst full of pansporoblasts, which appear under higher magnification in Fig. 710.



Pathology.—The parasite spreads in the body by the rupture of the cyst and the liberation of the spores. We suspect that it may, at times, give rise to a condition resembling a septicæmia.

Symptomatology. The patient has his attention drawn to his nose by profuse bleedings, and in a little time notices a growth. On examination this is found to be a small vascular pedunculated tumour, about the size and shape of a pea, freely movable and painless, attached to the anterior and upper part of the cartilaginous septum. In appearance it resembles a strawberry or a raspberry.

It may, however, form polypi in other regions, as, for example, on the conjunctiva, or papillomata on cutaneous surfaces, as, for example, on the penis.

Diagnosis.—The diagnosis can only be made by removal of the whole or a portion of the growth, which in most cases has the appearance of a nasal polypus, followed by a microscopical examination, when the parasite will be easily seen as a roundish cyst filled with granules which, when examined under a higher power, are seen to be the pansporoblasts.

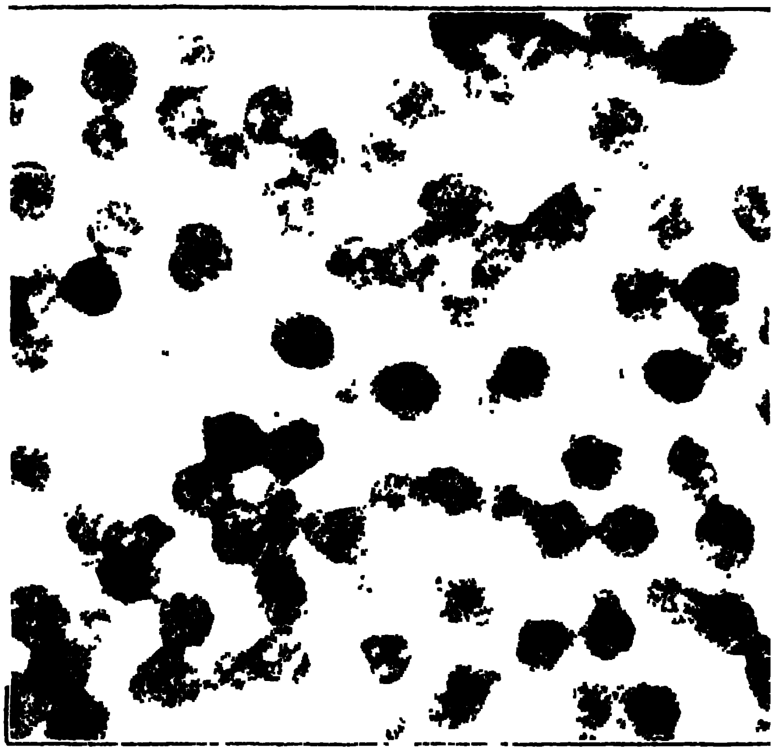


Fig. 711.—*Rhinosporidium seeberi* Wernicke as seen at 2 in Fig. 708 (×1,000.) Ceylon Case. (Photomicrograph.)

Prognosis. This is usually said to be good, but if it can cause, as we suspect, a general infection, it may be dangerous to life.

Treatment. The treatment is to remove the growth and cauterize its base.

Prophylaxis. As we are entirely ignorant of the life-cycle of the parasite or where it exists outside the human body, no remarks can be made as to the prophylaxis.

THE SARCOSPORIDIOSES.

Definition. Sarcosporidiosis is a chronic infection caused by the invasion of the body by *Sarcocystis lindemanni* Rivolta, 1878, *Sarcocystis muris* R. Blanchard, 1885, and perhaps other allied organisms.

History. In 1868 Lindemann found some indefinite bodies in the myocardium and on the valves of the heart of a person who had died of dropsy. It is thought that these bodies may possibly have belonged to the genus Sarcocystis, but it is very doubtful what they really represented. In 1887 Koch described the first genuine case in Egypt. In 1894 Baraban and St. Remy found these parasites in the laryngeal muscles of a man who had been executed. In 1902 Rosenberg reported a doubtful case, and Kartulis another doubtful case. In 1903 Et. and Ed. Sergent described a parasite which later was called *Sergentella hominis* Brumpt, 1910, in the blood (*vide* p. 537), and in 1905 Castellani and Willey described rather different bodies also in the blood (*vide* pp. 537 and 538), which they were inclined to consider of protozoal origin, and later similar, but somewhat larger, forms were found by Castellani and Sturgess in the blood of *Bos indicus* (Fig. 189, p. 531). In 1909 Darling described a case of sarcosporidiosis in a Barbadian negro in which the parasite appeared to be *Sarcocystis muris* Blanchard.

Climatology.—Sarcosporidiosis being only a chance infection in man, and the parasite normally occurring in monkeys, buffaloes, cattle, sheep, pigs, rats, and other animals, it is obvious that not merely will the disease be very widespread, but that different varieties will occur in the different zoological regions. The cases so far described are in Central America, Europe, and Egypt, and doubtful cases in Algeria and Ceylon. We are suspicious that the Ceylon case may have some connection with *S. tenellæ*, var. *bubalis* Willey, Chalmers, and Philip, 1904, which is very commonly found in buffalo meat in Ceylon.

Ætiology.—The causation of sarcosporidiosis is the presence of some species of sarcocystis in man, but the method of entry is not obvious. It would seem possible that eating undercooked meat infected with *Sarcocystis* might produce the infection, as Darling has shown that guinea-pigs can be infected by feeding them with rat's muscle containing *S. muris*, and by feeding them with the ripe sporozoites of the same species. In our opinion this is a very probable method of chance infection, because the buffalo meat in Ceylon is heavily infected (*vide* p. 531).

Morbid Anatomy. The spores can be found in the blood and the parasites in the muscle fibres.

Symptomatology. The incubation period in animals appears to be very long, some 152 to 104 days. During the invasion the patient suffers from an irregular fever, which may resemble enteric fever, and in severe cases this fever may be complicated with myositis and even necrosis of the muscles.

Diagnosis.—The symptoms are those of an irregular fever, which in some cases may be typhoidal-like, and in others of a very low type without much general disturbance, while some cases may never show pyrexia. The nature of these fevers may be suspected by finding bodies resembling the spores of *Sarcocystis* (*vide* Fig. 189, p. 531) in the blood. Failing this, and especially if there are any signs of myositis, the diagnosis can be cleared by excision and examination of a piece of diseased muscle.

Prognosis.—This is good after the parasites have become quiescent, for no one has so far been known to die of the disease.

Treatment.—The treatment is entirely symptomatic.

Prophylaxis.—Meat should be carefully inspected, and any found heavily infected with *Sarcocystis* should be condemned, while all meat should be well cooked.

SERGENTELLIASIS.

The brothers Sergent, in 1903, described a peculiar parasite (the description of which is found on p. 537) in a person suffering from night sweats and attacks of nausea. There was apparently no fever, and the general condition was good. This parasite, to which Brumpt has given the name of *Sergentella hominis*, might be the free spores of a species of *Sarcocystis*.

CHAPTER LXIV

PARAGONIMIASIS

Synonyms—Definition—History—Climatology—Ætiology—Pathology—Morbid anatomy—Symptomatology—Complications—Diagnosis—Treatment—Prophylaxis—References.

Synonyms.—Parasitic hæmoptysis, Pulmonary distomatosis, Endemic hæmoptysis.

Definition. Paragonimiasis is a chronic or subacute general or local infection of man by means of *Paragonimus ringeri* Cobbold, 1880, which produces cystic lesions, containing a thick, opaque, reddish fluid, in which are found at times the parasite or its eggs.

History. In 1879 Ringer discovered the parasite of this disease in a patient at Tamsui in Formosa, and it was named *Distomum ringeri* by Cobbold in 1880. In 1878 Kerbert had discovered similar parasites in the lungs of two Bengal tigers which died in the Zoological Gardens of Amsterdam and Hamburg. Subsequently it was considered that the two parasites were one and the same species, and as Kerbert had named his species *Paragonimus westermani* in 1878, this name was applied to the human parasite until Ward and Hirsch stated that the spines which cover the cuticle and which are arranged in groups are different in the two species. Thus *Paragonimus ringeri* has chisel-shaped moderately heavy spines, while *P. westermani* has lancet shaped and very slender spines. The human species is, therefore, known by Cobbold's name of *P. ringeri*.

In 1880 Baelz found bodies in cases of hæmoptysis which he thought were psorosperms, and, therefore, he called the disease 'gregarinosis pulmonum,' but when the bodies were shown to Leuckart he said that they were ova of a distomum.

In the same year (1880) Manson found the eggs in a case of hæmoptysis in a Chinaman from Northern Formosa, and later in a Portuguese with similar symptoms from Tamsui in Northern Formosa. This Portuguese died in Formosa, and Ringer discovered in the lungs during the post mortem examination a minute fleshy oval body, grey in colour. This specimen was forwarded to Manson, who sent it to Cobbold, who named it *Distomum ringeri*.

In 1883 Baelz also found adult specimens in the lungs, and gave them the name *Distomum pulmonale*. In 1890 Otani and Yamagiwa showed that it could give rise to a general infection and could be found in the brain. In 1902 Musgrave gave a very complete account of the disease as seen in the Philippine Islands. In 1910 Nagano reported upon the prevalence of the disease in Northern Formosa, around the prefecture of Shinchika; and Nakagawa in 1913 and 1914 found 1,249 cases, of which 922 occurred in that prefecture, and believes that there are not less than 13,000 cases therein. In 1912 Masuo and Yokokawa found the disease in Sansaka, Koryo, Jukirin, and Nansho. In 1914 Nakagawa investigated the inhabitants of the lowlands occupied by savage tribes, and found that about 50 per cent. of the population were infected: but in the highlands the cases were less in number.

In the meanwhile observations had been made as to the development of the worm in the egg by Nakahama in Japan, by Manson in China, and by Garrison and Leynes in the Philippines. In 1914 Nakagawa found that the cercariæ developed in the mollusc *Melania libertina* Gould, which lives in pools and sluggish streams: in *Melania obliquegranosa* Smith, which inhabits slowly moving streams; and in *Melania tuberculata* Mueller.

The life-history would be as follows: The miracidia attach themselves by means of suckers to the head, jaws, and feet of these molluscs, and then bore their way by means of their proboscis into the liver, the heart, and the kidneys, where they become sporocysts and cercariæ. These latter possess an unforked tail and measure 0·12 × 0·09 mm., and a tail of 0·054 mm. They also show a spine, two suckers, three pairs of poison glands, and a heart-shaped excretory vesicle. They encyst on the gills of certain crabs—viz., *Potamon* (*geothelphusa*) *obtusipes* Stimpson, the red crab; *Potamon* (*geothelphusa*) *dehaani* White, the dung crab; *Eriocheir japonicus* de Haan, the hairy crab; and perhaps on those of *Sesarma dehaanii* Milne Edwards, and *Potamon* (*parathelphusa*) *sinensis* Milne Edwards.

Dogs fed upon these crabs showed eggs in ninety days after infection. The young distome escapes from the cyst in the intestine of the dog, pierces the wall of the jejunum and passes into the peritoneal cavity, pierces the diaphragm and pleura and enters the lungs, where it encysts and becomes adult.

More recently other observers have doubted the necessity of the crab in the case of the infection of man, which apparently can take place via the skin.

Kobayashi believes that the cercariæ observed by Nakagawa in molluscs of the genus *Melania* are not those of *P. ringeri*.

Climatology.—Paragonimiasis is found in China, Corea, Japan, Formosa, the Philippine Islands, and Sumatra. The infection is more prevalent among people living along large rivers, according to Nakagawa, and less so among people who use well water.

Ætiology.—The causal agent is *Paragonimus ringeri* Cobbold (p. 573), which lives not merely in man, but also in the cat, the dog, and the pig. The intermediate hosts are molluscs of the genus *Melania*, in which the cercariæ are developed, and these pass to man either directly or through the agency of certain crabs, in which they become encysted. Infection may be by the alimentary canal, and also perhaps by the skin. The worms become adult in the lungs and other organs.

The disease appears to be very widespread in certain districts, and the old idea that it is more common in males than in females requires reinvestigation.

Pathology.—The pathology of the disease is by no means clear, and how the various pathological changes are evolved is unknown.

Musgrave has classified the lesions into:—

1. The non-suppurating lesion.
2. The tubercle-like lesion.
3. The suppurating lesion.
4. The ulcerative lesion—
    (*a*) in the skin:
    (*b*) in the bronchial mucosa;
    (*c*) in the intestinal mucosa;
    (*d*) in the bile-duct.

The simplest lesion appears to be an infiltration of the connective tissue of an organ with eggs, without any histological changes at first, but later with a proliferation of the connective tissue and the formation of a cirrhosis or a round-celled infiltration, with sometimes many eosinophiles, which may lead to abscess-formation, and finally to ulceration. The abscess-formation may at times produce caseous material, giving a tubercular appearance.

The non-suppurating lesion may therefore be simple infiltration of the tissue by eggs, with or without inflammation. On the other hand, cirrhotic changes may be seen, especially in the liver. In serous membranes an adhesive inflammation is often produced, associated with the presence of eggs in brown patches at the points of contact.

The inflammation of the organ may, however, proceed to pus-formation, resulting in a typical abscess. On the other hand, the tissues generally attempt to circumscribe this abscess by a fibrous wall, and thus produce what is called the typical lesion of the disease. In the centre of the abscess will be seen degenerated cells, blood, eggs, and perhaps a parasite. Then comes a capsular wall of fibrous connective tissue, smooth towards the centre, and joining the rest of the organ externally. Around this wall the connective tissue of the organ is proliferating and congested. In this way the typical little cysts, with dull blue-grey walls, smooth internally, and containing a thick, reddish fluid, with or without eggs or a parasite, are formed. These lesions may work their way to a cutaneous or mucous surface, and so open into a bronchus, or into the intestine, or the bile-duct, or on to the skin, thus giving rise to ulcers in those regions. The intestinal ulcers closely resemble dysenteric ulcers, and, indeed, may become secondarily infected with amœbæ or bacteria.

In course of time these lesions may show some attempt at healing and scar-formation, but generally this is not very successful.

The blood may show a deviation of complement with worm-body used as antigen.

Morbid Anatomy.—The body may be well nourished, but more usually is emaciated and anæmic. Ulcers can be seen at times in the axillæ and groin, leading into diseased glands. The muscles may contain abscesses. The pleura, pericardium, peritoneum, and, more rarely, the meninges, show the chronic inflammations and the non-suppurative lesions mentioned above. The lesions found in the lungs are diffuse cirrhosis, bronchiectatic cavities, pneumonia, and caseous abscesses, while those of the liver are cirrhosis, perihepatitis, and abscess-formation. The typical lesions mentioned above may be found in the spleen, pancreas, small and large intestines, kidneys, bladder, epididymis, prostate, and in the choroid plexus of the brain.

Symptomatology.—As the invasion of the body is so generalized, the symptoms are very varied. Musgrave differentiates four varieties—the generalized, the thoracic, abdominal, and cerebral; but there is nothing very characteristic about any of these types.

In *the generalized type* there may be fever, enlarged lymphatic glands, general muscular pains, and ulceration of the skin.

In *the thoracic type* there will be cough, with the expectoration of purulent or, more generally, blood-stained sputum, in which the eggs may be best seen by the addition of a little 0·1 per cent. solution of sulphuric acid. More rarely an adult parasite appears in the sputum, which also may contain Charcot-Leyden and creatinin crystals. The patient generally complains of pain in some part of the chest. The physical signs may indicate broncho-pneumonia or pleural effusion, which may be serous or purulent.

In *the abdominal form* of the disease there are only the vaguest symptoms of dull, aching pains and tenderness, while diarrhœa, appendicitis, epididymitis, or cirrhosis of the liver, may be demonstrated by the usual physical signs and symptoms. When diarrhœa occurs, the eggs may be found in the fæces

The cerebral type is associated with epilepsy, which may be Jacksonian in character, while neuritis or paralysis may also be present.

The blood and urine have not yet been fully examined. Though generally chronic, the course may be acute if complicated by septic or other diseases.

Complications.—The most usual complications are tuberculosis and entamœbic dysentery.

Diagnosis.—With the above symptomatology, it will be obvious that the diagnosis depends entirely upon finding the eggs of the parasite in the sputum, the fæces, the scrapings from the ulcers, or the fluids obtained by puncture of a hydro- or pyothorax. Suspicions as to the presence of the disease will be strongest when cases showing any of the above signs occur in the endemic area.

Treatment.—The treatment must be devoted to relieving individual symptoms, but Musgrave recommends treatment by iodide of potash. Removal from the endemic area is, of course, indicated. Perhaps tartar emetic injected intravenously might do good.

Prophylaxis.—In the endemic region drinking and bathing water should be boiled or filtered, and crabs should not be eaten.

CHAPTER LXV

KATAYAMA DISEASE

Synonyms — Definition — History — Climatology — Ætiology — Pathology — Morbid anatomy — Symptomatology — Varieties — Complications — Diagnosis — Prognosis — Treatment — Prophylaxis — References.

Synonyms. Urticarial fever, Asiatic schistosomiasis, Schistosomiasis japonica, Kabure (cutaneous symptoms).

Definition.—Katayama disease is caused by *Schistosoma japonicum* Katsurada, 1904, and is characterized by urticarial and dysenteric symptoms, painful enlargement of the liver and spleen, with or without fever, dropsy, progressive anæmia, and sometimes pulmonary and brain symptoms.

History.—In 1887 Mazumi drew attention to a peculiar form of cirrhosis of the liver which was found in certain districts in Japan, and was caused by the ova of some unknown parasite. His discovery was confirmed, and the ova were found in other organs besides the liver; and the disease, which became well known among Japanese medical men, was named 'Katayama disease,' from a town in Bingo, one of the districts in which it is common. In 1904 Katsurada, who was resident in the infected area, discovered that the ova were those of a *Schistosoma*, and, further, found the adults in the portal vein of a cat. He named the parasite *Schistosoma japonicum*. In the same year Fujinami discovered a female worm in a human being. Meanwhile Catto found the same parasite in a Chinaman from Fukien, and described it in 1905, and in the same year Stiles and Looss gave accounts of the disease. In 1906 Woolley, in a most excellent paper, described its occurrence in the Philippine Islands. Logan has found it in a Chinaman from Hunan, and in 1909 Peake recorded three cases from a small town on the Siang River, in the Hunan province of Central China. In 1911 Houghton, Logan, and Lambert, drew attention to cases of fever with urticaria, and eosinophilia connected with infections with *S. japonicum*.

In the same year Edgar drew attention to this fever in the Yangtze Valley, near Hankow, and noted that nearly every patient had bathed or waded in marshy ground near the river.

In 1912 Miyagawa did not believe that the worm was the cause of the dermatitis.

In 1913 Miyairi and Suzuki noticed that the eggs of the worm, when kept for one to two hours in fæces and water at a suitable temperature, hatched out, the shell being broken. The newly-born miracidia swim about vigorously and enter a snail, said at the time to be a species of *Limnæus*, in which after twelve days rediæ appear in the liver. They further found that mice placed in the same vessel with these snails for three hours a day develop *S. japonicum* in their livers.

Also in 1913 Katsurada found that the worms reached maturity in two weeks and produced eggs in three weeks, and that the method of infection of the vertebrate was by the skin, as could be demonstrated by producing the disease in cats and dogs (Katsurada), in cattle (Fujinami), in man (Matsura in himself).

In 1914 White gave an account of a case of the disease, as seen on H.M.S. *Cadmus*, under the term *urticarial fever*. The patient suffered from fever about 102° to 103° F. in the evening and normal in the morning, pains in the lumbar and epigastric regions, pulse-rate 90, with a temperature of 103° F., slight reduction of the red corpuscles, 4,800,000 per c mm., and 50 per cent. to 70 per cent. of eosinophiles, and loss of weight associated with the appearance of urticarial eruptions in various parts of the body.

In the same year Lanning noted that it was not uncommon for a fair proportion of the crews of gunboats patrolling the Yangtze River to become infected after wading through the water-covered paddy fields in search of snipe.

Miyairi's work induced Leiper and Atkinson, in 1914, to proceed to Shanghai and later to Katayama in Japan to investigate the parasite. Their results were published in 1915. At Katayama they found a small brown snail, with eight spirals and an operculum, known at that time as *Katayama nosophora*, which had an extraordinary attraction for the miracidia, its small head and foot becoming festooned with white specks (the miracidia), which appeared to irritate the snail. Later the liver was found to be full of cercariæ with bifid tails, which infected laboratory-bred mice by passing through the skin, male and female adult worms being found in the portal vessels one month after infection.

In 1916 Koiki drew attention to the fact that in forty-two cases found near Shushin, in Japan, all but three were farmers, and most had had an itchy eruption on the legs about a year before. In the same year Mann reported upon the disease, and said that salvarsan was beneficial in the second stage; and Narabayashi studied the life-history of the parasite (*vide* p. 592) and pointed out the relationship between it and the skin disease called kabure.

Climatology.—It occurs in Japan, China, and the Philippine Islands: in the first in the provinces of Bingo, Yamanashi, Hiroshima, and Saga; in the second it is reported up to date from Hunan, Honan, Hupeh, Kiangsi, and Anhwei provinces, and from Fukien. In Wuhu 8 per cent. of all male cases entering the General Hospital show either latent, active, or overwhelming infection. In China only the low-lying lands appear to be infected; no cases from the hills or mountains are known.

In the Philippine Islands one case has been reported by Woolley as occurring in a Filippino who had never left the islands.

Ætiology.—The cause of the disease is *Schistosoma japonicum* Katsurada, 1904, which is spread by *Blandfordia japonica*, in which the worm develops into cercariæ which penetrate the skin. The vertebrate reservoirs are cats, dogs, and pigs. For description of the worm see p. 590.

Pathology.—After penetrating into the skin the parasites enter either veins or arteries. In the former case they pass to the right heart and hence to the lungs, at the bases of which they collect, and then, passing through the mediastinum, diaphragm, and liver, reach the portal system. Sueyasu, in 1916 obtained complement fixation with the blood of immune animals.

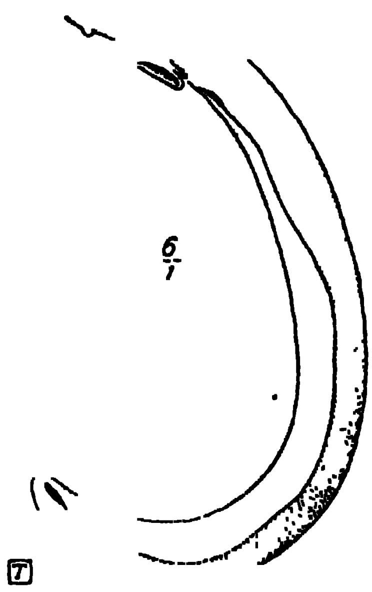

Fig. 711 — *Schistosoma japonicum* Katsurada. (After Manson.)

Morbid Anatomy.—On opening the abdomen, signs of old peritonitis may be seen, the appendices epiploicæ being matted together, and at times there are also signs of old pelvic peritonitis. The liver is cirrhotic and less than its normal size, and its surface is studded by nodules, usually larger than those of alcoholic atrophic cirrhosis. Glisson's capsule is thickened, and shows much connective tissue with round-celled infiltration, in which lie the ova of the worm.

The small and large intestines and appendix may be thickened, and their mucosa is swollen and hyperæmic, and shows patches of ulceration and necrosis, and, in addition, papillomata, resembling those of bilharziosis. The eggs may also be found in the mesentery and in the mesenteric glands, the wall of the gall-bladder, the pancreas, the walls of the mesenteric vessels, and the pylorus. The adult worms may be found in some of the veins of the portal system, especially at the bifurcations of the smaller mesenteric vessels.

In addition, the eggs may be found in fibrous and round-celled infiltrations in the lungs and in the brain. This infiltration often takes the form of nodules.

Symptomatology.—The early symptoms of the disease may be slight, or perhaps it may begin with attacks of fever, with urticarial rashes, in which there is marked eosinophilia, and this may be associated with cough, scanty expectoration, some impairment of resonance over the bases or other parts of the lungs, with fine crepitant râles on deep inspiration, and a diminution of the breath-sounds.

About two years later there are diarrhœic or dysenteric symptoms, with or without fever, and the presence of the ova in the fæces. Associated with these symptoms are abdominal pains, enlargement and tenderness of the liver, the hypogastrium shrinking, and the epigastrium enlarging and giving rise to a characteristic abdominal appearance. At the same time the dysenteric symptoms cease, and an irregular chronic diarrhœa sets in, with motions containing much undigested food, and associated with dyspepsia.

In course of time the preliminary enlargement of the liver may cease, and the organ may begin to shrink, but in any case the spleen becomes tender and enlarges, ascites appears, and the patient becomes steadily weaker, more and more anaemic, emaciated, and incapable of mental or physical work. The average of three differential blood-counts by Peake is as follows: Polymorphonuclears, 56·6 per cent.; mononuclears, 13·2 per cent.; lymphocytes, 15·6 per cent.; eosinophiles, 14·1 per cent., but the eosinophilia may reach 50 per cent. Attacks of fever may occur nightly, otherwise the temperature may be subnormal. The vascular, respiratory, nervous, and urinary systems are usually normal. If, however, the ova affect the lungs, there may be signs of bronchitis, broncho-pneumonia, and fibrosis; and if the brain, those of Jacksonian epilepsy. In children the development is stunted. Death may result directly from the action of the parasite, or be due to some intercurrent disease.

Lanning distinguishes three stages in the disease, viz.:-

Initial Stage.—This lasts three to six weeks, and is characterized by high afternoon temperatures, with slow pulse-rate, evanescent œdemas and urticarias, pains in the abdomen especially in the upper part, diarrhœa or constipation, marked eosinophilia, and often mental depression.

Second Stage.—During this stage the liver and spleen are enlarged with anaemia; there is loss of weight, slight fever at times, and the passage of blood-stained mucus, associated with more or less tenesmus and straining, and either diarrhœa or constipation. The characteristic ova can be found in the motions.

Third Stage.—This may or may not be present, and then only after three to five years, and especially if frequent reinfection takes place. It is characterized by cirrhosis of the liver, which may be enlarged or shrunken, ascites, œdema of the extremities, emaciation, anaemia, weakness, passage of blood and mucus in the motions, and a little fever.

Termination.—Death may occur from exhaustion or some terminal infection.

Varieties. Houghton recognizes the following types of the disease: (*a*) Typical cases, with enlarged liver and spleen, ascites, and blood in the motions; (*b*) cases with only splenic enlargement, and with or without blood in the motions; (*c*) cases with cerebral symptoms and marked eosinophilia, to which may be added—(*d*) urticarial fever, with marked eosinophilia in the early stages; (*e*) cases only showing eosinophilia, often associated with some other concurrent disorder; (*f*) latent cases showing ova in the motions, but no bodily disturbance.

The splenic type, when present without blood in the motions, may give rise to difficulties of diagnosis, which may be cleared up by an examination of the blood and fæces. The eosinophilia in these cases is from 25 to 51 per cent.

The cerebral type is exemplified by partial hemiplegia and slight disturbance of speech after high fever, and associated with an eosinophilia of about 50 per cent. Jacksonian epilepsy has also been reported as due to this parasite.

The urticarial fever is characterized by a remittent type of fever, usually ranging at first from 99° to 100° F. in the morning to 102° to 103° F. in the evening, and after a time from normal to about 100° F., associated with marked urticaria, followed by pale raised blotches on the arms, trunk, and legs, and associated with a marked urticarial rash. The fever lasts some weeks, and very closely resembles malaria at first, because the daily fall of temperature is associated with sweating.

Complications. The infection is generally complicated by the presence of *Trichuris trichiura*, *Ancylostoma duodenale* or *Necator americanus*, and *Ascaris lumbricoides*. Dysentery is a complication which may occur and prove fatal to the patient.

Diagnosis. The characteristic signs are chronic painful enlargement of the liver and spleen, associated with ascites and chronic irregular diarrhœa, and marked eosinophilia (10 to 50 per cent.). A definite diagnosis is to be effected by finding the ova in the fæces. These ova are large (0·1 by 0·07 millimetre), oval, non-operculated, laterally spined (75 per cent.), smooth, and transparent, with a double contour sometimes showing a *Miracidium*, and when kept in water for a short time give rise to a free-swimming ciliated *Miracidium*. These ova are apt to be mistaken for *Ascaris lumbricoides*, or less likely for an *Ancylostoma* ovum. The ova require to be looked for carefully.

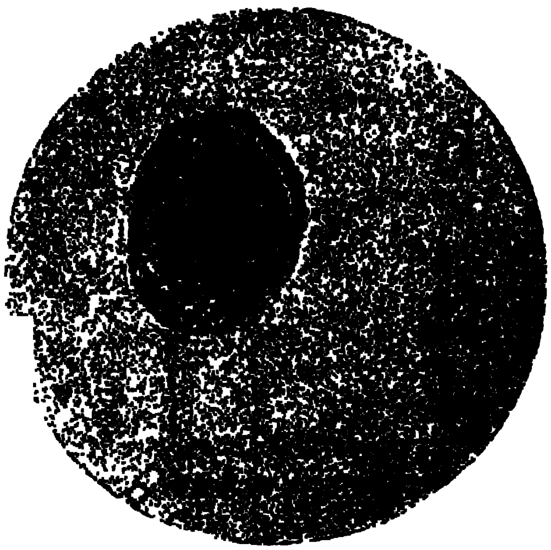

FIG. 712.—EGG OF *Schistosoma japonicum*.

(From a photomicrograph by J. J. Bell.)

Other points which assist in the diagnosis are the greatly exaggerated knee-jerks, the peculiar muddy complexion suggestive of anæmia, the lack of leucocytosis (the counts in uncomplicated cases being about 2,000 to 8,500 per cubic millimetre), and the emaciation without obvious cause.

Prognosis.—The prognosis is very bad, as the parasite directly or indirectly leads to the death of the patient. The mortality is not known, but Katsurada met with between thirty to fifty-four cases every year for five years in the infected area in Japan, and saw three to five deaths per annum, which he considered directly due to the parasite—*i.e.*, a mortality of about 10 per cent.—but he thinks that the indirect mortality would raise the percentage considerably.

Treatment.—The only treatment that can be suggested is to administer salvarsan or tartar emetic.

Prophylaxis.—Avoid contaminated water in drinking and bathing —*i.e.*, use boiled water in infected areas for both purposes. Wading in swamps, lakes, and paddy fields, is very dangerous, and is the method of infection of man.

CHAPTER LXVI

THE FILARIASES

Synonyms—Definition—Filariasis caused by *Filaria bancrofti* Cobbold, 1877—History—Climatology—Ætiology—Pathology—Clinical description—Filarial lymphangitis—Filarial orchitis and hydrocele—Lymphatic varix—Varicose lymphatic glands—Chylous effusions—Elephantiasis—Rarer affections—Filariasis caused by other Filaridæ—References.

Synonyms.—Filarial disease. *French*, Filariose, Maladies filariennes; *Italian*, Filariasi; *German*, Filaria Krankheit.

Definition.—Filariasis is a term denoting the infection of man or animals by any species of *Filaria*—*e.g.*, *Filaria bancrofti* Cobbold, 1877, and some others.

FILARIASIS CAUSED BY FILARIA BANCROFTI Cobbold, 1877.

The diseases produced in man by *Filaria bancrofti* Cobbold, 1877, include lymphangitis, orchitis, varix in lymphatics and lymphatic glands, chylous and lymphatic extravasations, and elephantiasis.

History.—The appearance of the huge leg of elephantiasis is so striking that it was early noticed by ancient Indian writers, who give descriptions of diseases which clearly refer to elephantiasis of the leg and of the scrotum, and also less clearly to lymph scrotum. Further, they appear to have known that elephantiasis could affect the hands and other parts of the body.

The word 'elephantiasis' was first used by Celsus to indicate leprosy, and in this he was followed by most writers until Galen, who included true elephantiasis under the same term, an error which became firmly established as time passed. In the ninth and tenth centuries Rhazes and Avicenna, and other Arabian physicians, described true elephantiasis of the leg under the term 'da-fil' or 'dau-ool-fil,' or elephantine disease, which, however, only served to make the confusion between the two diseases more complete. In the seventeenth century Leonicenus and Varandaeus pointed out that they were two distinct clinical entities, and in 1709 Clarke described elephantiasis on the Malabar coast of India under the term 'Cochin leg.' In 1712 Kaempfer described endemic hydrocele, under the term 'andrum,' as occurring in India, and being associated with erysipelatous eruptions on the scrotum, which recurred at the time of the new moon. He also described a large foot under the term 'perical,' but his description agrees more with Madura-foot than with elephantiasis, though it is probable that he was confusing both diseases under the same term. In 1750 Hillary, a most careful and skilled observer, gave the first full and accurate account of the evolution of the large leg of elephantiasis, which he clearly differentiates from true leprosy, describing the successive attacks of fever, the lymphangitis and lymphadenitis, and the swelling of the limb, which, gradually becoming permanent and slowly increasing, produces the well-known condition.

He was ably supported in 1784 by Hendy, who, in a subsequent treatise in 1789, gave the first full account we have been able to trace of the development of elephantiasis of the scrotum, which he clearly recognized to be the same disease as that affecting the legs. He describes and figures an elephantiasis of the scrotum 24 inches in height and 6 feet in circumference at its base, and he further notes cases of spontaneous cure by sloughing. In 1809, and again in 1824, Alard wrote most excellent treatises on the elephantiasis of the Arabs.

In 1812 Chapotin was the first to describe hæmatochyluria in Mauritius, and he was followed by Salese in 1832, whose paper aroused so much interest in Brazil, where the disease had for long been well known, that in 1835 a conference on the subject was held in Rio de Janeiro, after which there were many investigations, among which may be mentioned those of Rayer in 1838, Quevenne in 1839, Siguad in 1844, and Mozae-Azema in 1858, the last-named observer reporting it in Réunion. In 1854 Jamsetjee described lymph scrotum. The result of all this work was to produce a consensus of opinion among Brazilian, French, and Indian physicians that hæmatochyluria and elephantiasis were merely different aspects of the same disease, and at the same time the classical researches of Danielssen and Boeck in 1848 on leprosy, and of V. Carter in 1860 on mycetoma, ended the confusion of these two diseases with elephantiasis.

In 1863 Demarquay, in Paris, discovered a *Microfilaria* in the fluid from a hydrocele in a person who had come from Havana, but this discovery passed unnoticed at the time. In 1866 Wucherer, stimulated by the discovery of *Schistosoma hæmatobium* in hæmaturia in Egypt, found a *Microfilaria* in the urine of a case of hæmaturia in Brazil, but at first thought it to be of no importance, but when, after two years of careful work, he regularly found the same small worm in the urine of persons suffering from hæmatochyluria, he published his discovery in 1868, in the same year in which Lewis independently found the same parasite in the urine of a case of chyluria in India. Lewis also found the same small worm in the blood and lymph of persons suffering from elephantiasis of the leg, and concluded that it was the cause of the chyluria and the elephantiasis. In 1876 Winckel found the same small parasite in the fluid from a case of chylous ascites.

In 1876-77 Bancroft discovered adult female worms in a lymphatic abscess in the arm, and in a hydrocele of the cord, and these worms were later described by Cobbold, who gave them the name *Filaria bancrofti*. About the same time Manson found the *Microfilariæ* in the lymph from the enlarged lymphatics of a lymph scrotum and from varicose lymphatic glands, and suspected that the so-called malarial orchitis must be of filarial origin. He also obtained a female worm from a case of elephantiasis of the scrotum, and in 1879 Lewis found pieces of male and female worms; while in 1888 Sibthorpe obtained perfect specimens of a male and female from a lymph scrotum, the former being described by Bourne. Lastly, in 1898, Maitland drew attention to the occurrence of synovitis in cases of filariasis, which he considered could not be looked upon as accidental, and must be held to be of filarial origin, but this view cannot be regarded as proved.

In this way arose the knowledge that the causation of a form of lymphangitis, of lymphatic abscesses, of varices of lymphatics, and of lymph glands, of hæmatochyluria, of chylous extravasations, and of elephantiasis, was the invasion of the body by *Filaria bancrofti* Cobbold, 1877.

In the meanwhile the epoch making discovery of the agency of the mosquito in the dissemination of *Filaria bancrofti* was made by Manson in 1878, as well as the periodicity of the *Microfilariæ*, which only appear in the blood in large numbers at night, and in 1899 he discovered that they retire to the vessels of the lungs during the day. With regard to this periodicity, Bahr has shown that it does not depend upon the human host, but upon the habits of the insect host being nocturnal when the host is *Culex fatigans*, and nocturnal and diurnal when the host is *Stegomyia pseudo-scutellaris*, which is a day-feeding mosquito. Thorpe's view with regard to the diurnal and nocturnal periodicity is that it is caused by the irregular habits of the human hosts, but this latter theory has not been supported by Fülleborn's observations on Samoan natives. Low, Grassi, Noé, and Fülleborn, have supplied the information as to the method by which the *Filaria* escapes from the mosquito and enters man during the act of biting. While, therefore, much has been done to elucidate the nature of the lesions due to the worm, researches are still required with regard to the method by which the worms produce the various pathological phenomena attributed to them, especially elephantiasis, and the rôle of a secondary bacterial infection in the production of the lymphangitis, abscesses, and elephantiasis.

The morbid anatomy has been investigated by but few observers, notably by Mackenzie, Manson, Low, Young, and Bahr.

Climatology.--The fact that ancient Indian writers were acquainted with elephantiasis of the leg and scrotum, while Celsus does not appear to have known the disease, and the further fact, mentioned by both Hillary and Hendy, that elephantiasis was rare in Barbados at the beginning of the eighteenth century, together with Hillary's views that the disease was introduced into that island by negro slaves from Africa, awaken suspicions that the endemic home of filariasis is Asia, and that it has spread from thence to Africa, and from Africa to America. If this gradual dissemination of filariasis is correct, it may explain many features of the epidemiology which are difficult at the present time to comprehend.

Be this as it may, filariasis is now widely distributed throughout the tropics and the subtropics, extending from about 41° N. to about 28° S. in the Eastern Hemisphere, and from about 31° N. to about 23° S. in the Western Hemisphere.

In *Asia* it is known in Arabia, India, Ceylon, Burma, Indo-China, the Philippine Islands, Guam, China, and Japan.

It is known in *Australasia*, especially in Queensland, and in Oceania, especially in Fiji, in Samoa and the Friendly Islands, but is absent in the Sandwich Islands. It is also known in New Guinea.

In *America* it occurs in the Southern United States, in Central America, the West Indies, in Guiana, Venezuela, Brazil, Peru, and Columbia.

In *Africa* it is common on the West Coast, in South Africa, East Africa, Madagascar, Réunion, Mauritius, Morocco, and Egypt and Northern Africa.

In *Europe* it is said to exist near Barcelona and in Turkey.

In these countries its distribution is unequal, being in general more common along sea-coasts and the banks of large rivers, but presenting peculiar circumscribed endemic areas. Thus, Daniels points out that in the Shiré Highlands filariasis and elephantiasis are only found in immigrants, while along the lower Shiré River both are common.

Still more interesting is his observation that at the southern end of Lake Nyassa there was only one case of filariasis met with, and none of elephantiasis, while at the northern extremity both were frequently seen.

Low has also studied the distribution in the West Indies. Here, again, this is very unequal, some of the islands—Barbados, for example—being heavily infected, while in others, Grenada, the infection does not appear to exist.

The distribution must depend upon the presence or absence of mosquitoes capable of disseminating the worm, but this aspect of the epidemiology still requires a considerable amount of research; further, the distribution of the suitable mosquitoes must depend upon many factors concerning which we are quite ignorant. When these conditions are better understood, the climatology will be rendered more explicable.

Two atmospheric conditions—viz., high air-temperature and considerable atmospheric humidity—have long been known to be associated with the prevalence of filariasis and elephantiasis, and the reason of this has recently been explained by Fülleborn's experiments on *Dirofilaria immitis*. This observer found, as the result of most careful experiments, that the *Dirofilaria* developed better in mosquitoes if the air-temperature was high, and in that respect resembled the malarial parasite; and, further, that at high temperatures the *Dirofilariæ* are able to leave the proboscis more easily, and to penetrate the skin more quickly than at a low temperature.

Further, the moisture in the air is of importance, as the *Dirofilaria* passes from the proboscis on to the skin, and either makes its own way through this into the tissues, or enters the aperture of the mosquito's bite after it has withdrawn its stilettes, and, therefore, has to be for some time in contact with the skin, which, if dry, will have a harmful effect upon it, but if moist, will not be injurious to it.

With reference to Fiji, Bahr concludes that it is possible that at one time or another nearly every Fijian is the subject of filariasis, because 27·1 per cent. were found to harbour *Microfilariæ* in their blood, and adult worms could be found in the lymphatics and other tissues, and others (25·4 per cent.) were found to suffer from filarial disease when no *Microfilariæ* could be found in the blood; and, lastly, in patients while still under observation the *Microfilariæ* have disappeared from the blood.

Ætiology.—The causation of the various pathological phenomena mentioned above is *F. bancrofti* Cobbold, 1877 (p. 633), introduced into the body by the bite of a mosquito.

The known carriers of the worm, as given by Theobald, are *Culex fatigans* Wiedemann, 1828; *Mansonia uniformis* Theobald, 1901; *M. pseudotitillans* Theobald; *Pyretophorus costalis* Loew, 1866; *Myzomia rossii* Giles, 1899; *Myzorhynchus nigerrimus* Giles; *M. minutus* Theobald, 1903; *Cellia albimana* Wiedemann, 1821; *Stegomyia pseudo-scutellaris* Theobald, 1910; while the worm is known to be capable of undergoing a part of its development in certain other mosquitoes already mentioned in Chapter XXIV.

The reason of the non-completion of full development in any and every mosquito is not known.

After development in the thoracic muscles of the mosquito the embryo passes into the labium, and when the mosquito bites, it works its way through Dutton's membrane on to the skin, its passage being favoured, according to Fülleborn, by high air-temperatures and moist conditions of the skin. Arrived on the skin, it may work its own way into the body through the skin like an Ancylostoma embryo; or it may enter through the aperture of the mosquito-bite when the stilettes have been removed, for before this takes place it is impossible for it to pass through this aperture, which is completely filled by these appendages.

Its further history and wanderings in the body are quite unknown until the adult condition is reached. The adults (males and females) are generally found lying together, though the females appear to be in preponderant numbers in lymphatic vessels, but they can also be found in the lymphatic glands; while dead and calcified worms have been found not merely in lymphatic glands, but also in the testes, epididymis, spermatic cord, and tunica vaginalis. Here the female produces the thin *Microfilariæ*, which pass through the lymphatic glands and thoracic duct into the blood stream, in which they are found in large numbers at night, retiring in the day-time mostly into the bloodvessels of the lungs.

When taken into the mosquito's stomach they escape from their enclosing egg-shell, and, entering the thoracic muscles, complete the cycle of development.

It is interesting to note that in various parts of the tropics natives believe that elephantiasis and other filarial diseases may be transmitted through sexual intercourse.

The adults lying in the lymphatic vessels may mechanically cause obstruction to the flow of lymph, and thus produce varices, inflammation of vessels and glands, and if the varicose vessels rupture, extravasation of lymph or chyle.

While this ætiological relationship of the worm to the lymphangitis and lymphatic abscesses, to the varices in lymphatics and lymphatic glands, to hæmato-chyluria and chylous extravasations, is admitted by all observers, there are those who doubt this relationship with regard to elephantiasis. These authors base their objections upon the facts that the worm and its larvæ may be absent in well-developed cases, and that the disease can occur in countries in which filariasis is believed not to be present, both of which are quite true, but are capable of explanation. There is an undoubted general relationship between the number of cases of filariasis and of elephantiasis in a district. Where there is no filariasis, elephantiasis is either extremely rare or unknown; where there is abundant filariasis, there are also many cases of elephantiasis.

In investigating this point in a locality care must be taken to exclude immigrant cases of both filariasis and elephantiasis. Thus, Low failed to find either condition in the inhabitants of the forests of British Guiana and in the Wagandas, natives of Uganda, though immigrant cases were met with.

The adult *Filaria* has been found in the tissues removed by operation from a case of elephantiasis of the scrotum; and, further, the condition of elephantiasis is produced as a rule by a series of attacks of lymphangitis, which in every particular resemble undoubted filarial lymphangitis.

It is true that a secondary bacterial infection may possibly assist the development of the disease, for a diplococcus has been found by Dufogeré, which he calls the 'lymphococcus,' and his findings have been confirmed by Foulerton. Le Dantec describes a similar organism, which he calls the 'dermatococcus'; but the main cause of elephantiasis in the tropics is *Filaria bancrofti*, though it is quite possible that, exceptionally, other causes may lead to occlusion of lymphatics and the formation of elephantiasis.

Pathology. -If the parent worms live in positions in which they do not obstruct the flow of the lymph, and if they are not accidentally injured, no pathological effects will be produced on the host: and our observations support Manson's theory that the presence of the worms may produce no ill-effect upon the host, for we know of a case where for years they have produced no symptoms.

But if the parent-worms obstruct the circulation of the lymph mechanically—for example, when three or four come together in an important main lymphatic trunk then the retained lymph is certain by mechanical pressure to damage the tributary channels. Further, if any accidental injury is inflicted upon the female parent-worm, this may cause abortion, and as a result the production of oval eggs instead of elongated embryos (Fig. 268), and these, as will be explained below, are liable to block up the small lymph channels of the skin or of a lymphatic gland. Therefore Low is quite correct in his statement that 'the *Filaria* is not entirely compatible with health,' for very slight causes will produce disease.

In certain districts from 5 to 27 per cent. of the population is infected with filariasis, and therefore if there are many mosquitoes capable of carrying the worm, there ought to be multiple infection of the individual host; and one would also assume that the heavier the infection, the greater the liability to obvious disease. Multiple infection would be more liable to occur in natives than in Europeans. As a matter of fact, heavy infections with the parent-worms have not yet been described, though it must be admitted that but few post-mortem examinations are on record; and, moreover, as Fülleborn has shown, it is at times by no means easy, even with the utmost care, to find the adult worms, though they may be found even in fair numbers after considerable search in those parts of the lymphatic system which appear to be least affected. When the case is one of varicose lymphatics, or lymphatic glands with clear lymph, the obstruction must be looked for below the junction of the lacteals with the receptaculum chyli, but when the fluid is milky, it is obvious that the obstruction must be beyond this point. The cause of the obstruction may be a coiled-up mass of worms—

e.g., Young found six females and one male in such a bundle— and they may be discovered behind a valve or in a dilated sinus. A single female worm may, however, be found lying in a dilated lymphatic, the draining gland being probably blocked by the aborted ova. The irritation caused by the worms may lead to a permanent blocking of a main lymph channel, which will persist even after the irritating worms have died and disappeared, as has been observed by Mackenzie; or, again, the thoracic duct may be found dilated in part of its course, but quite patent throughout, though associated with enormous varicose glands and vessels and a complete absence of worms, which simply means that the parasites having caused the lesions have died and disappeared.

Low and Bahr have shown that the worms lead to great fibrosis in the glands, and that lymphocytes are collected in clusters between the strands of this tissue. This fibrosis is associated with an excessive number of eosinophile cells in the glandular substance.

In chylous extravasations the blocking of the thoracic duct leads to engorgement of the renal, the lumbar, and the pelvic lymphatic channels with lymph, as well as that of engorgement and dilatation of the lacteal vessels themselves.

If the lymphatic vessels of the bladder or other parts of the urinary tract rupture as a consequence of this pressure, the result will be chyluria, and if, as often happens, some bloodvessels also rupture, there will be hæmato-chyluria. Wise states that in chyluria the milky opacity is due to a large amount of proteid, and not to fat, and this observation has been confirmed by Low, who in one case found the lacteals normal, and showed that the milky fluid was lymph proceeding from dilated lymphatics in the kidneys, ureter, and bladder. If the abdominal lymphatics rupture, there will be chylous ascites, if those of the tunica vaginalis, there will be chylocele.

If, on the other hand, the obstruction is posterior to the junction of the lacteals with the receptaculum chyli, then ordinary ascites, hydrocele, and varicose lymphatics of the scrotum (lymph scrotum), of the leg, and varicose groin glands, will result. More rarely the lymphatics of the arm may be affected in the same manner.

The lowered resistance of the tissues engorged with lymph renders them specially liable to inflammation, which may at times go on to abscess-formation, and which, if often repeated, will end in elephantiasis.

Manson believes that elephantiasis arises by a damage to the female worm, causing her to produce immature embryos, which lie coiled up in the egg-shell, instead of stretching it considerably. The immature egg is 50 μ in length by 34 μ in breadth, while the fully-developed *Microfilaria* is 250 to 300 μ in length by 5 to 8 μ in breadth; therefore it is not difficult to imagine that a lymphatic, along which the slim *Microfilaria* passes with ease, might be quite blocked by the immature egg, and that if sufficient channels in the skin or in the lymphatic glands were blocked, lymph stasis would occur, and, as a result, the connective tissue would become inflamed and hypertrophied, which, together with the excess of lymph, would increase the size of the part. Manson bases this theory on his observation of eggs escaping from the ruptured vesicles of a lymph scrotum. Bahr is of the opinion that tropical elephantiasis can best be explained by the blockage of the lymphatic channels of the diseased area by the frequent and long-continued invasion of the adult *Filariæ*. He finds that the *Microfilariæ* may not reach the blood, but die in the gland or organ in which they are lying. He also finds that the periodical discharge of these *Microfilariæ* may be a factor in the production of lymphangitis, orchitis, and funiculitis, and that the parent-worm may die after these inflammatory attacks.

It is believed that the smooth elephantiasis (elephantiasis glabra), in which the skin is smooth, is due to blocking of the channels in the groin glands, and rough elephantiasis (elephantiasis verrucosa), in which the skin is very nodular, is due to blocking of the small skin capillaries, but we are not acquainted with definite proofs of this theory.

The Blood. The blood in filariasis does not exhibit anaemia unless there is hæmato-chyluria or diarrhœa: the number of leucocytes is normal, but there may be leucocytosis during the attacks of fever. The eosinophiles are at times increased.

Morbid Anatomy. The morbid anatomy naturally varies with the variety of the pathological lesion produced.

In lymphangitis the lymphatic vessels will be found enlarged and inflamed, and abscesses of varying size may at times be found containing the dead worms, which are apt to become calcified by the deposition of lamellar plates of calcium carbonate in the interior of the worm. The calcified worms were first described by Wise as small yellow bodies, with the shape and structure of *Filariæ*, which he found in the pelvis of the kidney. Bahr states that at a later stage the calcareous deposit may be gradually absorbed until only minute yellow spicules are left. The calcified (and also the living) worms are surrounded by eosinophile cells in large numbers. Bahr has found filarial abscesses to be of common occurrence amongst the Fijians in the substance of the gastrocnemius, the popliteal space, the groin, and in the quadriceps extensor in the leg, and over the internal condyle, in the axilla, in the latissimus dorsi and serratus magnus muscles in the arm. In these abscesses the dead worm was found associated with *Staphylococcus pyogenes aureus* and *Streptococcus pyogenes*.

With regard to the lymphatic vessel, Bahr is of the opinion that the worm, both during its lifetime as well as after its death, exerts an influence on the vessel wall, leading to proliferation of the endothelium and to an invasion of the vessel wall with fibrous tissue. In this manner the lymphatic becomes thickened, but shows also numerous cyst-like dilatations in which the dead worms may be found.

The fugitive swellings found in filariasis have been proved by

Young to be composed of dilated lymphatic tissue. Inflammatory masses adherent to the skin in various parts of the body have been found to contain the adult worm.

In lymphatic varix or varicose lymphatic glands the obvious lesions may, and generally do, form part of a much larger dilatation of the pelvic and lumbar lymph vessels and glands. The vessels are found enormously dilated with thickened walls, while the glands are riddled with dilated channels. At first the appearance of the gland may not be much altered, and on section it may show the appearance of a sieve riddled with holes, but in more advanced cases all appearance of a lymphatic gland disappears, and it is transformed into a large sac divided by fibrous tissue, septated into numerous compartments.

In chylous extravasations the thoracic duct may or may not be found impervious, but in any case the lacteals, the lumbar, pelvic, pudendal, and crural lymph vessels will be found enormously dilated, and the lumbar lymph glands converted into septated sacs. The site of the ruptured lymphatics is, however, by no means easy to find.

In elephantiasis the lymphatic vessels will be found dilated and thickened, and in early cases a round-celled infiltration may be seen in the connective tissue of the part: but in later cases this has led to a hypertrophy of the connective tissues of the skin and the fasciæ, including those around the muscles, the vessels, and nerves, while all the tissues are sodden with retained lymph. The muscles of the affected regions are found to be in a state of fatty degeneration; the bones may be thickened and covered with osteophytes, or more rarely atrophied, and still more rarely invaded by caseous abscesses.

Microscopically the epidermis may be normal, or thickened with atrophied or elongated papillæ; the sweat glands and hair follicles may or may not be degenerate.

In cutting into the tissue of a region affected with elephantiasis the skin may be noted to be thickened, and below it there will be found dense fibrous trabeculæ, with the spaces filled with yellow, oily, fatty substance, which exudes lymph, while the vessels and nerves will be found much increased in size.

THE CLINICAL DESCRIPTION.

General Remarks.—The clinical description of the various lesions will be arranged under the headings Filarial Fever, Filarial Lymphangitis, Orchitis, Lymphangiectasis, Phlebectasis, Varicose Lymphatic Glands, Chylous Effusions, and Elephantiasis of various parts of the body—*e.g.*, scrotum, leg, etc. and, finally, a few remarks will be made with regard to rarer lesions. As regards *general treatment*, salvarsan, neosalvarsan and galyl have been recommended and tartar emetic might be tried, but no good results have so far been obtained in our experience. *Prevention* is to be based on antimosquito measures as described in the chapter on malaria, p. 1202.

FILARIAL LYMPHANGITIS.

Synonyms.—Elephantoid fever, Liliwa (Fijian term for a rigor), fever and ague (Barbados).

Definition.—Filarial lymphangitis is an inflammation of lymphatic vessels in any part of the body caused by *Filaria bancrofti.*

Remarks.—Attacks of lymphangitis, associated with an erysipelatous eruption of the skin, are extremely common in the tropics, and are often of a filarial nature, and by their repeated recurrences produce elephantiasis.

Symptomatology.—The attack often begins with a shivering fit, and a rise of temperature to any degree from 101 to 104° F., with vomiting and headache. In some cases there is no pain in the affected area, but a careful examination, or the sensation of pain on the part of the patient, will lead to the discovery of a red oedematous area of skin, from which the inflamed lymphatic may be noted extending towards the nearest lymphatic glands, which may or may not be inflamed and painful. Usually the temperature falls quickly in a couple of days to normal, and does not rise again, though it may be several days before the erysipelatous rash disappears and the lymphatics return to normal.

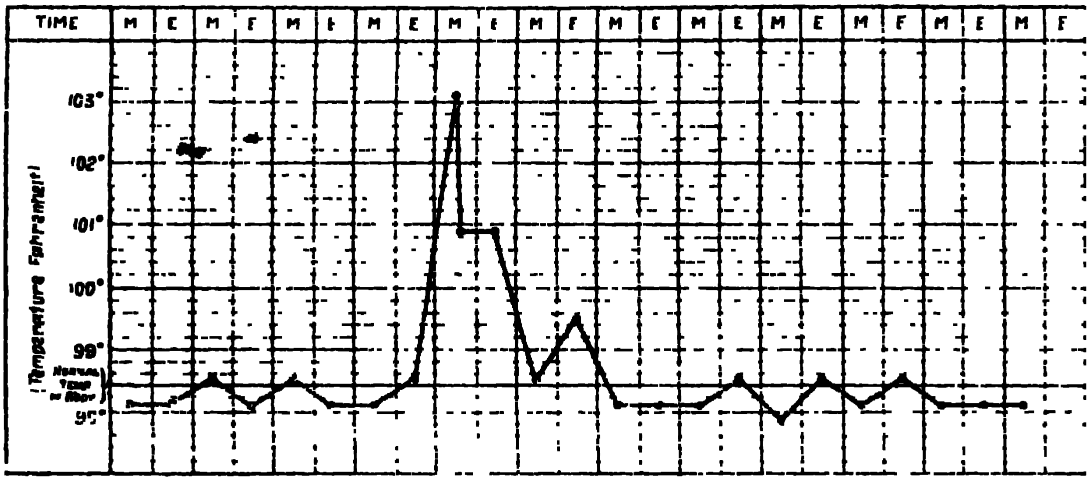

FIG. 713.—TEMPERATURE CHART OF A CASE OF ELEPHANTIASIS OF THE LEG DURING AN ATTACK OF FILARIAL FEVER.

Complications.—Rarely does this condition go on to abscess, which may be caused by a dead filarial worm or a secondary infection.

Sequelæ.—Sometimes, after the acute inflammation has subsided, a lymphatic can be felt as a hardened cord, which, if excised, will be found to contain adult *Filariæ*.

Diagnosis.—The only condition which could reasonably be mistaken for this affection is a caterpillar sting, which closely resembles it in all details. The history of the case will indicate the correct diagnosis.

Treatment.—The treatment consists of rest in bed, a mild purgative, and a little phenacetin and caffeine to relieve the headache, while some of the old authors advise arsenic or tinctura ferri perchloridi, ♏x.-xx., given three times a day, well diluted. Locally, at first lead and opium lotion, and later an ointment, composed of ichthyol and lanoline, gives relief. If an abscess forms, it must be evacuated and treated on ordinary principles.

FILARIAL ORCHITIS AND HYDROCELE.

Symptomatology.—This complaint begins with pains in the testicle, fever, and at times rigor, pains in the back and lower part of the abdomen and groins, and bilious vomiting. The testicle enlarges, and is tender and painful, while an effusion forms in the tunica vaginalis of either lymph or chyle. The lymph thrown out is at first inflammatory, and may coagulate, and is usually absorbed after the fever subsides, but may persist and form a filarial hydrocele. The effusion of chyle is, however, more usually permanent, and forms one of the varieties of chylocele to be mentioned later.

Treatment. The treatment consists of rest in bed and the application of lead and opium lotion, and cool applications, together with fairly vigorous purgation of the bowels.

FILARIAL LYMPHANGIECTASIS.

Synonyms. Lymphatic varix, Lymph scrotum.

Definition. Filarial lymphangiectasis is the dilatation of lymph vessels brought about by obstruction to the flow of lymph, due to the presence of *Filaria bancrofti*.

Remarks. Filarial lymphangiectasis can, of course, take place in any part of the body, but the most common situations are in the scrotum, where it is called 'lymph scrotum,' in the spermatic cord, in the leg, and in the arm.

FIG. 714.—FILARIAL LYMPHANGIECTASIS.

Symptomatology.—In the scrotum the affection begins with an attack of fever, associated with redness, swelling, and pain in that region. When the fever has subsided, the whole scrotum is found swollen and elastic. It may be smooth or rugose, and on inspection the skin shows a number of small clear vesicles, which, if ruptured, discharge either lymph or chyle containing filarial embryos, or, much more rarely, eggs.

If the vesicles are ruptured, the discharge of lymph may be quite considerable in the twenty-four hours, and may produce such marked exhaustion in the patient as to necessitate an operation.

In the spermatic cord the disease begins with pain and swelling in the testicle, cord, and lower part of the abdomen, associated at times with fever. When the acute symptoms have subsided, a swelling like a varicocele, which disappears in the prone position and reappears when standing erect, will be noticed along the cord, but the vessels constituting the swelling will be noted to be softer, less tortuous, and more like a series of pouches than a true varicocele.

FIG. 715.—FILARIAL LYMPHANGIECTASIS.

In lymphangitis of the leg there is the same fever, with swelling of the glands, leaving a soft swelling in the groin, which disappears on lying down and reappears on standing up, and which has no impulse on coughing.

Treatment.—As the local condition is simply part of a much more generalized varicosity of the lymphatic vessels, it is best to treat it symptomatically with antiseptic dusting-powders, such as boracic acid, zinc oxide, and dermatol, etc.

If, however, lymphorrhagia is taking place and the patient is becoming exhausted, it is necessary to remove some of the diseased tissue and to ligate the dilated vessels, but in so doing it is as well to warn the patient that this will not cure the disease, and, indeed, may be followed by elephantiasis or even chyluria.

FILARIAL ABSCESSES.

Manson, Low, Wise, Bahr, and others, have called attention to the frequency of filarial abscesses in various parts of the body. The most important are those found in the thorax and in the retroperitoneal tissues. In the latter situation the symptoms may be those of peritonitis.

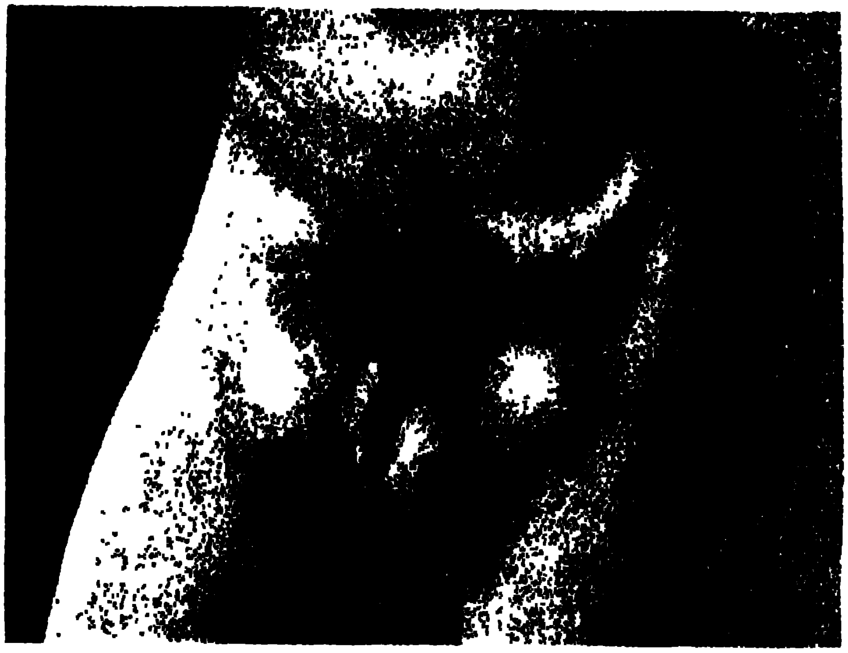

FIG. 716.—FILARIAL PHLEBECTASIS SIMULATING VARICOSE LYMPHATIC GLANDS, AND VARICOCELE: PATIENT IN THE UPRIGHT POSITION.

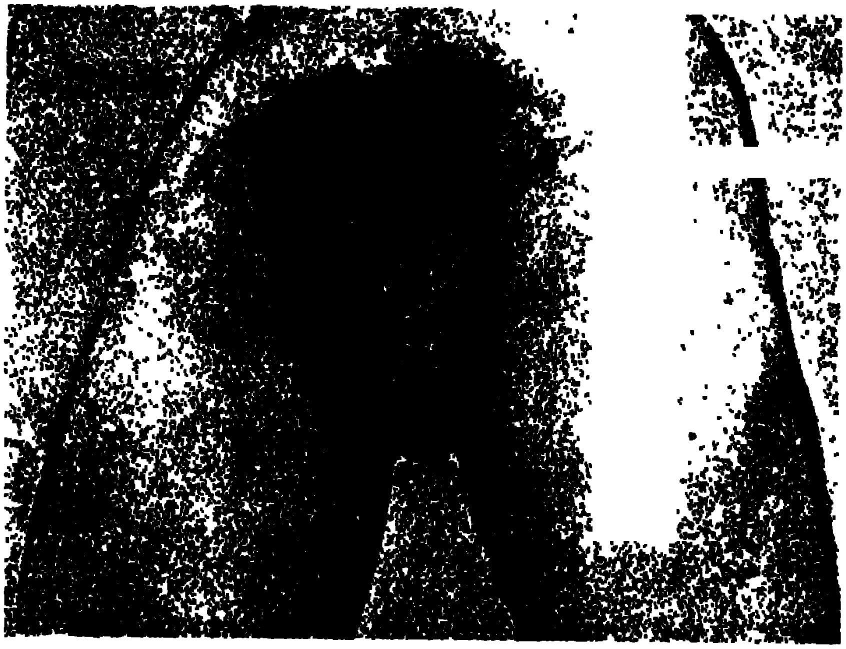

FIG. 717.—FILARIAL PHLEBECTASIS: SAME PATIENT LYING DOWN. (Photograph taken from above. Note the disappearance of the swellings.)

FILARIAL PHLEBECTASIS (FILARIAL VARIX).

At times persons suffering from filariasis exhibit, as observed by us, marked varicose conditions of various veins. Occasionally in association with enlarged superficial veins large masses are to be seen in the axilla, groins, and other regions, which on superficial examination might be taken for enlarged glands, but on palpation it can be ascertained that they are composed of veins, the same sensation being obtained as that experienced when palpating a varicocele. When these masses occur in the groins they disappear when the patient lies down.

VARICOSE LYMPHATIC GLANDS.

Synonyms. Helminthoma elastica, Adenolymphoceles.

Definition. Varicose lymphatic glands are glands enlarged, sometimes to an enormous extent, by dilatation of their lymph paths, brought about by obstruction to the flow of lymph.

Remarks. The glands most commonly found enlarged in patients are the groin glands, less frequently those of the axillæ, while even the parotid lymphatic gland has been recorded to have been affected. In post-mortems, as already noted, the lumbar glands may be found converted into septated sacs.

Symptomatology. The glands enlarge after attacks of fever, and are usually found as soft, elastic swellings, which are easily movable when small, and are covered with normal skin. They are found in the groin, inguinal or femoral regions, and in the axilla. If punctured with a hypodermic needle, lymph or chyle can be obtained at times containing *Microfilariæ*. Usually small, they may assume enormous proportions, reaching below the knee, and seriously impeding locomotion.

Treatment. They may be removed if necessary, but this should not be done without due cause, as they are only part of a more widespread disorder. Radium treatment has been advised by Sir Havelock Charles.

FILARIAL LYMPH AND CHYLOUS EXTRAVASATIONS.

Lymph and chylous extravasations are due to the rupture of dilated lymph or lacteal vessels into the urinary passages, the bowel, the tunica vaginalis, or peritoneum.

They may, therefore, be considered under the headings of Chyluria and Lymphuria, Chylous and Lymphatic Diarrhœa, Chylocele, and Chylous Ascites. Perhaps further investigations will show that Wise and Low are correct, and that in addition to hæmato-chyluria and other chylous conditions there may also be a pure hæmato-lymphuria, lymphatic diarrhœa, lymphocele, and lymphatic ascites.

Chyluria and Lymphuria.

Definition.—Chyluria is the passage of chyle with the urine, and is due to the rupture of dilated chyle-containing lymphatic vessels; when mixed with blood it is known as hæmato-chyluria. When lymph only is passed the term lymphuria, suggested by Low, should be adopted, and if mixed with blood, hæmato-lymphuria.
